Melanins (brown and black) are derived from the amino acid tyrosine by melanogenesis, involving initial oxidation to dopa and dopaquinone, catalyzed by tyrosinase, followed by polymerization and decarboxylation to produce eumelanin in fish. Melanins are insoluble in water and organic solvents, but soluble in alkalis.

Carotenes (yellow and orange) are hydrocarbons and xanthophylls are oxygen-containing derivatives, such as astaxanthin, predominant in red marine fish. Carotenoid color is influenced by the number of double bonds, occurrence of certain radicals, and concentration. Carotenoids are insoluble in water, but soluble in oils and organic solvents, and are also known as 'lipochromes'. Animals cannot synthesize carotenoids, being dependent on plants for their supply, but can modify them into pigments found only in animals. Pteridines are heterocyclic nitrogenous catabolic products, with a pyrimidine ring and a secondary pyrazine ring, chemically and metabolically related to the purines. Their solubility in water is variable.

Although purines are colorless, they produce opaque whiteness or glistening silvery and iridescent colors in fish skin. They have limited solubility in water; ultrastructure studies reveal that they occur as uniformly spaced crystalline platelets in parallel stacks in iridophores. In general, blue colors are produced by iridophores and by the structure of the integument, including ordered dermal collagen arrays producing extracellular differential light scatter. Whitear and Mittal have shown that the ultrastructure of the epidermis of the pogge, *Agonus cataphractus*, and shanny, *Blennius pholis*, reveals a capacity for its superficial cells to develop labyrinthine patterns of microridges; the possible differential light-scattering potential of these, and of the cuticular composition, in brightly colored species calls for investigation.

Individual species may possess some or all types of chromatophores. Their relative frequencies can change during prolonged exposure to background, or in seasonal color changes during the reproductive cycle. The skin color is a summation of separate pigmentary and structural factors. In blue-green damselfish, *Chromis viridis*, such summation produces a characteristic green by means of chromatophore units, in which several small iridophores and sometimes small xanthophores, in that order, occur above a melanophore in the dermis.

How Do Fish Change Color?

Color change in fish chromatophores results from moving the pigment within a cell that stays in the same shape and size. This intracellular chromatosome, or crystalline platelet, motility producing color changes is in response to neural or hormonal stimuli. Such movement in dendritic chromatophores occurs along the radiating microtubules. Bidirectional movements are based on interactions between microtubular tubulin and various motor proteins with adenosine triphosphatase (ATPase) activity. Melanosome aggregation (**Figure 1**(**a**)) pales dendritic processes (not visible) and skin, whereas their dispersion (**Figures 1**(**b**)–**1**(**d**)) darkens dendritic processes and skin. In leukophores, the direction of leukosome movements is opposite to that in light-absorbing chromatophores, consistent with their contrasting contribution to skin coloration.

Iridophore platelets are very refractive and light reflective compared with the cytoplasm separating them (**Figure 2**).

The alternating layers are thin relative to light wavelength. A stack of platelets increases reflectivity considerably, the interference hue being influenced by the refractive index and thickness of the platelets and cytoplasmic layers. In leukophores, light is scattered in all directions by the leukosomes. Iridophores are densely distributed in pale and silvery areas, particularly the lower surface, which may be devoid of other chromatophores. Iridophore reflecting platelets do not necessarily move. However, the platelets can simultaneously change their inclination in *Paracheirodon innesi*, or move apart in some other species, in response to neural stimuli. This changes interference coloration by varying platelet spacing and might involve the cytoskeleton tubulin–dynein system within these cells.

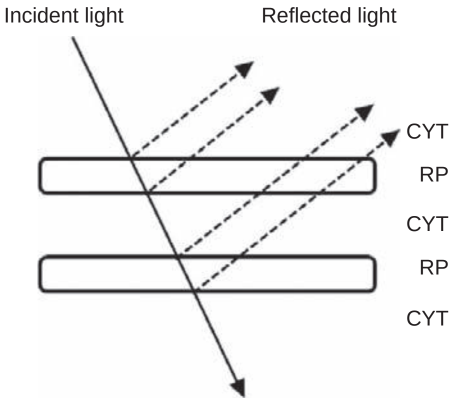

Figure 2 Simplified schematic of light reflection from two platelets of a stack within an iridophore. Different distances traveled by reflected light of each wavelength (not shown) result in a range of phase shifts, interference, and iridescent colors. CYT, cytoplasmic layers; RP, reflecting purine platelets. Graphics assistance: C. Short.

Color changes and pigment movements can be estimated or recorded at macroscopic or microscopic levels. *In vivo*, recording may involve visual comparisons with Munsell or Ostwald gray scales. Both *in vivo* and *in vitro* recording can employ a photocell, or a scale such as the Hogben melanophore index in which 1.0 represents complete melanosome aggregation (appearing pale) and 5.0 complete dispersion (appearing dark). Some accounts do not include a microscopic description of the chromatophores present, making it difficult to determine whether data represent the activity of one or more types. The variety of chromatophores present and the objectives of the experiment determine the suitability of a method. The often-quoted statement by Parker that "no single method has such superiority than it can be said to enjoy exclusive possession of the field" still holds today.

Physiological and Morphological Color Changes

Color changes may be physiological responses to background change (**Figure 3**), stressors, and photocycle and are rapid (seconds/hours), involving intracellular chromatosome movements as in the freshwater European minnow and marine flatfish. Physiological color changes can be primary responses of chromatophores directly to incident light, or, secondary, mediated through nervous and/or endocrine control. These criteria represent the current position in a prolonged debate on the two responses. Primary responses occur in those larval stages in which chromatophores are not yet under neural and/or endocrine control. There have also been reports of primary responses of chromatophores, both innervated and denervated, in adults of a few species, such as the dark chub, *Zacco temmincki*, and medaka, *Oryzias latipes*.

Morphological longer-term (days/weeks) responses to background or diet are due to changes in pigmentation within chromatophores or in the number of chromatophores. Thus, tilapia, *Sarotherodon mossambicus*, displays extensive increases and decreases in dermal melanophore numbers within 10 days' exposure to black and white backgrounds, respectively. However, the distinction between physiological and morphological color change is becoming blurred as our knowledge increases. In general, physiological color change precedes background-related morphological responses; both can involve the same hormones, neurotransmitters, and paracrine agents. Background-related morphological color change is now

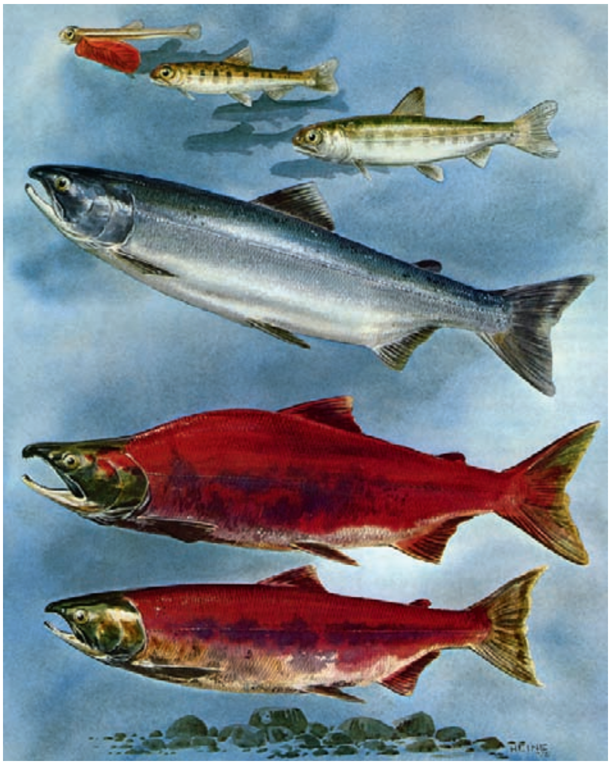

Figure 3 Sockeye salmon life-history stages. (Top to bottom) Alevin, fry, smolt, ocean phase, spawning male, and spawning female. Illustration courtesy of the estate of Harry Heine. Reproduced from plate 4 in Burgner RL (1991) Life history of sockeye salmon (*Oncorhynchus nerka*). In: Groot C and Margolis L (eds.) *Pacific Salmon Life Histories*, pp. 1–117. Vancouver: UBC Press, with permission from UBC Press.

considered a physiological phenomenon, representing a balance between differentiation of chromatophores from stem cells and their apoptosis (cell death), which is as an example of tissue homeostasis. Cytoplasmic cyclic adenosine monophosphate (cAMP) signaling pathways are involved in physiological color change and appear to regulate chromatophore survival and apoptosis, as well as their differentiation and dendricity (the number of processes).

Skin coloration may not be a reliable criterion in fish taxonomy, or a reliable discriminator of stock structure. Diet can influence xanthophore pigmentation. For example, the golden cod of Labrador is a population of Atlantic cod, *Gadus morhua*, in which skin color is influenced seasonally by an invertebrate diet that is rich in carotenoids. Morphological color changes can be associated with specific life-cycle stages, as in salmonids (**Figure 3**). The parr markings (vertical bars) of young salmonids are replaced by silvery sides and a darker dorsal surface during smoltification (**see also Hormonal Control of Reproduction and Growth:** Endocrinology of Fish Growth). When salmon return to breed in freshwater, nuptial red coloration is observed. The red pigment deposits in the fins and skin, as well as the pink muscle tissue of salmonids, come from dietary carotenoids, including the pigment astacene from oceanic crustacean.

The Regulation of Color Changes

In cyclostomes and elasmobranchs, neural control is unlikely. Instead, cyclostome melanophores are under agonistic pineal and pituitary regulation and elasmobranch melanophores are under pituitary control.

In teleosts, background-related physiological color change is mediated through rapid sympathetic adrenergic nervous regulation and/or slower hormonal control. There is considerable interspecific variation in the extent of neural and hormonal regulation of teleost physiological chromatic change. In paradise fish, *Macropodus opercularis*, rapid responses of melanophores to black and white background changes involve the nervous system alone; in *Phoxinus*, there is rapid neural initial control and slower pituitary secondary control; and in eel, *Anguilla anguilla*, there is predominantly slower pituitary control. Both neural and pituitary controls are essential in attaining final chromatic equilibrium in *Phoxinus*.

Background-related color changes involve photic stimulation of the eyes; subsequent central processing is only partly understood. The dorsal retina receives light reflected from the substrate, direct light from above being received by the ventral retina; the ratio between the two, or albedo, determines responses. There is evidence for excitatory and inhibitory synapses at different levels within the brain, including the optic tectum and medulla oblongata (**see also Brain and Nervous System:** Functional Morphology of the Brains of Ray-Finned Fishes and Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern). A melanosome-aggregating spinal cord pathway originates from a paling center in the medulla oblongata and has a local outflow, varying between species, to the sympathetic chain. The neural pathways then follow anterior and posterior sympathetic routes, connecting through spinal nerves to an adrenergic neural plexus associated with the dermal melanophores.

It has been demonstrated that, in *Phoxinus*, the spinal pigmentomotor tracts have a dorsomedial distribution within the substantia gelatinosa Rolandi and corpus commune posterius. Microsurgical lesions, including unilateral ones, in the spinal pigmentomotor tracts produce bilateral dark mottled patterns over the entire dorsal and lateral skin in white-adapted *Phoxinus*. This indicates a diffuse neural distribution to the melanophores, including some contralateral decussation. Individual melanophores can display degrees of postsurgical asymmetrical dispersion, demonstrating their multiple neural associations with the dermal plexus. Similar asymmetrical responses, along margins of surgically produced caudal bands, lead to the same conclusion. Functionally, cutaneous pigmentomotor axons appear to retain their integrity rather than synapse within the dermal nerve plexus; a conclusion supported histologically in *Phoxinus*.

Dineuronic control in teleosts (i.e., two separate types of control neurons), involving melanosome-aggregating and -dispersing neurons, as opposed to mononeuronic control involving a single neuron type (adrenergic), has been debated extensively. Currently, there is no support for cholinergic neural control of melanosome dispersion. Alternatively, spinal pigmentomotor neuron activity could be regulated by excitatory and inhibitory centers within the brain, providing a basis for mononeuronic control of bidirectional responses, dependent on melanophore adrenoceptor physiology.

One mechanism for mononeuronic bidirectional regulation involves the presence of α- and β-adrenoceptors on the melanophore plasma membrane. Such adrenoceptors can facilitate mononeuronic control, since concentration level of a single neurotransmitter changes the bias between α- and β-adrenoceptor activity. α-Adrenoceptors mediate melanosome aggregation; α_2-adrenoceptors are the effective subtype, but α_1-adrenoceptors are functional in at least some teleosts. β-Adrenoceptors mediate melanosome dispersion; both β_1- and β_2-adrenoceptors coexist on melanophores of two gobies, *Tridentiger trigonocephalus* and *Chasmichthys gulosus*, and winter flounder, *Pseudopleuronectes americanus*. Melanophore α-adrenoceptors have a higher stimulation threshold. In *Pseudopleuronectes*, melanosome dispersion in response to lower concentrations of catecholamine is reversed over a transition range as α-adrenoceptor activity overrides that of β-adrenoceptors at higher concentrations. An alternative mononeuronic mechanism occurs in melanophore control in tilapia, guppies, and siluroid catfish. ATP is released from adrenergic nerves as a co-transmitter; adenosine resulting from its dephosphorylation reverses aggregation by the clearing catecholamine.

The major intracellular second messenger in teleost melanophores is cAMP, which mediates melanosome dispersion. Stimulation of β-adrenoceptors increases adenylate-cyclase activity, raising cAMP levels. α_2-Adrenoceptor stimulation reduces adenylate-cyclase activity and cAMP levels. When α_1-adrenoceptors are present on chromatophores, they mediate more rapid pigment aggregation through another second messenger, inositol 1,2,5-trisphosphate (IP_3), by release of intracellular Ca^{2+}.

Pituitary hormones control slower (hours) physiological and prolonged (days/weeks) morphological color changes. Melanophore-stimulating hormone (MSH), synthesized in the pars intermedia, increases chromatophore intracellular cAMP levels, triggering chromatosome dispersion on a black background. Darkening is associated with increased plasma MSH and pituitary MSH cell activation. During morphological color change, this hormone stimulates melanogenesis through cAMP signaling to trigger activation of tyrosinase. MSH, continually released from an implanted minipump, can stimulate melanophore development *in vivo* in tilapia on a white background. Another hormone, melanin-concentrating hormone (MCH), hypothalamic in origin but stored in the pars nervosa, aggregates melanosomes on a white background by decreasing melanophore cAMP signaling. Long-term MCH treatment on a black background inhibits melanin increase. MCH also inhibits MSH secretion. It is not clear whether MCH is involved in melanophore apoptosis during prolonged adaptation to a white background, although neuronal noradrenaline is considered important.

Chromatophore physiological responses can involve the pineal body, and its hormone melatonin (*N*-acetyl-5-methoxytryptamine), in nighttime blanching associated with circadian rhythms. There are diurnal changes in plasma melatonin in flounder, *Platichthys flesus*, in continuous darkness, indicating the presence of an intrapineal oscillator. This contrasts with direct regulation of melatonin by light intensity acting on the pineal in rainbow trout, *Oncorhynchus mykiss*. Melatonin aggregates melanosomes and erythrosomes in some species, but others are refractory, which may relate to ethological differences.

Additional hormones implicated in chromatic physiology include adrenaline, adrenocorticotropic hormone, and gonadal steroids, so also are paracrine factors. Melanization may be influenced locally by melanization-stimulating factor (MSF) and melanization-inhibiting factor (MIF) within the skin. A few reports indicate that prostaglandins, endothelins, and nitric oxide influence melanophore physiological responses.

Integumentary Patterns in Fish

Integumentary coloration ranges from a single hue to chromatic patterns, which may undergo short-term or longer seasonal change. Skin patterns are important in the lives of fish; they may have blending or disruptive cryptic roles, be epigamic or associated with stress and excitement. Causal ethological analysis has been used, with variable success, to determine whether particular patterns, and their intensity, represent indicators for motivational states, which control the motor performances of fish. Such analysis may provide a bridge toward physiological research on mechanisms controlling particular behavioral attributes. Detailed accounts of the basis of patterns are available for relatively few fish species. These involve local variations in the chromatophore types, their relative size, and numerical distribution. In addition, rapid pattern changes may involve differential physiological responsiveness of chromatophores.

Seasonally, iridescence, coupled with erythrophore-based red coloration and zigzag dancing behavior, in male sticklebacks (*Gasterosteus aculeatus*), attracts females. This nuptial coloration is a secondary sexual characteristic dependent on testicular androgen levels. *Phoxinus* has lateral vertical stripes with macromelanophores distributed differentially, resulting in a disruptive pattern. Macromelanophore patterns in *Xiphophorus* have been studied for evidence of a genetic factor in human melanoma formation. Hybrids of platyfish, *Xiphophorus maculatus*, and swordtail, *Xiphophorus helleri*, develop spontaneously, malignant melanoma induced by genes clearly defined by classical genetics. In paradise fish (*Macropodus opercularis*), alternate red and green vertical banding is associated with a numerical distribution of different types of chromatophores. They also display a gradient of physiological responses of melanophores, at various depths of the skin, to background changes. In flatfish (Pleuronectiformes), the patterns have morphological attributes, but changes involve differential physiological responses. Local variations in α- and β-adrenoceptor transition ranges facilitate simultaneous paling and darkening of different pattern areas of flatfish by adrenergic neurons alone. These fish are exceptional among animals in their sensitivity to both substrate texture and color (**Figure 4**).

Intrapattern scale autografts demonstrate that in yoshinobori, *Rhinogobius brunneus*, differential activity is a neural function rather than a chromatophore function. In green sunfish, *Lepomis cyanellis*, and bluegill, *Lepomis macrochirus*, localized electrical stimulation of the anterior medulla oblongata produces banding patterns, while stimulation of its posterior region elicits paling. In pencil fish, *Nannostomas trifasciatus*, melatonin may be involved in circadian rhythms of patterns; treatment with it during the daytime induces night patterns. It aggregates melanosomes in most of the pattern, while macromelanophores in dark spots display pigment dispersion, implicating two types of melatonin receptors.

In cichlids, pattern displays can depend on differentially responding superficial and deep melanophores. In the cichlid *Haplochromis burtoni*, territorial males possess a dark eyebar with melanophores differentially controlled during social signaling by an eyebar nerve. There are intermorph differences; eyebar melanophores of barless males have less pigment and are more responsive to noradrenaline. A wide variety of color pattern polymorphisms occur in cichlid fish in Africa; Lake Victoria being remarkable for its diversity of both interspecific and intraspecific color morphs. How this diversity is maintained is a problem that continues to be addressed.

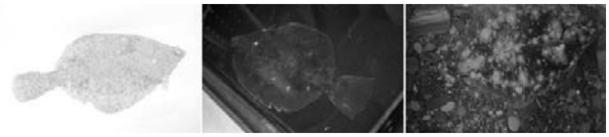

Figure 4 Color of *Pseudopleuronectes americanus* on (left to right) white, black, and pebble backgrounds. On pebbles, responses vary between different areas of skin producing a disruptive camouflaging pattern. Photographic assistance: G. Hillier and C. Hawkins.

During pattern metamorphosis in zebrafish, *Danio*, selective survival and apoptosis of melanophores are essential for stripe formation; larval and adult patterns being different. In channel catfish, *Ictalurus punctatus*, MIF inhibits melanization in white ventral skin; MSF stimulates melanization in black dorsal skin. Local variations in activity of these two factors may be a major influence in developing fish pattern morphology.

Within the ancient taxa represented by fish, chromatic cellular and regulatory processes have undergone widespread adaptations, resulting in diverse integumentary patterns and their control, related to habitat and behavioral requirements. Historically, individual research programs on fish coloration have dwelled either on chromatophores and their control, or on ethological aspects; greater emphasis needs to be placed on combining both approaches.

Glossary

Bathypelagic Aphotic ocean-depth zone from 1000 to 4000 m.

Bioluminescence Light produced by a chemical reaction that originates in an organism,

Counter-illumination A defensive measure by bioluminescent midwater cephalopods, decapod crustaceans, and fishes that camouflages an animal being viewed from below by mimicking downwelling light and reducing its silhouette.

Isolume A line joining points of equal light intensity.

Luminescence Light emission that does not derive energy from the temperature of the emitting body, as in bioluminescence.

Mesopelagic A biogeographic region of open oceans between 200 and 1000 m depth and not near the ocean floor.

Photophore Light-emitting organ in bioluminescent animals.

Many people's experience with bioluminescence is limited to firefly displays or observing their own ghostly outline while swimming through dinoflagellates during nocturnal forays into the ocean. Yet, beneath the ocean's surface, creatures spanning the scale from bacteria to jellyfish to sharks are capable of a dazzling array of luminescent displays. However, the diversity of bioluminescent organs reaches its apex in teleosts with approximately 190 genera in over 45 families containing bioluminescent individuals. Most luminescence is produced by endogenous chemical reactions involving a substrate (luciferin) catalyzed by either luciferase or a photoprotein. Bioluminescence has clearly evolved many times independently, although the substrates are relatively conserved and only four principal luciferins are responsible for most marine bioluminescence. Moreover, the majority of fish luminescence is based on Cypridina or Coelenterazine luciferin. A number of fish species harbor symbiotic bioluminescent bacteria that provide light and these prokaryotes use a different biochemical pathway.

Light Organs

Light organs or luminescent tissues come in a diverse array of shapes and sizes, ranging from simple photophores to complex protuberances. A number of species culture bioluminescent bacteria that can be located in a large organ under the eye (flashlight fish), in luminescent lures at the end of long stalks (anglerfish), or internally in organs that transmit light through translucent tissue (pony fish). As the bacteria appear to luminesce constantly, some species have developed shutter or filter mechanisms, to regulate the light. Although the bioluminescence from these organs can be diffused over large areas, there is rarely more than one site where the bacteria are cultured.

In contrast, other fish have evolved hundreds of small, circular dermal photophores that are scattered on their ventral and/or lateral surfaces, are neurally controlled, and emit variable flashes. Many deep-water species have evolved pairs of orbital organs. Other families, such as the myctophidae (lanternfish), have streaks of luminous tissue on their head or caudle peduncle in additional to photophores. The tube shoulders (platytroctidae) squirt luminescent ink into the environment from anterior-situated glands situated on their shoulders. In his 1978 review, John Buck postulated at least 20 functions of luminescence spanning three main areas: predation, defense, and communication (**see also Sensory Systems, Perception, and Learning**: Communication Behavior: Visual Signals). Virtually every example is found among teleost fish with organ, tissue, and/or photophore combinations allowing multiple functions.

Light Environment

The brighter the environment, the less effective is luminescence. Therefore, the majority of luminescent fish are black-water creatures and live where there is little or no light that could interfere with their displays (**see also Vision**: Visual Adaptations to the Deep Sea, Physiological Optics in Fishes, Photoreceptors and Visual Pigments, and Adaptations of Photoreceptors and Visual Pigments). These habitats include dark caves or crevices in shallow-water reefs, the variable twilight of the mesopelagic ocean, or the constant darkness (except for bioluminescence) of the abyssal plain. A number of species undergo diurnal migration, following dim isolumes and ascending in the water at night before returning to the darker depths during the day. The majority of luminescent fishes are meso- or bathypelagic, inhabiting an environment where spatial refuge is scarce and a premium is placed on remaining inconspicuous. Yet, by their very nature, light displays can compromise the emitter's location and expose it to predators. Therefore, luminescent animals must balance the advantage of luminescent displays against the risk of detection.

As light originates from astral sources, the prevailing light direction is downward. Seawater filters both the intensity and the spectral composition of the downwelling light relatively quickly with blue light the dominant wavelength at depth. The majority of fish luminescence is blue or blue-green, with emission maxima rarely exceeding 515 nm, which is consistent with wavelengths that would be maximally transmitted through the water column. Midwater visual systems show a general trend toward trading visual acuity for visual sensitivity to maximize photon capture and many retinas are dominated by rods and/or possess a reflective tapetum. Upward-looking eyes, best suited for discerning faint silhouettes illuminated by the downwelling light, are common and the visual pigments of most luminescent fish are maximally sensitive to blue-green light. It is estimated that visual adaptations allow the detection of daylight in midwater animals at depths up to 1000 m in the open ocean.

Luminescence Observation

As the vast majority of luminescent fishes inhabit the deep ocean, only a few shallow water species or hardy midwater dwellers have been captured in sufficient condition to study the physiology and function of luminescent organs. More often than not, mesopelagic fish are moribund, and while some remain alive long enough to observe flash patterns and quantify light intensities, one must wonder how representative these displays are to the natural condition. While submersibles and remote-operated vehicles (ROVs) have provided great insight into the midwater world, their bright lights scare or blind luminescent fish and make *in situ* observations of natural luminescence impossible. Therefore, much information on luminescent fish is inferred and based on the morphology, size, types, and body position of luminescent organs.

Flash Kinetics

The flash kinetics of the light displays is highly variable. Symbiotic bioluminescent bacteria emit a continuous glow that can be blocked by shutter mechanisms or perhaps modified by oxygen regulation to the colony. However, many bacterial symbionts are used for defense, so that the continuous glow may not increase the risk of predation. Photophores or other luminous tissue that are neurally controlled can regulate flash duration, frequency, and intensity, resulting in irregular single flashes to trains of high-frequency flashes. However, the majority of these displays are brief (<1 s), and as pharmacological manipulation of these organs can produce long-lasting glows, it does not appear that the displays are substrate limited. Rather, it could represent the continual balance of display versus detection.

Counter-illumination

The prevailing downward direction of light has been a strong evolutionary driving force in selecting the pigmentation of near-surface fish resulting in dark backs and lighter ventral surfaces. A lighter underside results in less-visible silhouette to visual predators lurking below. In contrast, the majority of luminescent fish are uniformly black, presumably an adaptation to minimize light reflection and remain unseen. Forward-facing or upwardly directed eyes, combined with the darker depths, result in ventral blind spots for fish. The lateral line only provides short-range detection, so predators that discern a faint silhouette can close in from below with little chance of detection. For defensive purposes, fish have evolved ventral counter-luminescence organs that match the intensity and angular distribution of downwelling light. The luminescence can originate from internal bacterial organs that diffuse light through translucent tissue or serially arranged ventral photophores. The long-term glow from these organs is consistent with a need for extended periods of counter-illumination.

Bioluminescent Fish

Hatchetfish

While ventrally directed light has been hypothesized for counter-illumination, few studies have empirically demonstrated it. Hatchetfish, such as *Sternoptyx* and *Argyropelecus*, are small, laterally compressed fish with rows of photophores lining the ventral portion of their thin silhouette (**Figure 1**). Moribund on capture, the ventral photophores normally will emit long-lasting glows; however, *Argyropelecus* can emit brief (<100 ms), high-intensity flashes. *Sternoptyx* has two large luminescent organs in the roof of its mouth that produce longer flashes (~1 s). Large tubular reflector channels are associated with the ventral photophores and match the angular distribution of luminescence with the downwelling light. A preorbital organ in *Argyropelecus* shines directly into the eye and is hypothesized to control ventral photophore intensity by acting as a reference for ambient light. Whether the oral organs are used in a similar fashion or used to lure prey remains to be determined.

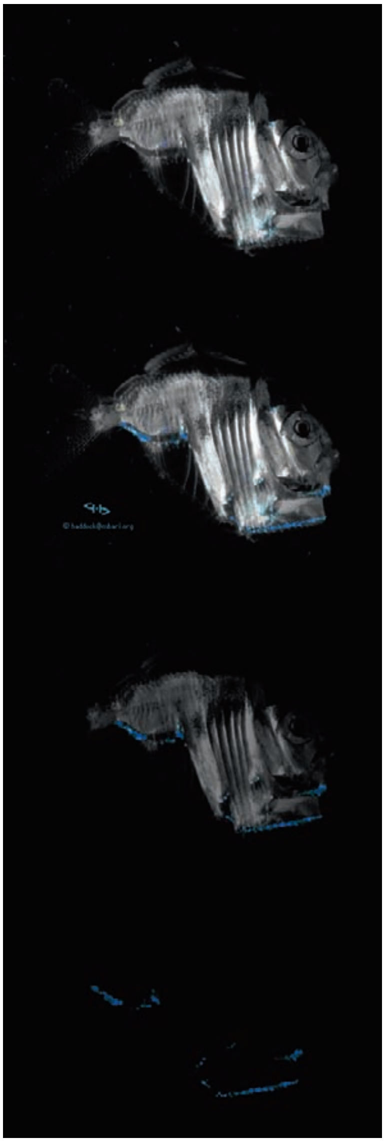

Figure 1 The hatchetfish, *Sternoptyx*, has many photophores beneath its body and contains the substrate luciferin which will fluoresce under ultraviolet (UV) light. Under normal circumstances, bioluminescent light would be emitted from these same fluorescent photophores. The glow is directed downward through light guides, presumably to function as counter-illumination (fish length, approximately 3 cm). Photograph by Steve Haddock.

Midshipman

Perhaps, the best example of counter-illumination is in the midshipman *Poricthys notatus*. Its name originates from the 800 ventral photophores that resemble the buttons on a midshipman's coat (**Figure 2**). The fish is found along the Pacific coast of the continental US, and probably is best known for its relatively loud and incessant hum generated during the spring mating season, which disrupts the sleep of houseboat owners. Fish are buried in the sand during the day, but ascend the water column at night to feed. They migrate from offshore depths to the intertidal habitat to breed. The male fish acoustically attract females and guard the developing young until they detach from the nest. Although the juvenile fish obtain luciferin from the egg yolk, the fish need to acquire dietary sources of luciferin to remain luminescent. The main source of exogenous luciferin in the wild appears to be the luminescent ostracod, *Vargula tsujii*; however, cannibalism of luminescent conspecifics also restores luminescence.

The ventral photophores, which are neurally controlled, approximate the angular distribution and intensity of downwelling irradiance rendering the silhouette of *P. notatus* invisible to dark-adapted observers. Counter-illumination was also effective in reducing predation by larger conspecifics. Interestingly, the counter-illumination was only initiated when a hydrodynamic stimulus was paired with an appropriate light presentation. Thus, luminescence is only initiated when the fish sense a disturbance such as a potential predator. This is in contrast to the continuous glows exhibited in other counterilluminating fish, and may conserve luciferin and/or energy. The fish also preferentially preys on organisms that have been illuminated by dinoflagellate luminescence in one of the few demonstrated examples of the luminescent burglar-alarm theory.

Flashlight Fish

The most widely known group of luminescent fishes to both science and the public are the flashlight fish

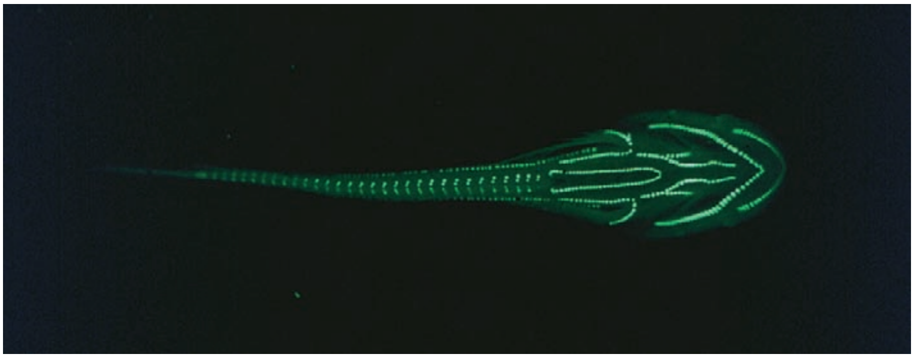

Figure 2 Ventral view of the midshipman, *Porichthys notatus*. Its photophores are stimulated to fluoresce under ultraviolet light and function for counterillumination.

(Anomalopidae), which are often displayed in public aquaria and are amenable for laboratory studies. Although almost exclusively nocturnal, they will depart from daytime hiding spots in reef caves and venture to shallow water during the night. A single, kidney-shaped light organ lies beneath each eye, and harbors dense concentrations of continuously luminescent bacteria. The light can be turned on or off by a black curtain that is raised from the lower border of the socket or by rotating the organ downward into a black pocket. The fish have exquisite control over the shutter, and can flash over 100 times min^{-1}. Jim Morin has studied the fish in the field and laboratory and has postulated that the lights are used to attract or illuminate prey, avoid predators, and for intraspecific signaling.

Anglerfish

Anglerfish also culture bacteria in an esca, a fleshy growth at the end of a modified dorsal fin spine (**Figure 3**). The spine is movable and the esca is used as a luminescent lure to attract prey to the fish. The bacteria appear to glow continually. However, flashes or pulses of light have been observed from live fish. The control mechanism is not understood, but blood flow and concomitant oxygen availability to the organ may be involved in regulation. Only female anglerfish are luminescent, which is consistent with their unusual natural history. The much smaller, nonluminescent males permanently attach to the female, who provides nutrients to the male throughout its life. Esca are species specific and range from simple bulbs to

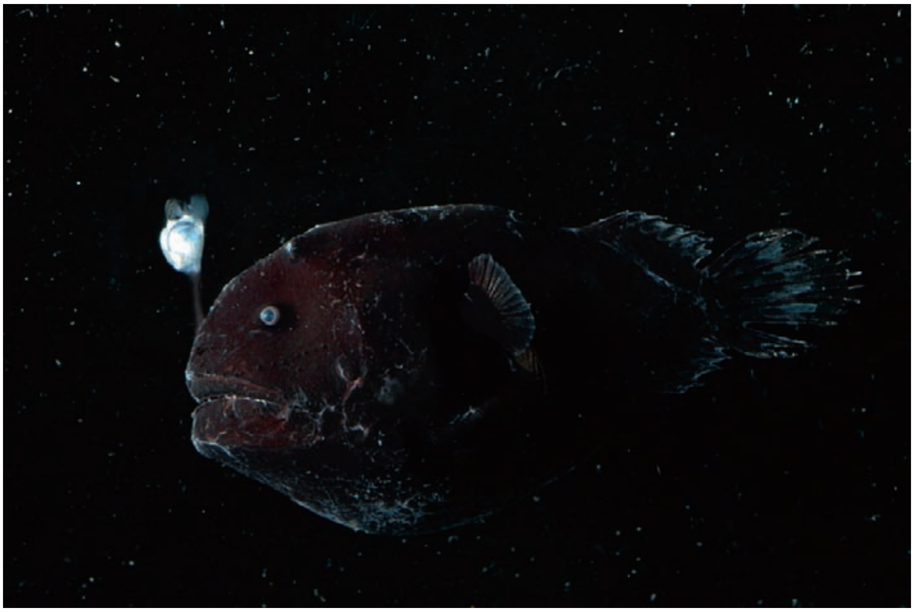

Figure 3 The anglerfish *Chaenophryne longiceps.* Anglerfish culture bacteria in an esca, which is a fleshy growth at the end of a modified dorsal fin spine. The spine is movable and the esca is used as a luminescent lure to attract prey to the fish (fish length approximately 4 cm). Photograph by Steve Haddock.

elaborate protuberances that may assist in the male locating the correct mate.

Cardinal Fish

Another group of relatively shallow-water species, the cardinal fishes (Apogonidae), have evolved visceral light organs. The light organs can be undifferentiated portions of the intestinal tract or specialized out-pockets of the alimentary canal. The unique aspect of this group is that luminescence has evolved independently within the family, with some species housing luminescent bacteria while others rely on endogenous biochemical reactions. Fish in the genus *Siphamia* have an organ containing luminescent bacteria that sits on top of the ventral musculature that is covered with chromatophores. Recent findings indicate that at least two species of *Siphamia* harbor an additional oral bacterial light organ that may be used to lure prey into the mouth. Endogenous light organs are formed from out-pockets of the intestine or pyloric ceca with some fish having an additional pair of anal light organs. The glow from either the bacterial or the glandular organs is projected through transparent keel muscles that contain chromatophores (**see also The Skin**: Coloration and Chromatophores in Fishes). The muscles act to diffuse the light with the intensity perhaps regulated by the chromatophores, and is presumably used for counter-illumination.

Ponyfish

Ponyfish (Leiognathidae) also project light through translucent tissue. These fish are found in coastal areas of the tropical and subtropical Indo-Pacific, and have evolved a light-organ system (LOS) that contains a circumesophageal bacterial light organ complete with reflectors, chromatophores, shutter, translucent and reflective swimbladder tissue, and translucent bone, muscle, and skin. An intense but diffuse blue-green light can be emitted ventrally for counter-illumination. Translucent patches on the flanks, opercular margin, and/or buccal cavity can emit rapid flashes of light, and the strong sexual dimorphism of the LOS combined with *in situ* observations of schooling fish suggests sex-specific signaling. The flashing may also function in prey attraction, predator avoidance, or schooling.

Barreleye Fish

Barreleye fish (Opisthoproctidae) are named for their unusual barrel-shaped, tubular eyes with symbiotic bacterial bioluminescence reported in three genera. The ventral surface of the mirror belly Opisthoproctus is characterized by a flattened and projecting sole that may act to reflect the luminescence downward from a single rectal organ for counter-illumination. The eyes were originally considered to be directed permanently upward to search for prey, but recent observations show that eyes can pivot forward.

Tubeshoulders

Tubeshoulders are a family (Platytroctidae, formerly Searsiidae) of mid- to deep-water fish that possess multiple luminescent organs. Ventrally directed photophores and patches of white tissue are found on the body. However, they can also eject a blue-green luminous fluid from a black sac located under the pectoral girdle. The secretion is bright and long lasting and may be analogous to squid ink, blinding, or confusing predators. The ink is composed of modified cells that form sheets or balls, which may stick to potential predators that could turn the hunter into the hunted.

Lanternfish

The lanternfish or myctophids are very abundant midwater fish found throughout the world's oceans, consisting of approximately 300 species, many of which undergo diurnal vertical migrations. The lanternfish account for over 60% of all deep-sea fish biomass and play an important ecological role as prey for larger organisms; thus, there is strong selective pressure to remain inconspicuous. The fish possess species-specific serial photophores and/or luminous tissue. The mostly ventral primary photophores are well developed and contain lenses, while smaller, less-developed secondary photophores are distributed over the body. Streaks or patches of luminous tissue may appear on the flanks and heads, but more often are found on the caudal peduncle as supra- and infracaudal organs (**Figure 4**). Although moribund on capture, specimens can remain alive for several hours allowing estimation of flash intensity and kinetics. Serial photophores produce a dim glow for hours, and can also increase light intensity during rapid flickering events.

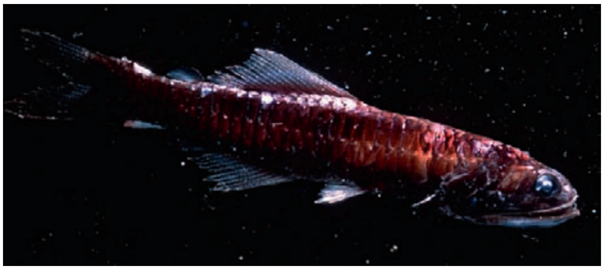

Figure 4 Some lanternfish (myctophids) have very bright light organs near their tail (white caudal organs). These stern chasers produce a blinding flash at the instant that the animal darts away, leaving a confused predator in its wake. Photograph by Steve Haddock.

The intensity of these photophores can be modulated by ambient light intensity, suggesting a role in counter-illumination. Luminous tissue displays much quicker (<100 ms) and intense flashes with frequencies up to 30 Hz. Cephalic tissue in Diaphus, producing flashes of 300–400 ms, appears suited for prey illumination; however, species-specific signaling is also possible. The caudal organs have been characterized as stern chasers, whose quick flashes combined with tail flips could confuse trailing predators. Although photophore patterns were hypothesized originally to serve for species recognition, the minute differences in photophore location within genera and the tendency of midwater animals to sacrifice visual acuity make identification unlikely at the species level.

Dragonfish

The dragonfish (family Stomiidae) comprise 27 genera of midwater fish that all contain a prominent postorbital photophore. As with the myctophids, many of these fish survive capture for a short period of time, allowing bioluminescence to be observed. The typical member of this family is an elongated fish, equipped with impressive detention and possessing diverse luminescent organs. Most bear well-developed, serial ventral photophores in addition to minute photophores scattered over the rest of the body. Many have two orbital photophores, glandular patches of luminous tissue, and/or luminous bodies found among fin rays. The barbels are quite diverse, ranging in length from stubby chin protrusions to filaments longer than the fish, and in morphology from simple stalks to elaborate fleshy protrusions (**Figure 5**). The luminous tissue may extend the whole length or be confined to the terminal end of the barbel. The glandular patches can emit trains of high-intensity light, and are thought to deter predators. Barbels may act for species recognition or to lure prey.

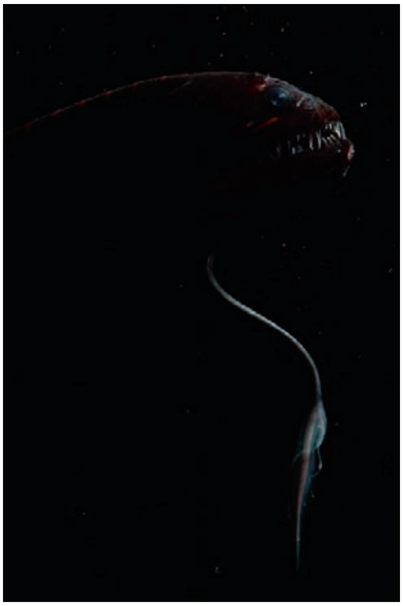

Figure 5 The Pacific Black Dragonfish (*Idiacanthus antrostomus*) is one of the most amazingly bioluminescent animals in the sea. It is covered with photophores along lower and upper surfaces, and has photophores under its eyes and at the end of a long barbel. When disturbed, it lights up all over, even down the lengths of its fins. Photograph by Steve Haddock.

The postorbital organs emit intense blue-green light and flash for 1–2 s. Many of the organs can be rotated and may act as headlights, although the effect of these high beams on dark-adapted eyes needs to be studied. Sexual dimorphism in organ size is common; so, perhaps, they have evolved to attract mates. Three genera, Malacosteus, Aristostomias, and Pachystomias, have evolved a suborbital organ that emits red light, which appears to be a stealth form of luminescence (**Figure 6**). Long-wave luminescence was a surprising discovery because red light is rapidly attenuated and has a much shorter range than blue light. The subsequent discovery of red-sensitive photopigments in the family confirmed that the fish can detect their own light (**see also Vision**: Photoreceptors and Visual Pigments and Adaptations of Photoreceptors and Visual Pigments). While limited in distance, few midwater animals have red-sensitive visual pigments, which may allow these animals to operate their luminescence without fear of detection, which is consistent with the long flashes (~4 s) from the red organs. Additionally, many midwater species have evolved bright red carapaces that, like black pigmentation, would function to absorb most ambient and bioluminescent wavelengths. The red bioluminescent may be an adaptation to illuminate prey that would reflect the long wavelengths.

The Future

With the advent of submersibles and ROVs, scientists are moving forward in understanding many of the mysteries of the midwater environment. New species of luminescent fish are discovered yearly but the function and physiology of the light organs remain more speculation than scientific fact. Although the stress of capture probably does not distort the emission spectra of the light, flash intensity and kinetics of moribund specimens may not adequately represent the natural signaling of the animals. The frequency of spontaneous or evoked luminescence from midwater fish remains completely unknown. While *in situ* observations could advance the field in quantum leaps, the task is daunting: how does one noninvasively observe the behavior of small, black fish swimming in a dim, deep, depauperate environment. The advent of long-endurance autonomous gliders fitted with image-intensifying and infrared cameras that could

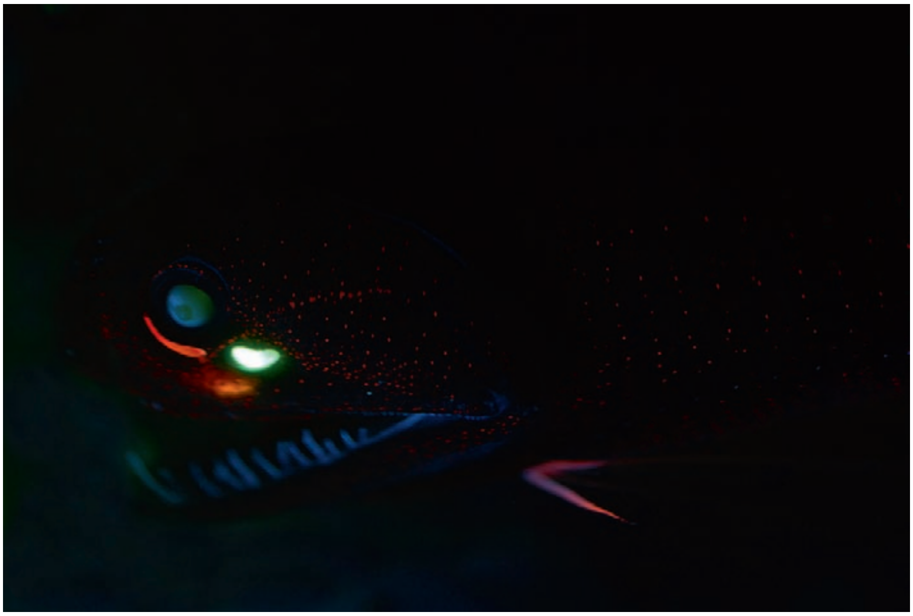

Figure 6 Close-up of the head of *Aristostomia* under fluorescent light. The postorbital photophore produces blue light; the crescent-shaped suborbital photophore emits red wavelengths. The small red dots on the fish's dermis are primitive photophores. Photograph by Steve Haddock.

sample the water columns for extended periods of time might be the best approach. While the field has moved incrementally forward since Harvey's 1952 monograph, *in situ* observations and controlled laboratory experiments remain infrequent. Access difficulties, expensive ship and submersible coast, and low funding have hamstrung efforts and our knowledge of bioluminescent fish lags behind all other areas of marine ecology. Hopefully, novel *in situ* observation instruments coupled with twenty-first-century technology will shed new light on the ecology and physiology of bioluminescent fishes.

Glossary

Exocytosis The process by which neurotransmitters or hormones, which are stored in secretory vesicles or granules, are released from a nerve or endocrine cell when these storage granules fuse with the plasma membrane

Gland mucus cell Cell within hagfish slime glands that give rise to the mucus component of hagfish slime.

Gland thread cell Cell within hagfish slime glands that give rise to the fibrous component of hagfish slime.

Hagfish slime The material that is formed when hagfishes forcefully release the glandular contents of their numerous slime glands into seawater.

Hagfish slime exudate The thick white fluid that is ejected from hagfish slime glands and that interacts with seawater to form hagfish slime. The exudate contains numerous mucin vesicles and thread skeins.

Holocrine secretion Mode of secretion in which entire cells are ejected from a gland.

Intermediate filaments The 10-nm-diameter cytoskeletal filaments that make up hagfish slime threads.

Mucin vesicles Small, membrane-bound structures containing condensed mucus that are released when gland mucus cells are ejected from hagfish slime glands.

Slime threads Fine protein fibers that permeate hagfish slime and arise from the deployment of ejected thread skeins.

Thread skein Intricately coiled intermediate filament bundle that develops within gland thread cells and deploys after ejection from the slime glands to form the fibrous component of the hagfish slime.

Introduction

Hagfishes are best known for their ability to produce alarming amounts of slime when they are stressed or provoked (**see also Hagfishes and Lamprey**: Hagfishes). In fact, many of their common names include the word slime, such as slime eel and slime hag. The Atlantic hagfish, *Myxine glutinosa*, is twice named for its slime (myx = slime, glutin = glue). Many animals release slime under stress, but hagfish slime is unique because of the large volumes that are produced (up to several liters from a single hagfish) (**Figure 1**), the impressive speed with which it is made, and the fact that it contains tens of thousands of fine protein fibers (**Figure 2**).

Hagfish slime can be defined as the material that is formed when hagfishes forcefully release the glandular contents of their numerous slime glands into seawater. Many marine animals, including hagfishes, make some sort of epidermal mucus or slime that coats their body, but hagfish slime is different from these secretions in many ways. For one, epidermal mucus is secreted at a slow and relatively constant rate to replace the dispersal of mucus from the outer surface (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes), whereas hagfish slime is released infrequently from specialized glands. Another difference is that hagfish slime exudate is released via holocrine secretion in which entire cells are ejected from the glands, whereas epidermal mucus is secreted via exocytosis of mucin granules at the apical plasma membrane of goblet cells.

The Hagfish Slime Gland

The slime originates within numerous slime glands located along both sides of the hagfish's body (**Figure 3**). *Eptatretus stoutii*, the Pacific hagfish, typically possesses about 150–200 slime glands. The glands are dominated by two cell types: gland mucus cells (GMCs) and gland thread cells (GTCs), which are responsible for the mucus

Figure 1 Hagfishes are able to produce vast amounts of slime when they are provoked. Here, a Pacific hagfish (*Eptatretus stoutii*) has produced liters of slime in response to being handled in an aquarium. Photo courtesy of Andra Zommers.

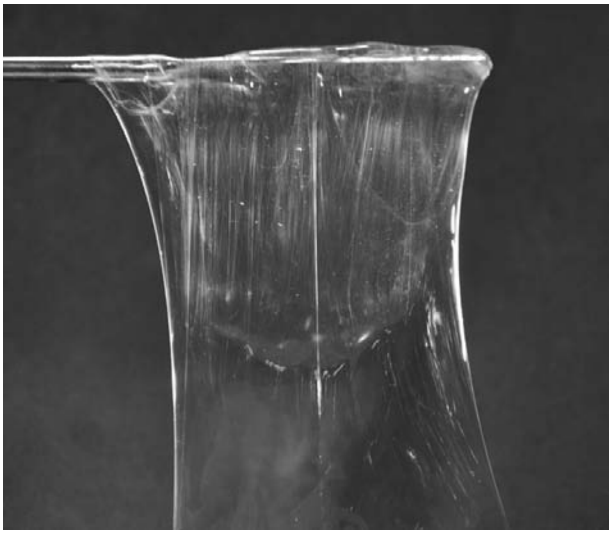

Figure 2 Hagfish slime contains tens of thousands of fine protein fibers that are over 10 cm long and about 2 μm in diameter. From Fudge DS, Winegard T, Ewoldt RH, *et al*. and fibrous components of the slime, respectively. GMCs and GTCs originate in the germinal layer of the gland and are pushed toward the gland lumen as they mature. The glands are approximately spherical in shape and are encased by a capsule of connective tissue, which is, in turn, surrounded by a thin layer of striated muscle fibers. When these muscle fibers contract, mature GMCs and GTCs are ejected from the gland via the holocrine mode into seawater through the gland pore.

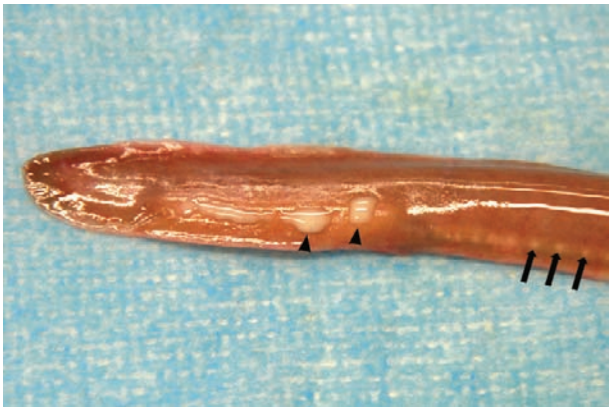

Figure 3 Hagfish slime is produced in numerous slime glands (arrows) that line both sides of the animal's body. Here, slime exudate (arrowheads) has been expressed from several slime glands via mild electrical stimulation of the muscle layer that surrounds the gland capsule. GMCs and Mucin Vesicles

GMCs are distinct from the small and large mucus cells found in hagfish epidermis. The sole function of GMCs is to package condensed mucins into disk-shaped membrane-bound vesicles that are about 7 μm in diameter (**Figure 4**). When mature GMCs are ejected from the slime gland, they lose their plasma membrane (presumably via shearing within the gland duct) and release numerous vesicles that swell and rupture upon contact with seawater. Compared with GTCs, GMCs and their secretion products are poorly studied. The genes for the molecules that make up the mucus component of hagfish slime have yet to be characterized, but histological staining and immunolabeling suggest that they are mucins. Mucins are very large (0.5–30 MDa), heavily glycosylated proteins in which up to 85% of the dry weight is carbohydrate. Hagfish mucins are unique in that they comprise only 12% carbohydrate and contain less serine and more sulfate than typical mucins. Hagfish slime also has been shown to contain higher levels of lysozyme, alkaline phosphatase, cathepsin B, and proteases relative to hagfish epidermal mucus.

Hagfish slime mucin vesicles are believed to have an internal osmolarity of about 897 mOsm based on the fact that they rupture in magnesium sulfate solutions with osmolarities lower than this, and are stable in magnesium sulfate solutions with higher osmolarities. The vesicles are stable in 1 M solutions containing the anions citrate, sulfate and phosphate, acetate, or tartrate, but rupture in similar solutions containing chloride, bicarbonate, or nitrate ions. These experiments suggest that the vesicle membrane is permeable to univalent anions but

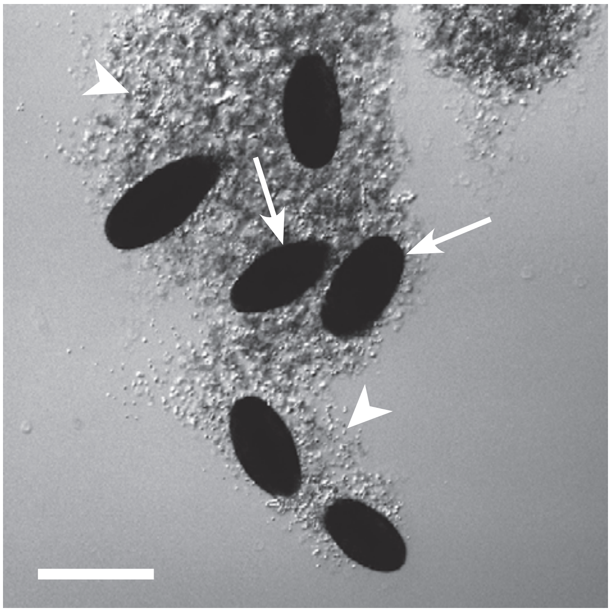

Figure 4 A small blob of exudate collected from a slime gland and pipetted into a drop of seawater. Hagfish slime gland exudate contains two main solid components – thread skeins (arrows) that consist of a single coiled intermediate filament bundle, and mucin vesicles (arrowheads), which appear as the granular material between the thread skeins. The material shown represents about 5 nl of exudate. impermeable to polyvalent anions. Vesicle rupture likely occurs not via a simple osmotic influx of water (as the vesicle is about the same osmolarity as seawater if not slightly hypoosmotic), but rather via the influx of ions such as chloride across the vesicle membrane, which then causes a subsequent secondary osmotic influx of water molecules. The water causes the vesicle to swell and then rupture, (**Figure 5**), resulting in the release of the mucin molecules into the external environment, where they are then free to interact with the fibrous component of the slime. This model predicts the presence of anion channels in the vesicle membrane; however, at this point, there is no direct evidence for them.

The fact that the mucin vesicles rupture readily in such a wide range of solutions raises the question of how they might be stabilized within the gland mucous cells prior to release from the slime gland. Chemical analysis of the fluid component of slime exudate has revealed high concentrations of methylamines such as betaine, trimethylamine oxide (TMAO), and dimethylglycine (DMG) (**Table 1**). Although these compounds are known osmolytes in other organisms, neither TMAO nor betaine (the two most abundant compounds) is capable of stabilizing the vesicles,

Table 1 The concentration of identified inorganic and organic osmolytes in the fluid component (supernatant) of fresh slime exudate

Osmolyte	*Concentration (mmol L^{-1})*
Cl^-	191.5 ± 6.6
K^+	143.0 ± 3.0
Na^+	41.2 ± 2.6
Mg^{2+}	2.15 ± 0.76
Ca^{2+}	0.000 45 ± 0.000 09
pH	7.31 ± 0.02
Total inorganic	379
Betaine	218 ± 7
TMAO	101.3 ± 4.8
Glycine	79.9 ± 7.5
Dimethylglycine	68.6 ± 6.0
Creatine	15.0 ± 1.4
Inositol	2.30 ± 0.68
b-alanine	2.17 ± 0.68
Taurine	2.13 ± 0.42
Glucose	1.23 ± 0.22
Total organic	490 ± 10

The total osmolarity of the supernatant is approximately 888 mOsm.
Values are means ± SEM, *N* = 5.
Inorganic ions were measured using ion-specific electrodes.
Organic solutes were analyzed using HPLC, and TMAO was analyzed using ferrous sulfate and EDTA.
TMAO, trimetheylamine oxide.

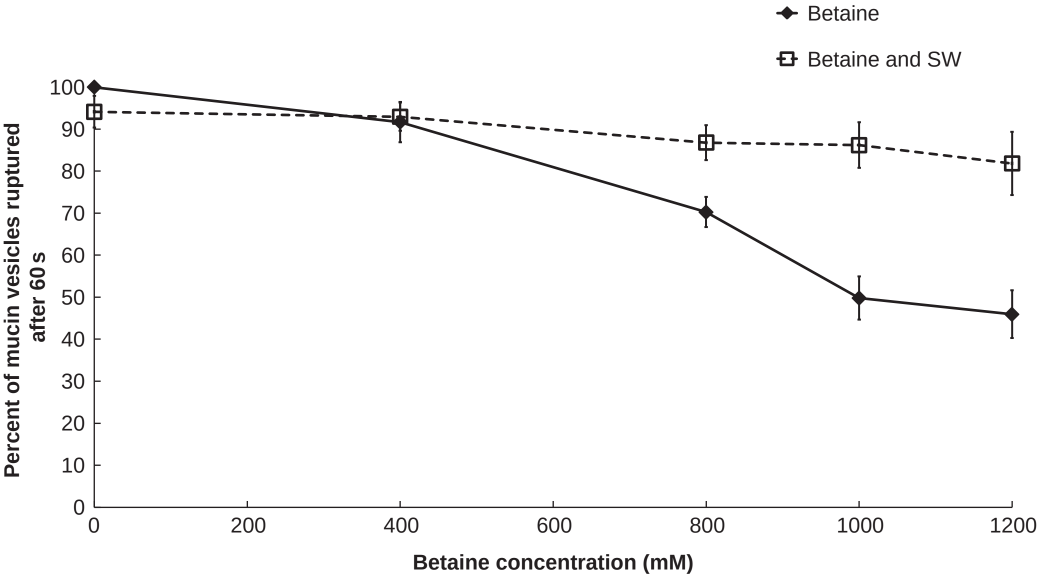

Figure 6 The percentage of isolated mucin vesicles from the slime of *Myxine glutinosa* that ruptured after 60 s of exposure to varying concentrations of betaine in 5.0 mM Tris, pH 8.0 (solid line). The dotted line represents the effect of changing betaine concentration in the presence of sea salts (33‰). Values are means ± SEM ($N = 6$ in each treatment). Two-way ANOVA showed significant effects of betaine concentration and the presence or absence of sea salts ($P < 0.05$). even at concentrations exceeding the internal osmolarity of the vesicle itself (**Figure 6**). Even more intriguing is the fact that the clear supernatant that is obtained when fresh slime exudate is centrifuged also is not stabilizing (**Figure 7**). This suggests that stabilization of vesicles within the gland may depend upon the chemical microenvironment within GMCs or another mechanism such as elevated hydrostatic pressure.

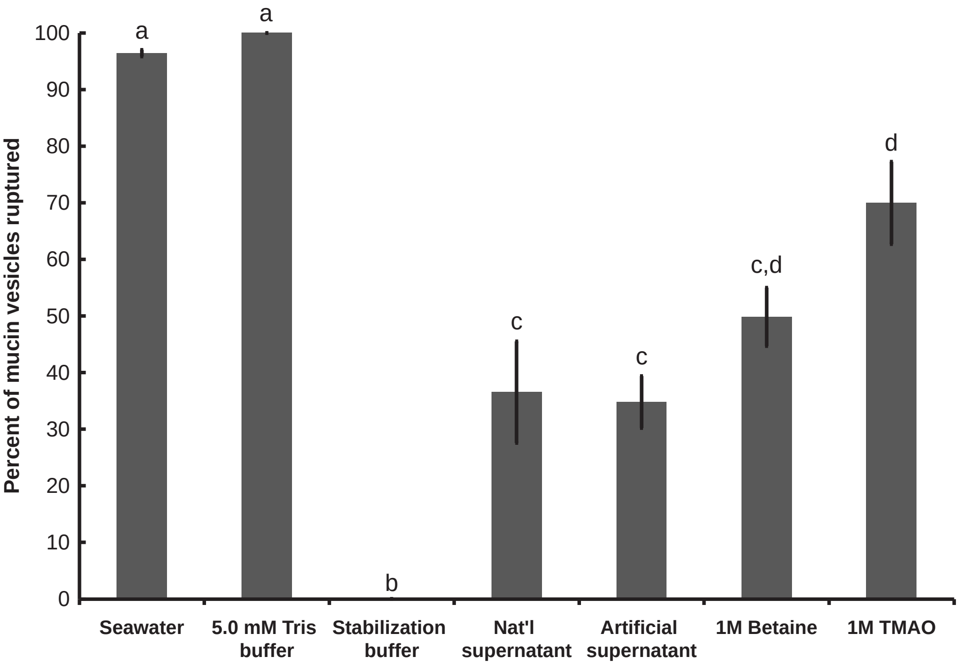

Figure 7 The percentage of mucin vesicles that ruptured after 60 s of exposure to different solutions. Values are means ± SEM ($N = 6$ in each treatment). Different lowercase letters denote significant differences between means ($P < 0.05$). Gland Thread Cells

The fibrous component of hagfish slime originates in the GTCs. The function of these cells is to package 10-nm-diameter cytoskeletal elements known as 'intermediate filaments' into a single, continuous, intricately coiled protein thread that, in mature cells, occupies the vast majority of the cell volume. GTCs are large and roughly ellipsoidal in shape, with distinctive blunt and pointed ends (**Figure 8**). Estimates in the literature of slime thread length vary between 6 and 60 cm, and this value certainly depends on the size of the GTC and presumably the species. More direct measurements of unraveled thread skeins suggest that slime threads are between 11 and 17 cm long, and can be stretched to 34 cm before they break.

How the cell assembles a thread that is about 100 000 times longer than its width and 1000 times longer than the cell itself is not well understood. Some clues about the mechanisms of thread assembly and packaging have come from a detailed study of GTC maturation within the slime gland. This work suggests that a short primal thread arises near the blunt end of the cell near the nucleus. The primal thread is believed to be capped at one end and increases in length via the addition of intermediate filaments at the other. Thread diameter increases by the addition of intermediate filaments laterally. This model is consistent with the changes in thread morphology that occur as immature GTCs develop into mature thread cells, but does not explain how the cell regulates thread diameter and quality and achieves such exquisite packing.

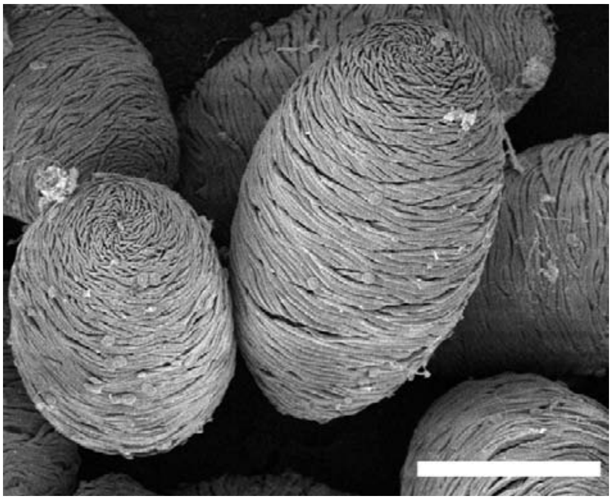

Figure 8 Scanning electron micrograph of gland thread cells that have lost their plasma membranes during ejection from the slime gland. These ball-of-yarn-like structures are referred to as thread skeins. Scale = 50 μm. Image courtesy of Douglas Fudge.

The mechanism of assembly aside, simply describing the anatomy of the thread within mature GTCs, is not trivial and has attracted the attention of several investigators. The majority of the thread is organized as if it were laid down in staggered loops within an egg-shaped barrel. Within these loops, the thread takes on three main trajectories – an ascending trajectory toward the pointed end of the cell, a curved trajectory in which the thread winds circumferentially around the cell periphery for about 60°, and a descending trajectory toward the blunt end. Because of the 60° peripheral runs, the loops are staggered around the longitudinal axis of the cell, and about six of these three-dimensional loops define a cone-like structure that points toward the pointed end of the cell. Although it is meaningless to delineate the beginning of one cone and the end of another, for the purpose of this description, successive cones are neatly nested on top of each other, and occupy the majority of the cell volume. The packing of the loop segments in the peripheral runs gives a cabled appearance to the surface of intact slime thread skeins, but this cabling effect is an illusion, which is sensible because twisting of the thread around itself would hinder effective unraveling. At the blunt end of the cell, the hollow space inside the cones is filled by a series of loops that are oriented parallel to the longitudinal axis of the cell. This staggered loop packing of the thread within GTCs has been compared with the faking of a rope on the deck of a ship to prevent its fouling as it is paid out. Thread diameter within the GTC is not constant, with the largest diameter occurring in the middle of the thread (~3 μm) and the ends tapering down to less than 1 μm.

Volume and Concentration

Estimates of the sliming capacity of a single hagfish vary widely in the literature, but most agree that, in a typical sliming event, a hagfish can produce a mass of slime that is many times larger than itself. For a Pacific hagfish, a typical sliming event induced by a pinch on the tail produces about 900 mL of slime. As for the total amount of slime that a hagfish can produce, estimates in the literature vary from 7 to 100 L. The most recent estimate puts this number at about 25 L for the Pacific hagfish. This number is based in part on the mass of stored slime exudate in the glands, which is about 3–4% of body weight.

One reason that hagfishes are able to produce so much of the slime is that it is remarkably dilute, containing only about 20 mg of threads and 15 mg of mucins per liter, which is about 1000× more dilute than typical mucus such as gastric mucus. These measurements suggest that the vast majority of the volume of hagfish slime is seawater.

Mechanics and Function

Recent work has begun to characterize the mechanical properties of hagfish slime and its components. One aspect of the behavior of the slime that is fairly well documented is its tendency to contract, especially when it is agitated. Slime volume decreases by a factor of 50 when it is stirred, and this presumably occurs due to a collapsing of the mucin and thread components of the slime and egress of the bulk seawater that makes up so much of the slime volume just after it is formed. Isolated slime threads are soft and extensible in water, but ultimately quite strong (**Figure 9**). Their high extensibility means that they can stretch to a length greater than 3 times their original length before they break. At low strains, the threads are elastic, but when they are stretched to strains greater than 0.35, they become stiffer and recover less (**Figure 10**). This change in properties has been demonstrated to occur due to a conformational change in the constituent proteins in which α-helices are stretched out to form β-sheets (**Figure 11**). Although there is little information on the mechanical properties of the mucus component of the slime, hagfish slime mucin solutions have been shown to exhibit low

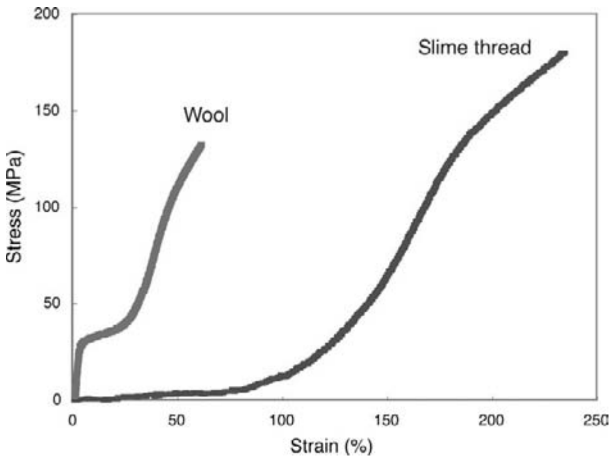

Figure 9 Stress–strain curve for a slime thread tested in water compared to a wool fiber in water. Note the low stiffness of the slime thread at low strains, the extreme strain stiffening that happens at higher strains, and the high breaking stress. (b) Typical load cycle at higher strains, showing that deformation past the yield point is mostly plastic. (c) Results from trials in which threads were extended to a given strain, held, and allowed to recover. Note that deformation is elastic up to a strain of 0.35 and plastic thereafter. From Fudge DS, Gardner KH, Forsyth VT, Riekel C, and Gosline JM (2003) The mechanical properties of hydrated intermediate filaments: Insights from hagfish slime threads. *Biophysical Journal* 85: 2015–2027.

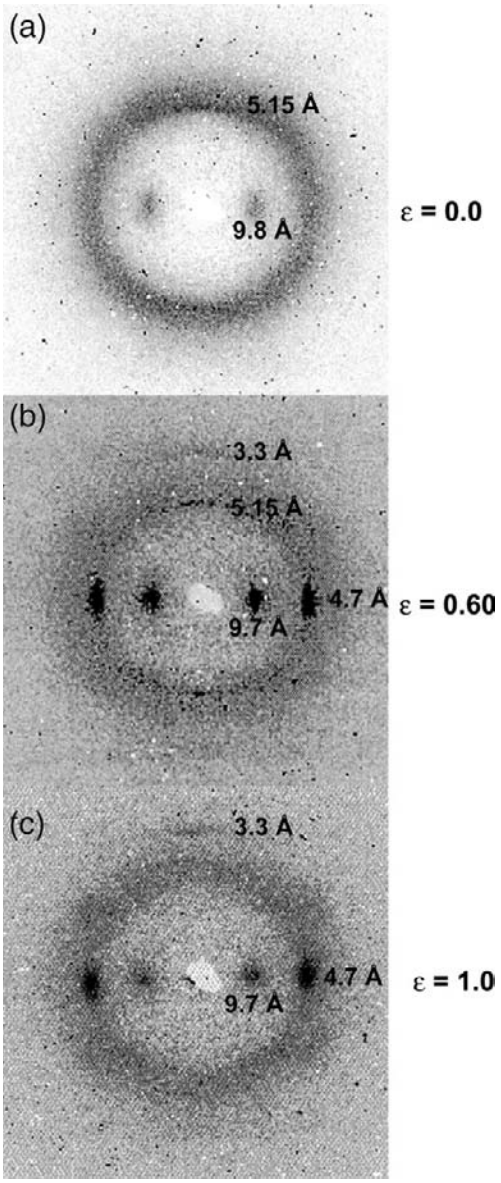

Figure 11 X-ray diffraction patterns for bundles of hagfish threads as a function of prior strain. (a) Unstrained threads exhibit a typical α-pattern, whereas threads extended to a strain of 1.0 exhibit a typical β-pattern (c). Threads extended to a strain of 0.60 exhibit a mixed pattern, suggesting the presence of both α-helix and β-sheet structure (b). Diffraction maxima (dark spots) are labeled according to the molecular spacings (in Angstroms, Å) to which they correspond. From Fudge DS, Gardner KH, Forsyth VT, Riekel C, and Gosline JM (2003) The mechanical properties of hydrated intermediate filaments: Insights from hagfish slime threads. *Biophysical Journal* 85: 2015–2027.

viscosity similar to seawater, even at mucin concentrations many times higher than natural concentrations. Recent work on the mechanical response of fresh slime suggests that it is an ultra-soft material with material properties that are unlike any other polymer.

Slime Deployment and Maturation

One of the more remarkable aspects of hagfish slime is the speed at which it expands from a thick glandular exudate into an ultra-dilute material with a volume over a 1000 times greater. High-speed video has revealed two behavioral phenomena that aid in the rapid deployment of the slime. The first is the fact that the exudate is forcefully ejected from the slime glands (**Figure 12**). The second is the convective mixing that occurs as the hagfish struggles to escape whatever has provoked it (**Figure 13**). Exudate transferred into still seawater in a beaker does not form competent slime, but simply sinks as a coherent blob, whereas modest amounts of mixing allow the slime to fully deploy (**Figure 14**).

Perhaps the most impressive aspect about deployment of the slime is that it involves the unraveling of slime threads from a condensed form within GTCs to an unraveled form that is 1000× longer (150 μm GTC→150 mm slime thread). Early hagfish slime researchers hypothesized that the thread skein was assembled under significant pressure within the GTC, with deployment triggered by osmotic rupture of the GTC membrane upon contact with seawater. Later it was shown that the thread skeins lose their plasma membrane during ejection from the slime gland, which precludes any mechanism involving osmotic swelling across a membrane. More recent work has shown that disruption of the mucin

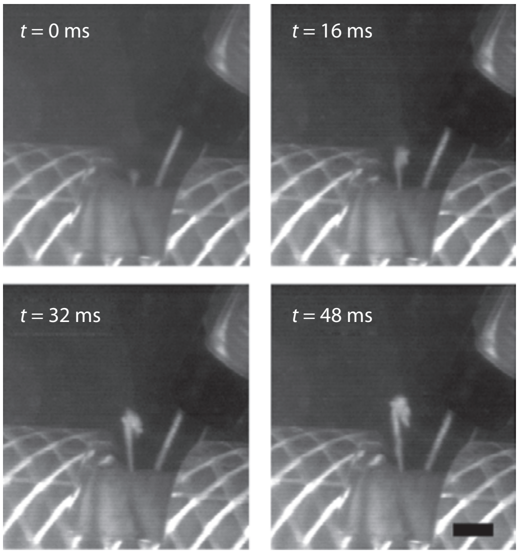

Figure 12 Close-up of slime release from a single slime gland of a hagfish constrained in a tube with a window cut in it. Note that the slime is released as a coherent jet. These events were filmed at 125 frames s^{-1}, and the mean jet velocity was 0.17 m s^{-1}. Scale = 5 mm. Figure 14 Slime exudate introduced into still seawater from a syringe fails to hydrate as it does *in vivo*. From Lim J, Fudge DS, Levy N, and Gosline JM (2006) Hagfish slime ecomechanics: Testing the gill-clogging hypothesis. *Journal of Experimental Biology* 209: 702–710.

network with dithiothreitol (DTT) has an inhibitory effect on whole slime formation, and these effects are mediated at least in part by an inhibition of thread skein unraveling (**Figure 15**). Further exploration of this phenomenon revealed that mucin vesicles shear into long mucus strands (**Figure 16**) that attach to the thread skeins and initiate unraveling via the transmission of hydrodynamic mixing forces to them (**Figure 17**; **Video Clip 1**). The subsequent entanglement between threads and mucin strands further unravels the thread skeins until the slime has fully deployed. These findings provide evidence for a unique biological process in which the thread skeins, which are immune to turbulent mixing forces because of their small size, are critically dependent on the mucin vesicles for their deployment. This suggests that mucins preceded the thread skeins in the evolution of the slime in hagfishes.

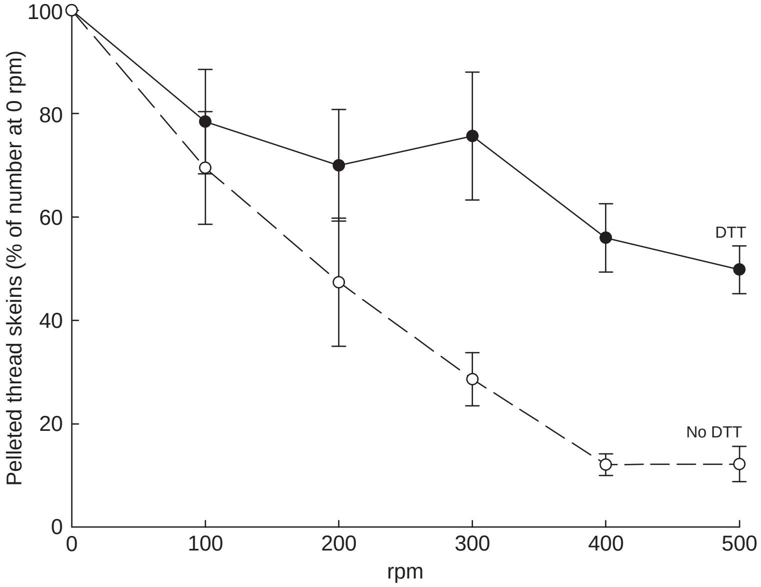

Figure 15 Mean (±SEM) number of condensed thread skeins as a function of mixing rate expressed as the percentage of the number of skeins at 0 rpm. These data provide an inverse measure of the degree of thread skein unraveling in the whole slime. Solid line indicates data for trials in which mucins were disrupted with 10 mM dithiothreitol (DTT). The data demonstrate that the effects of DTT on whole slime formation are mediated at least in part by an inhibition of thread skein unraveling. These data also suggest that mucins play a critical role in the unraveling of the threads. From Winegard TM and Fudge DS (2010) Deployment of hagfish slime thread skeins requires the transmission of mixing forces via mucin strands. *Journal of Experimental Biology* 213: 1235–1240.

Structure and Function

Early models of slime structure hypothesized that swollen mucin vesicles decorated deployed slime threads. However, visualization of the mucin network with fluorescently labeled lectins disproved this hypothesis and suggested that mucins form a separate network of fibers that interacts with the thousands of deployed slime threads in mature slime (**Figure 18**). The current model of slime structure suggests that the vast majority of the volume of mature slime must be bulk seawater. This idea is supported by the fact that hagfish slime that is lifted out of seawater into air will decrease in volume as water runs out of it, leaving only about 5% of its original volume in a matter of minutes. These observations suggest that the slime is adapted not to bind water irreversibly, but rather to entrain a large volume of seawater within countless microchannels defined by the intermingling networks of slime threads and mucin strands.

Many functions have been proposed for the slime, including defense against predators, feeding, localization of eggs, and avoidance of competition while scavenging, but few of these hypotheses have been tested experimentally. Videos of hagfishes scavenging on baited traps show that they sometimes release slime while feeding, which may serve to discourage competitors from approaching too closely. One group of researchers tested the hypothesis that hagfish slime functions as a defense against gill-breathing predators by measuring the hydrodynamic resistance across the gills in isolated fish heads with and without slime. They found that the slime is superbly suited to catching on the gills and increasing the resistance to flow through them (**Figures 19** and **20**). Regardless of the exact function of hagfish slime, it is a

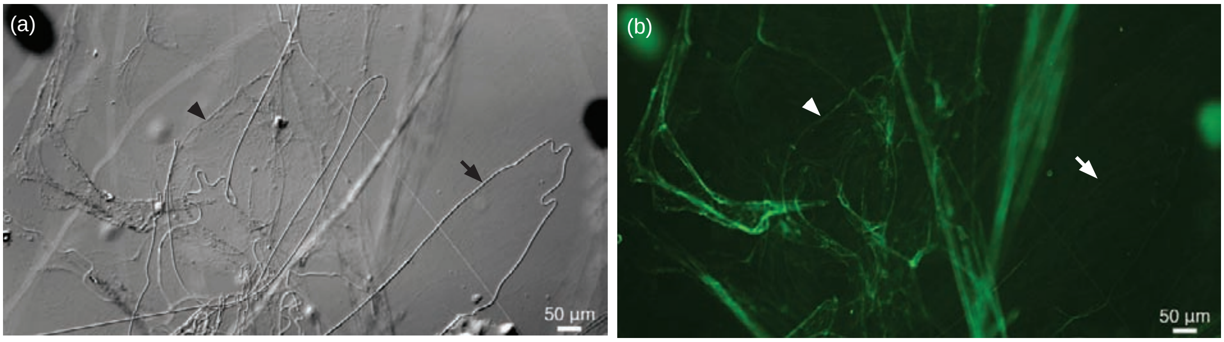

Figure 18 Whole slime formed in seawater containing a fluorescent lectin dye that binds to hagfish slime mucins. (a) Differential interference contrast (DIC) image of whole slime network depicting unraveled threads and mucin strand network. Glossary

Biomimetics The analytical and synthetic process by which biologists and engineers duplicate biological structure, function, or both.

Buoyancy, **positive and negative** A positively buoyant organism is less dense than the surrounding fluid, so tends to rise to the surface. A negatively buoyant one is denser than the fluid and tends to sink.

Electromyography (EMG) A technique for measuring the electrical activity associated with muscle contraction. Sensing electrodes implanted in the muscle tissue detect timing of muscle action as a high-frequency burst of voltage spikes.

Fast start A sudden acceleration from resting or swimming. It can be an escape response or a predator strike, or a maneuver observed during social interactions.

Lift A hydrodynamic force acting at right angles to a body's direction of motion through a fluid. For example, the force on the wings of airplanes that keeps them airborne.

Mauthner cells Two giant neurons located in the hindbrain of most fish species and usually control escape responses. However, non-Mauthner cell escapes have also been reported, and the Mauthner cells may be involved in other behaviors such as post-feeding turns.

Particle image velocimetry (PIV) A technique for revealing complex patterns of flow in a fluid by automatically tracking the motion of suspended particles.

Reynolds number The ratio of inertial to viscous forces in a flow.

Root effect An extreme pH sensitivity of the hemoglobin; at low pH Root hemoglobin remains in a deoxygenated state even at very high oxygen partial pressures.

Swimbladder A gas-filled sac present in the abdominal cavity of most teleost fishes.

Vortex A mass of fluid in whirling or circular motion. Vortices always appear where hydrodynamic lift is being generated.

A Short Historical Perspective on Buoyancy and Locomotion

The extraordinary and, insofar as we are aware, the only historical account of the development of theory, ideas, and devices to test these ideas concerning biomechanics in fishes is given by Alexander in the book *Fish Biomechanics*. Alexander presents a historical account from the time of Aristotle up to 1983 and the brief summary and figures presented here concerning buoyancy and locomotion are taken from his account.

The idea that the swimbladder may play a role in buoyancy – based on the Archimedes principle a submerged body displaces a volume of water equal to its volume – was expanded by Rondelet in 1554 to include the idea that swimbladder in fishes was a buoyancy organ. In 1662, Robert Boyle published Boyle's law showing that the volume of a gas is inversely proportional to the pressure at a constant temperature (i.e., while one increases, the other decreases). Hence, when a fish descends in the water column resulting in an increase in ambient pressure, the volume and thus the buoyant force of a swimbladder decrease. A few years later, workers at the Accademia del Cimento reduced the pressure in a container containing a fish and showed that the fish swelled, floated to the surface, and could not swim down. **Figure 1** is well suited for the present series of articles because the three panels on the left concern the role of the swimbladder in buoyancy and the panel on the right shows how a fish swims using its tail rather than paired fins. Confirmation (or more exactly, partial confirmation) of the application of Boyle's law to swimbladders occurred with the classic studies by Alexander. However, the mechanisms of gas secretion were the subject of much debate. It was not until Pelster (**see also Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes) and Berenbrink (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems) resolved the important problems at the biochemical and cell level that a relatively complete understanding of the mechanisms involved was achieved.

Borelli (1680) (**Figure 1**) was apparently the first to argue that fish swim with force generated by the tail rather than rowing with the paired fins. An idea supported by his observation that a fish could still swim after the paired fins had been removed (the precursor of similar experiments on pared paired fins subsequently carried out by Paul Webb in 1977). Although there was very little experimental work on how fish swim for 200 years following Borelli's suggestion, the theoretical groundwork was established by various workers during this period. It was not until the early 1800s that the ideas relating body shape to streamlining and drag appeared. Even so, these theoretical underpinnings were understood by a very few workers in the field until Steve Vogel made them accessible to all biologists in 1981 with the publication of his book *Life in Moving Fluids*.

The ability to take photographs in rapid succession was a major key to gaining some understanding of all aspects of animal locomotion, including fish swimming. Marey, in 1894, published a series of photographs of an eel swimming and showed that there is a wave that passes down the body and that the wave pushes the water, resulting in the fish moving forward (**Figure 2**). Little progress was made on the problem until the series of studies by Gray. His

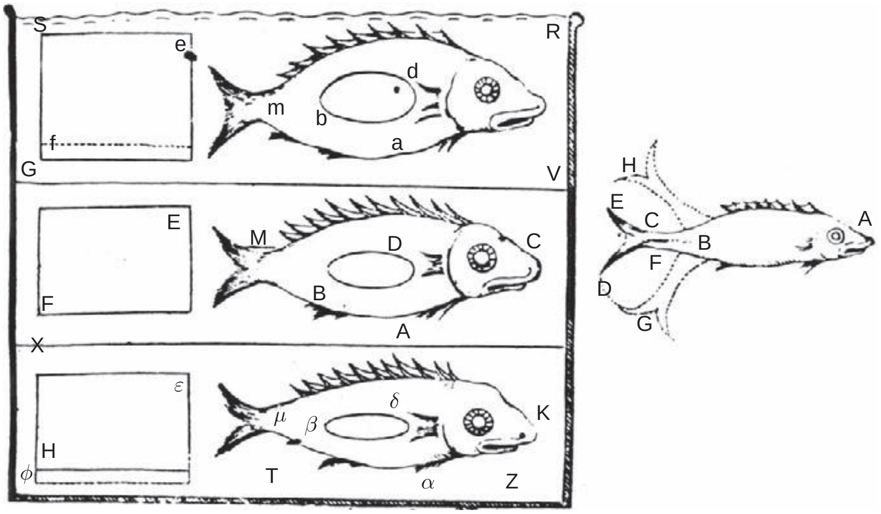

Figure 1 Fish with swimbladders of different size in water with different densities on the left. Diagram on the right illustrates how fish swim by moving the tail back and forth rather than rowing with their paired fins. From Borelli GA (1680) De motu animalium pars prima. Romae. http://books.google.ca/books?id=A48PAAAAQAAJ&pg.

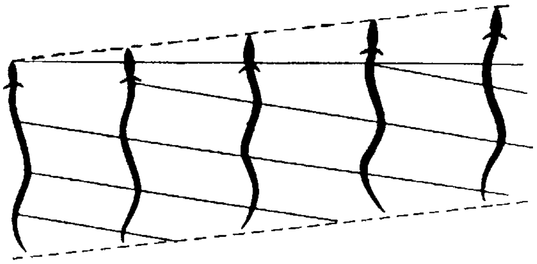

Figure 2 Films of an eel (*Anguilla anguilla*) swimming. Lines illustrate that the propulsive waves of muscle contraction progress from head to tail as the eel swims forward. From Marey EJ (1894) *Le mouvement*. Paris: Masson.

detailed analysis related the waves passing down the body in response to sequential contraction of muscle in different segments at different times. Harris, a colleague of Gray, using a model of a shark in a wind tunnel, showed that movement of fins could account for stability and maneuverability. Many studies of fish locomotion have followed along as technology has allowed for higher frame rates. As discussed in many of the articles in the present section, combining high frame rate with a laser to illuminate a slice of water and adding reflective particles to the water (PIV or DPIV, digital particle image velocimetry) has provided an extremely important window to understanding how fish swim.

Buoyancy and Locomotion Today

This section provides a synthesis of current knowledge concerning two related areas: buoyancy (largely concerned with movement in the vertical direction) and locomotion (largely concerned with movement in the horizontal direction).

Buoyancy

Some fish have no adaptations for buoyancy and are denser than both freshwater and seawater (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). Many have a gas-filled swimbladder and some have deposits of low-density organic compounds large enough to match their density to that of the water. As a fish swims deeper, its swimbladder is compressed by hydrostatic pressure. To maintain buoyancy when it swims deeper, fish must secrete gas into the swimbladder (**see also Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes). Similarly, it must absorb gas or expel gas from the swimbladder during ascent. Gas secretion into the swimbladder requires the activity of gas gland cells (**see also Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes), which acidify the blood and thus induce a decrease in its gas-carrying capacity. The decrease in gas-carrying capacity is due to the evolution of hemoglobins with special properties (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems) so that their affinity for oxygen markedly decreases in the presence of acid, the so-called Root effect (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). The second step in the process of gas secretion, the increase in gas partial pressure, is multiplied by back-diffusion and countercurrent concentration of gas molecules in a countercurrent system, the retia mirabilia (**see also Design and Physiology of Arteries and Veins**: The Retia). Thus, the functional swimbladder required the evolution of several likely independent features that were subsequently combined to allow the secretion of gases at very high partial pressures into the swimbladders at a water depth of several thousand meters.

Locomotion and Movement

Understanding how fish swim requires an understanding of the way water moves around swimming fishes because the water motion provides information about the forces that fishes generate as they interact with their environment (**see also Buoyancy, Locomotion, and Movement in Fishes**: Experimental Hydrodynamics). Viscosity and viscous forces are much more important for a fish swimming in water than for locomotion of a land animal. Consequently, animal size is very important in water because Reynolds numbers, the ratio of inertial forces to viscous forces, scale with length. When fish move their fins or tail, they create vortices in the water and this rotation is important because it is strongly related to force. A technique called PIV is the most important experimental technique used for hydrodynamic measurements; it reveals how all the water molecules are moving around the fish as the fish swims or feeds.

Many fish swim using lateral movements of the tail, undulatory swimming (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming). Waves of curvature progress along the axis from the head to the tail by progressive waves of muscle activity driving sequential contraction of the myotomal muscle blocks (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops). Regions of active muscle contraction on one side of the body cause local shortening, whereas muscles on the opposite side are stretched while inactive. A great deal has been learned about how fish muscles contract and power swimming by studying isolated muscles and having them contract and relax in a fashion analogous to that which occurs during swimming – the so-called work-loop method (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops).

Some fish swim using their paired fins especially at low speeds (**see also Buoyancy, Locomotion, and Movement in Fishes**: Paired Fin Swimming), but the paired fins also have many other functions including maneuvering (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability), stability (**see also Buoyancy, Locomotion, and Movement in Fishes**: Stability and Turbulence), display, protection, and reproduction. About 20% of living fishes rely on pectoral fin swimming as their primary mode of propulsion and all fish use these fins for maneuverability and stability. Maneuvers underlie most behaviors of fishes and are executed by all body and fish surfaces that steer or power rotational changes in posture or swimming trajectory (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability). Agility is greater for maneuvers powered by the body and tail. The other side of this coin is that in turbulent water or when swimming at high speeds, it is important for the fish to maintain stability (**see also Buoyancy, Locomotion, and Movement in Fishes**: Stability and Turbulence). The body as well as median and paired fins act as trimmers or power control surfaces to minimize and correct displacements due to turbulence in the water.

A different type of locomotion, the fast start, is unique to fishes (**see also Buoyancy, Locomotion, and Movement in Fishes**: Fast Start). Fast starts are unsteady maneuvers performed during predator–prey encounters or social interactions, usually of very short duration. Interestingly, they are carried out by both the predator in trying to capture the prey and the prey in trying to escape predation. Escape responses are usually controlled by Mauthner cells (**see also Brain and Nervous System**: Physiology of the Mauthner Cell: Discovery and Properties) and **Brain and Nervous System**: Physiology of the Mauthner Cell: Function) and usually consist of the fish bending into a C-shape and so are called C-starts.

The final type of movement discussed in this collection of articles concerns feeding in fishes (**see also Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics). Despite the considerable diversity in feeding morphology and ecology among fishes, suction feeding is the most common mode of capturing prey. It involves the rapid expansion of the buccal (mouth) cavity that generates a negative pressure inside the mouth relative to the surrounding fluid and thus draws the water and the food into the mouth. The evolution of jaws that can protrude was an important additional feature that enhances suction feeding performance.

The last articles in this section concern the development of robotic fish, an area of study referred to as biomimetics (**see also Buoyancy, Locomotion, and Movement in Fishes**: Biomimetics: Robotics Based on Fish Swimming) and applied aspects of fish swimming performance (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance). Fish robots are built for three reasons: (1) to test biological hypotheses, (2) to engineer novel designs for underwater vehicles, and (3) to entertain. First, biologists and engineers formulate the intended function or behavior of the robot, the subprocesses that will create the function or behavior, and the specific design plans. Robots are built to model individual structures, particular species, or whole populations of fish. Fish robots may or may not be self-propelled, behaviorally autonomous, powered by on-board batteries, or controlled by computers. Many robotic fish projects study propulsion, with body and fins built to produce bio-realistic locomotion.

In summary, here the collection of articles provides an up-to-date account of what we know about how fish move and the methods that scientists use to gain this knowledge.

Glossary

Benthopelagic Habitually swimming close to the bottom at great depths.

Bohr and Root effects Two related effects whereby acids tend to release oxygen from hemoglobin.

Buoyancy, positive and negative A positively buoyant organism is less dense than the surrounding fluid, so tends to rise to the surface. A negatively buoyant one is denser than the fluid and tends to sink.

Deep-scattering layer A layer in the sea with a sufficiently rich population of small fish and other plankton to be detected by echo-sounding. It is much nearer the surface at night than by day.

Ground effect A hydrodynamic effect that reduces the energy cost of generating lift when an aircraft flies close to the ground, or a negatively buoyant organism swims close to the bottom.

Kilopascal (kPa) SI unit of pressure, 1000 N m^{-2}. Atmospheric pressure at sea level is about 100 kPa. Used for blood pressure, hydrostatic pressure, and partial pressure of gases.

Leptocephalus The leaf-like larva of an eel.

Lift A hydrodynamic force acting at right angles to a body's direction of motion through a fluid. For example, the force on the wings of airplanes that keeps them airborne.

Particle image velocimetry A technique for revealing complex patterns of flow in a fluid by automatically tracking the motion of suspended particles.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

Squalene A hydrocarbon present in large quantities in the livers of some sharks.

Swimbladder A gas-filled sac present in the abdominal cavity of most teleost fishes.

Triglycerides Compounds of glycerol and fatty acids, including the typical fats and oils found in animals.

Vortex A mass of fluid in whirling or circular motion. Vortices always appear where hydrodynamic lift is being generated.

Wax esters A class of low-density oily compounds present in large quantities in the coelacanth and some lantern fishes (Myctophidae).

Introduction

Visitors to an aquarium may notice that some fishes can remain almost motionless in mid-water, while others sink as soon as they stop swimming. The former must be very close to the density of the water they live in, and the latter are obviously denser than the water. This article is about the densities of fishes, about the differences of body composition that affect density, and about the associated costs and benefits. It may seem obvious that the ability to hang effortlessly in mid-water can save fish energy, but it will be argued that, for some life styles, a density greater than water may be preferable.

Densities of Fishes

Density is mass divided by volume. Very small differences of density between fish and water are of interest in studies of fish buoyancy. Fish densities must therefore be measured accurately. It is of course easy to measure mass accurately by weighing. The most obvious way to measure the volume of a fish is to put it into a container filled to the brim with water, and measure the volume of water that overflows. This is very difficult to do accurately. **Figure 1** illustrates a much better method. The fish is dried with a towel and weighed (a). Then it is weighed again, totally immersed in water (b). If its density is very close to that of the water, it may be necessary to hang a

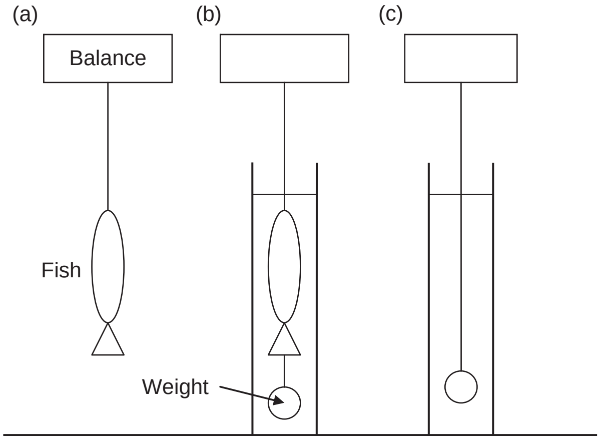

Figure 1 A method for measuring the densities of fishes.

small weight from its tail as shown. In this case, a third weighing is necessary, of the weight (without the fish) immersed (c). The difference (b, c) is the weight of the fish in water. By Archimedes' principle, an upward force equal to (fish volume × water density × gravitational *g*) acts on the immersed fish, so

$$\text{Weight in air} - \text{weight in water} = (\text{fish volume} \times \text{water density} \times g)$$

Also,

$$\text{Weight in air} = \text{mass} \times g$$

Hence,

$$\begin{aligned}\text{Density} &= \text{mass/volume}\\ &= \text{weight in air}\\ &\quad \times \text{water density}/(\text{weight in air} - \text{weight in water})\end{aligned}$$

Freshwater has a density of 1000 kg m^{-3}, and seawater about 1026 kg m^{-3}. These densities are affected only slightly by differences of temperature, or by differences of pressure corresponding to depths of 1 km or less. Differences of salinity between different seas have a larger (but still small) effect.

Most of the essential constituents of fish bodies are denser than either freshwater or seawater. For example, three typical marine teleost species had muscle of density 1055 kg m^{-3}, guts of density 1038 kg m^{-3}, skin 1054–1066 kg m^{-3}, and bone 1300–1500 kg m^{-3}. The densities of their livers, however, ranged from 986 kg m^{-3} (less even than freshwater) to 1050 kg m^{-3}. Triglyceride oils have densities around 930 kg m^{-3}, so oily livers have low densities. The muscles of freshwater teleosts and selachians have about the same density as those of marine teleosts, and selachian cartilage has a density of 1060–1180 kg m^{-3}.

Because most of their tissues are denser even than seawater, fish lacking buoyancy adaptations are denser than the water they swim in, with densities around 1075 kg m^{-3}. Many fish, however, have adaptations that reduce their density to match that of the water. A large proportion of teleosts have a swimbladder, a gas-filled cavity that reduces their densities by increasing their volumes without adding significantly to their masses. Some sharks contain large volumes of the low-density hydrocarbon squalene (860 kg m^{-3}), as does the chimeroid *Hydrolagus*. Some lantern fishes (Myctophidae), the castor oil fish *Ruvettus* and the coelacanth *Latimeria*, contain large quantities of wax esters (density also about 860 kg m^{-3}). Some benthopelagic fish (fish that swim close to the bottom at great depths) are brought close to neutral buoyancy by gelatinous muscle containing less protein and more water than ordinary fish muscle and by poorly ossified bone. They include the bristlemouth *Gonostoma* and the smooth-head *Xenodermichthys*. Similarly, the leptocephalus larvae of eels are neutrally buoyant due to their bodies consisting largely of dilute, low-density jelly.

Table 1 Fractional volumes of low-density materials required to match the densities of typical fish to those of freshwater or seawater

		Fractional volume required in	
	Density ($kg\ m^{-3}$)	*Freshwater*	*Seawater*
Gas	Negligible	0.07	0.05
Squalene or wax esters	860	0.35	0.23
Triglycerides	930	0.52	0.34

To calculate the effects of these and other low-density materials, consider a fish that is initially denser than water, but acquires a quantity of low-density material (referred to for brevity as a float). Its density is then

$$\text{Density} = (\text{initial mass} + \text{float mass})/(\text{initial volume} + \text{float volume})$$

This equation has been used in **Table 1** to calculate the fractional float volume (float volume/total volume) required to match the density of a fish of initial density 1075 kg m^{-3} to that of freshwater (1000 kg m^{-3}) or seawater (1026 kg m^{-3}). It shows that a small volume of gas would be sufficient, but that large volumes of squalene or wax esters, and enormous volumes of triglycerides, would be required. In the extreme case, adding enough triglyceride for neutral buoyancy in freshwater would double the volume of the fish.

Density and Lifestyle

Dense Fishes

Fish that spend much of their time resting on the bottom tend to have no buoyancy adaptations, and to be denser than the water they live in. They include selachians such as

Scyliorhinus and *Raia* and flatfishes (Pleuronectiformes), which have densities of around 1075 kg m^{-3}. It may seem surprising that some fish that swim perpetually also lack buoyancy adaptations, and are denser than the water they live in. They include most pelagic selachians (but not the Basking shark *Cetorhinus*) and tunnies such as *Euthynnus* and *Katsuwonus* (which have densities of 1080–1100 kg m^{-3}).

A very large majority of teleost fish have swimbladders. In most cases this occupies about 7% (freshwater teleosts) or 5% (marine teleosts) of the volume of the body, giving the fish a density very close to that of the water they live in. In some bottom-living teleosts, however, the swimbladder has been reduced but not eliminated. For example, some species of *Gobius* which inhabit marine rock pools have swimbladders occupying only 1–2% of body volume, and are denser than the water. Other examples include bottom-living catfish such as *Clarias*, with tiny swimbladders that make only a negligible contribution to buoyancy but still perform a valuable function as part of the Weberian apparatus which enhances the auditory acuity of them and of other ostariophysan fish.

Changing Depth

Dependence on a swimbladder for buoyancy gives rise to a problem for species that use a substantial range of depths. The swimbladder wall is flexible, so the swimbladder is compressed to a smaller volume as the fish moves to greater depths, where the pressure is greater. It expands as the fish moves up toward the surface again. In most cases, the volume changes are very close to the predictions of Boyle's law. Pressure increases by about 1 atm (100 kPa) for every 10 m of descent, so descent from the surface to 10 m halves the volume of the swimbladder, and descent to 90 m (where the pressure is 10 atm) reduces it to one-tenth of the surface volume. The effects on the fish's buoyancy are thus very large. (Ostariophysan fish are less sensitive to small pressure changes because their swimbladder gases are a little above ambient pressure, making the swimbladder wall taut.)

To change the depth at which it has neutral buoyancy, a fish must add gas to the swimbladder or remove gas from it. The more primitive groups of teleosts, notably the protacanthopterygians (e.g., salmon) and the ostariophysans (e.g., carps), have an open connection between the swimbladder and the gut. This enables them to release gas to adapt to shallower depths, but they cannot of course gulp air in to adapt to a greater depth except when they are at the surface. More advanced teleosts, the paracanthopterygians (e.g., cod) and the acanthopterygians (e.g., perch), have closed swimbladders and can change the quantity of gas in the swimbladder only by secretion from the blood or by resorption into the blood. These processes generally occur through specialized parts of the swimbladder wall that are much more richly supplied with blood vessels than the rest of the wall (**see also Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes; **The Skin**: Functional Morphology of the Integumentary System in Fishes).

Resorption is passive. The partial pressures of dissolved gases at the surfaces of seas, lakes, and rivers are generally in equilibrium with the atmosphere, about 20 oxygen and 80 kPa nitrogen. At substantial depths, the partial pressure of nitrogen is the same, but that of oxygen may be greatly reduced by the respiration of organisms. The blood tends to equilibrate with the water as it passes through the gills, so the total of the partial pressures of gases in the blood is 100 kPa or less. The pressure of the gases in the swimbladder, however, increases with depth; it is 100 kPa at the surface, 200 kPa at 10 m, and so on. Except at the surface, gases will tend to diffuse out of the swimbladder into the blood. Gas is lost from the swimbladder continuously, and must be replaced by secretion if buoyancy is to be maintained. Unwanted losses are minimized by a layer of tightly packed plates of guanine, which greatly reduce the permeability of the swimbladder wall to diffusion of gases. Specialized regions of the swimbladder wall, however, enable the fish to make an opening in this diffusion barrier to allow gas to diffuse out quite rapidly when required. For example, cod and their relatives have a pocket called the oval in the swimbladder wall. The oval can be opened or closed like a drawstring purse, and the flow of blood to it can be adjusted, to allow gas to diffuse out when required.

Another structure in the swimbladder wall, the gas gland, is the site of secretion of gas into the swimbladder. To secrete gas, the flow of blood through it is increased, and the gland cells secrete lactic acid into the blood. This increases the partial pressures of oxygen by the Bohr and Root effects, and of all gases by the salting-out effect (the effect that makes gases less soluble in seawater than in freshwater). These increases of partial pressure are amplified in a rete by countercurrent multiplication (**see also Design and Physiology of Arteries and Veins**: The Retia). When, as a result, the partial pressures of gases in the blood of the gas gland rise above their partial pressures in the swimbladder, gas diffuses from the blood into the swimbladder. Some deep-sea teleosts have very large retia, with capillaries up to 25 mm long, which enable them to raise the blood gases to the enormous pressures required to secrete into their swimbladders. Fish with gas-filled swimbladders have been captured at depths exceeding 2000 m. The pressure at 2000 m is 20.1 MPa (200 atm).

The rates at which teleosts can adjust the quantity of gas in the swimbladder vary greatly. For example, while salmon can release swimbladder gas instantaneously through the connection to the gut, they need more than 10 days to refill an empty swimbladder by secretion. They could adjust volume immediately to accommodate reduced depths, but would need at least a day to secrete enough gas to adjust to a 1 m increase of depth. Cod (which have closed swimbladders) are slower to adjust volume to reduced depths but can secrete gas much faster. Experiments in which depth changes were simulated by changing the pressure in a pressure tank showed that cod could compensate for depth reductions at the rate of only 1 m h^{-1} at a depth of 5 m, but at 20 m h^{-1} at a depth of 65 m. They could resorb gas faster at the greater depth because of the greater differences of partial pressure between the gases in the swimbladder and in the blood. They could compensate for depth increases at a rate of 1 m h^{-1} at 12 °C, or less at lower temperatures, at all depths in the above range. The bluefish *Pomatomus* can secrete gas more rapidly, fast enough to compensate for depth increases at a rate of 2.5 m h^{-1}.

Many teleosts make rapid, substantial changes of depth, too fast for compensation to be possible. In one set of experiments, chum salmon (*Oncorhynchus*) making their homing migration were fitted with data loggers and returned to the sea. Recovered data loggers showed that as the fish continued their journey they made vertical movements of 10 m or more several times per hour, frequently visiting the surface and occasionally diving to 100 m or more. Descents were faster than ascents but required lower tail beat frequencies, suggesting that the fish were denser than seawater through most of their vertical range. It seems that the quantity of gas in the swimbladder gave them approximately neutral buoyancy at the surface but was compressed, making them denser, as they dived.

In another set of experiments, cod (*Gadus*) caught at 25–110 m were brought slowly to the surface. They lost much of their swimbladder gas, leaving them reasonably close to neutral buoyancy at the surface. They were fitted with data loggers and returned to the sea. They made frequent short vertical excursions of 50 m or more but the general trend was downward until they reached their preferred habitat near the bottom, at depths up to 150 m. They appeared to adapt to increasing depth at an average rate of 10 m d^{-1}. When their descent was complete, their behavior suggested that they were neutrally buoyant at their preferred depth.

Some marine fish make daily vertical migrations, spending the night near the surface and the day much deeper. In the oceans, an abundant community of small fishes, crustaceans, and siphonophores swim near the surface at night but spend the day at depths of several hundred meters. They are so abundant that they appear quite conspicuously in echo-sounder traces, as the deep scattering layer. The most numerous of the fishes are lantern fishes (Myctophidae), some of which have been observed from submersible vehicles moving between the top 50 m of the sea at night and around 300 m by day. Some of them depend on swimbladders for buoyancy. These seem to be close to neutral buoyancy at their nighttime depths, but their swimbladders must be so greatly compressed at their day time depths as to be almost useless as buoyancy aids. Other lantern fishes have lost their swimbladders and depend on wax esters for buoyancy. Their buoyancy can be affected very little by depth changes, but the wax esters need to be very much bulkier than a swimbladder (**Table 1**).

Buoyancy Strategies

The preceding section showed that fish with different ways of life tend to have different buoyancy adaptations. This one looks for possible explanations, by examining the relative merits of different buoyancy strategies for different ways of life.

Life on the Bottom

We have seen that fish that spend much of their time resting on the bottom tend to have no buoyancy adaptations, but to be denser than the water they live in. For them, negative buoyancy may be advantageous, in two related ways. It results in frictional forces between fish and bottom that will tend to prevent displacement of the fish by water currents. Also, it tends to counteract any lift forces due to water flowing over the convex dorsal surface of the fish, which might raise the fish from the bottom and result in its being washed away by the current. Experiments in a flume showed that rays (*Raia*) and plaice (*Pleuronectes*) were liable to be lifted from the bottom and dislodged by currents as slow as 0.6 m s^{-1}.

Keeping Afloat

For fish that spend much of their time hovering in mid-water, neutral buoyancy can save energy. A neutrally buoyant fish can remain almost motionless in mid-water; this can be confirmed by watching fish in aquaria. If it has a swimbladder, however, it cannot remain completely motionless but must make occasional fin movements. This is because its equilibrium is unstable. Any slight upward displacement results in expansion of the swimbladder making the fish less dense. Unless it makes a correcting fin movement, it will rise further and eventually be carried to the surface. Similarly, an accidental downward displacement will make the fish denser and it will sink to the bottom, unless it takes corrective action.

To remain stationary in mid-water, a fish that is denser than water must generate a supporting force by driving water downward. This can be done by fin movements.

The principle is the same as that of helicopters, which support themselves by using the rotor to drive air downward. The theory of helicopters tells us that, for geometrically similar fish of equal density, the energy cost of hovering should be proportional to (body mass)$^{1.14}$. The maximum aerobically sustainable metabolic rates of fishes are roughly proportional to (body mass)$^{1.0}$, so hovering is easier for a small dense fish than for an equally dense large one. Nevertheless, hardly any fish that spend much time hovering lack buoyancy aids. The mandarin fish (*Synchiropus*) is a striking exception to the general rule. This small tropical marine fish has an unusually high density of 1120 kg m^{-3}, but spends much of the time hovering just above the sea bottom where the energy cost is much reduced by ground effect.

The energy cost of excess density has been investigated by measuring the metabolic rates of sea bass (*Dicentrarchus*) with lead weights attached. Weights that increased the effective density of the fish by 4% increased the nocturnal metabolic rate by about 33%. (The fish were less active at night than by day, but the proportions of time spent hovering and swimming were unfortunately not measured.)

A fish that is denser than water needs more power for forward swimming than a neutrally buoyant fish because it must generate lift to support its excess weight. It can get this lift either by using fins as hydrofoils, or by swimming with the body tilted at an appropriate angle so that the body itself generates lift. **Figure 2(a)** shows the forces on a negatively buoyant fish getting the required lift from fins. The drag acting backward on the body is counteracted by the forward thrust due to the fish's swimming action. The fish's weight acts downward at the center of mass and is largely counteracted by the upthrust due to Archimedes' principle which acts at the center of buoyancy (the geometrical center of the fish). The centers of mass and buoyancy are generally slightly separated because tissues of different densities are unevenly distributed in the fish. The upthrust is a little less than the weight if the fish is denser than the water, so lift is required from fins. In the diagram, the required lift is provided partly by the tail and partly by the pectoral fins, in the proportions needed to balance the moments about the center of mass. Until recently, negatively buoyant sharks such as the dogfish *Scyliorhinus* were believed to generate lift in these ways. It was known that their asymmetrical (heterocercal) tails drove water downward (generating lift) as well as backward, and it was believed that the pectoral fins were tilted at an angle of attack so as to provide lift in the same way as the wings of an aeroplane. Experiments with a leopard shark showed that this was not the case. The flow of water behind the pectoral fins was observed by particle image velocimetry as the fish swam in a water tunnel. In level swimming, there were no vortices there, showing that the pectoral fins were not generating lift. Indeed, the fins were held at an angle of attack at which no lift could be expected. The body, however, was tilted as shown in **Figure 2(b)**, and must have generated lift.

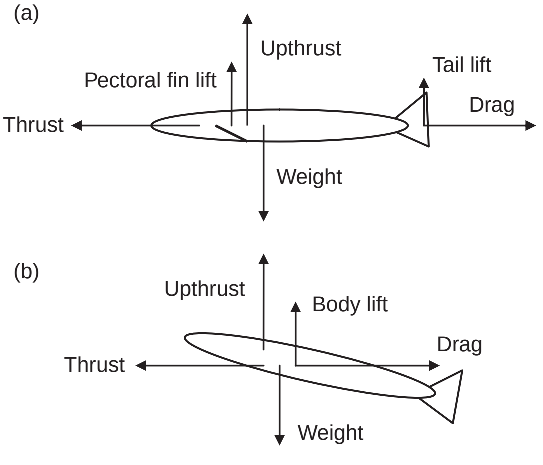

Figure 2 Forces acting on a swimming fish that is denser than the water. The fish obtains the required lift from: (a) fins and (b) its tilted body.

Hydrofoils generate lift by driving water downward. The power needed to do this, known as the induced power, depends on the span of the hydrofoil (the distance from one wing tip to the other). It is proportional to (lift/span)^2/speed. The body of a fish such as the dogfish is in effect a hydrofoil of very small span, much less than the span of the pectoral fins. Consequently, the induced power is much higher if the fish uses body lift as in **Figure 2(b)** than if it used lift from fins as in **Figure 2(a)**. The dogfish's use of the less economical option has not been explained.

Tunnies such as *Euthynnus* and *Katsuwonus* are denser than seawater and have to swim perpetually to avoid sinking. Like dogfish, they swim with their pectoral fins extended. It is possible that, unlike dogfish, they use these fins to generate lift. The experiments that would be needed to find out have not been performed yet.

The induced power can be avoided if the fish has a buoyancy organ that matches its density to that of the water, but this incurs other energy costs. Any buoyancy organ increases the size of the fish and so the profile power, the power that is required to overcome the drag on the body when it is not generating lift. This power is proportional to (cross-sectional area) × speed^3 × (drag coefficient). The drag coefficient depends on the Reynolds number, a function of the fish's length and speed. In the range of Reynolds numbers relevant to the swimming of most fish, it is approximately proportional to (length × speed)$^{-0.5}$. For geometrically similar fish, cross-sectional area is proportional to length^2. Thus, the profile power required by a swimming fish and the additional profile power due to a buoyancy organ are both about proportional to length$^{1.5}$ × speed$^{2.5}$.

Thus, a swimming fish has the option of using its fins or body to generate hydrodynamic lift and prevent sinking, at an energy cost proportional to $(\text{lift/span})^2/\text{speed}$; or of using a buoyancy organ at a cost proportional to length$^{1.5}$ × speed$^{2.5}$. As speed increases, the cost of hydrodynamic lift falls and the cost of using a buoyancy organ rises. This argument suggests that a buoyancy organ will be the more economical option for fish that habitually swim slowly, and hydrodynamic lift for fish that spend much of their time swimming fast. The critical speed at which it becomes more economical to do without a buoyancy organ will be greater if that organ is a swimbladder than if it is a denser organic compound, because an adequate swimbladder is smaller and adds less to drag. It will be less for a fish that uses fins to generate lift than for one that depends on body lift, because a larger span will provide the required lift for less profile power. A rough calculation for marine fish with the options of lift from pectoral fins or buoyancy from a swimbladder led to the conclusion that the critical speed would be about $0.5\,\text{m}\,\text{s}^{-1}$ for a 0.1 kg fish, and $1.4\,\text{m}\,\text{s}^{-1}$ for a 10 kg fish. It must be emphasized that this calculation was rough and depended on some doubtful assumptions. As already noted, most pelagic selachians, and tunnies such as *Euthynnus* and *Katsuwonus*, swim perpetually but have no buoyancy organs. These fish are noted for fast swimming, and it may well be that hydrodynamic lift is the more economical option for them.

So far in this discussion of energy costs related to buoyancy, we have considered only the work required of muscles. There are other energy costs that may be significant. First, consider the energy cost of secreting gas into the swimbladder. The work that must be done on the gas is easily calculated; it is the work needed to compress the gas from its partial pressure in the blood, to the (higher) partial pressure in the swimbladder. Unfortunately, however, the efficiency of the secretion process is unknown, so we cannot confidently calculate the metabolic energy cost. For fish that live at moderate, near-constant depths and need to only secrete enough gas to replace losses by diffusion through the swimbladder wall, the energy cost is probably small. For fish that live at great depths, and so have to secrete against very large differences of partial pressure, it may perhaps be large. It may be sufficiently large to make gelatinous muscle a better option than a swimbladder for benthopelagic fishes.

Additional energy is needed for gas secretion when a fish compensates for increased depth by adding gas to the swimbladder, as a cod did in an experiment described earlier. This energy cost seems never to have been measured, but maintenance of constant swimbladder volume seems not to be an option for fish that make substantial daily depth changes, because they cannot secrete gas fast enough.

Triglycerides, wax esters, and squalene are energy-rich compounds, so their synthesis as the fish grows requires substantial investment of energy. This should be recognized in comparison of their merits with those of other buoyancy strategies.

Glossary

Bohr effect Effect of the proton concentration (pH) on the oxygen affinity of hemoglobin.

Gas partial pressure The pressure exerted by a single gas with respect to total gas pressure.

Root effect An extreme pH sensitivity of the hemoglobin; at low pH, Root hemoglobin remains in a deoxygenated state even at very high oxygen partial pressures.

Rete mirabile (pl. retia mirabilia) A vascular network, usually consisting of a parallel array of both arterial and venous vessels with countercurrent flow. Retia facilitate transfer of heat or oxygen between the arterial and venous vessels. Rete is Latin for 'net or network', mirabile for 'wonderful' or 'miracle'.

R-state hemoglobin Relaxed (oxy) hemoglobin, at high oxygen tensions hemoglobin assumes relaxed state which has higher oxygen affinity than T-state hemoglobin.

Salting-out effect A decrease in physical solubility of gases in fluid due to an increase in salt concentration.

T-state hemoglobin Tense (deoxy) hemoglobin is a more stable hemoglobin form in the absence of oxygen (e.g., organic phosphates bind preferentially to T-state hemoglobin).

Introduction

Depending on their composition, fish are usually somewhat denser than the surrounding water, largely because of their skeleton and protein masses (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). Neutral buoyancy, however, is advantageous to any object in water, including a submarine or an animal, because it saves energy used to prevent sinking or rising. An air-filled chamber like the fish swimbladder is an excellent device to reduce the density of fish without adding much weight. In fact, the density of air is only $0.00125\,\mathrm{g\,cm^{-3}}$ at 1 atm, and still only $0.7\,\mathrm{g\,cm^{-3}}$ at 700 atm, a pressure experienced in the sea at a depth of 7000 m below the surface. Thus, by using a gas-filled swimbladder the status of neutral buoyancy may be achieved by adding very little volume to the overall volume of a fish compared with other materials like lipids (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). Nonetheless, there are problems using a swimbladder as a floating device, especially when the fish changes water depth.

A given swimbladder volume will grant the fish neutral buoyancy only at one particular depth, provided the gas-filled swimbladder obeys Boyle's law, which it apparently does. Swimming upward will result in expansion of the swimbladder gas, and the increased swimbladder volume will add additional lift. By the same token, any descent from the level of neutral buoyancy will reduce swimbladder volume, creating a sinking force, which increases with depth. Thus, like a Cartesian diver, the level of buoyancy constitutes a labile equilibrium, any deviation upward lifting the fish with increasing speed, and vice versa.

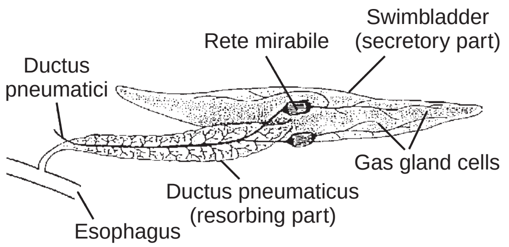
Pelagic fish behaviorally vary their depth, partly following a diurnal rhythm. Accordingly, changes in swimbladder volume can at least in part be compensated either by secretion of gas during descent or by resorption of gas during ascent. In addition, gas must be secreted continuously into the swimbladder in order to compensate for the diffusional loss of gas to the environment, because the total gas pressure inside the swimbladder exceeds gas pressure of the physically dissolved gases in the water, which hardly increases with increasing water depth.

Morphology

Physostome and Physoclist Fishes

The swimbladder originates as an unpaired dorsal outgrowth of the foregut (**Figure 1(a)**). In so-called physostomous fishes the embryonic connection to the gut may persist as the

(a) Physostome fishes (Eel)



(b) Physoclist fishes (Perch)

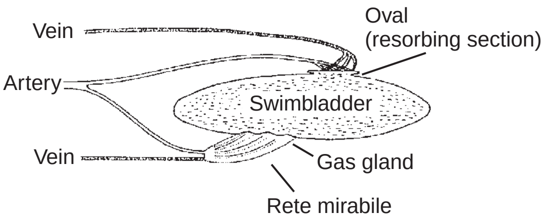


Figure 1 (a) Swimbladder structure of a physostome fish (*Anguilla anguilla*) with a persisting ductus pneumaticus. In the eel, the ductus pneumaticus is converted to a resorbing section of the swimbladder. (b) Swimbladder structure of a physoclist fish (*Perca fluviatilis*). In perch the rete mirabile is unipolar and in intimate contact to the gas gland. The oval represents the resorbing section of the swimbladder. pneumatic duct. The pneumatic duct can be used to transfer air, which can be released to the water or gulped at the water surface and pushed into the swimbladder. In the great majority of teleosts, however, this connection is completely lost at an early stage during development and the swimbladder is a closed gas cavity (physoclist fishes; **Figure 1(b)**). Deep-sea fish usually are physoclist.

Secretory and Resorbing Sections of the Swimbladder

The structural diversity in general swimbladder morphology is remarkable, but some features can be identified in all swimbladders. The two physiological phenomena associated with swimbladder function, namely gas secretion and gas resorption, do not occur at the same location. Therefore, every swimbladder must have a secretory section and a resorbing section that can be separated temporarily from the secretory part of the bladder. In cyprinids and wrasse, for example, the swimbladder consists of two chambers, a thick-walled section in which gas is deposited, and a thin-walled chamber in which gas is resorbed. In other fish, a special section of the secretory bladder, the oval (**Figure 1(b)**), can be closed off by muscular activity and is used as the resorbing part of the swimbladder (e.g., gadoid fishes). In the physostome eel, the pneumatic duct is transformed into a resorbing part of the swimbladder. It is separated from the secretory part of the swimbladder by a sphincter, and the opening to the foregut is functionally closed (**Figure 1(a)**). This means, the eel cannot gulp air at the surface in order to fill the swimbladder.

In many species, the arterial and venous blood vessels to and from the secretory section of the swimbladder are arranged in a countercurrent fashion (**see also Design and Physiology of Arteries and Veins**: The Retia). The arterial supply transiently splits off forming arterial capillaries, running parallel to venous capillaries returning from the swimbladder epithelium. This countercurrent system has also been named red body or rete mirabile, which can be easily seen in the European eel (**Figure 2**). Blood supply to the resorbing part of the swimbladder is separate and bypasses this rete mirabile.

Layers of the Swimbladder Wall

The wall of the secretory bladder consists of a number of thin tissue layers, the inner swimbladder epithelium, muscularis mucosae, submucosa, and tunica externa. The tunica externa represents a dense connective tissue capsule. The submucosa usually is impregnated with guanine crystals or may include layered lipid membranes, rendering the swimbladder wall relatively impermeable to gases in order to reduce diffusional loss of gases out of the secretory section. The muscularis mucosa mainly consists of smooth muscle cells which on contraction transfer gas from the secretory section of the swimbladder to the

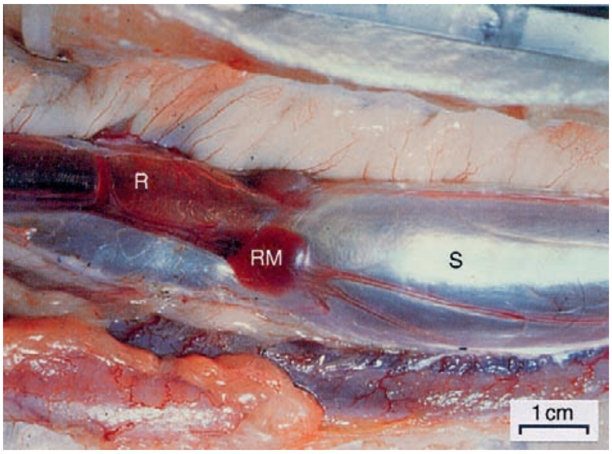

Figure 2 The swimbladder of the European eel with a secretory section (S) and the pneumatic duct, modified into a resorbing section (R). Two retia mirabilia (RM) are located next to the sphincter muscle separating the secretory and the resorbing section. The ductus pneumaticus is functionally closed, so that the eel cannot gulp air at the water surface to fill the swimbladder. From Pelster B (1993) Die Schwimmblase als hydrostatisches Organ. *Biologie in Unserer Zeit* 23: 254–258.

resorbing part. The resorbing part of the swimbladder consists of thin membranous structures with an extensive network of blood vessels (**Figure 2**).

Important for the secretion of gas into the swimbladder are the so-called gas gland cells in the swimbladder epithelium. Gas gland cells are specialized in the production of acidic metabolites. In the eel (*Anguilla*), a model species for the analysis of swimbladder function, the whole internal epithelium of the secretory bladder consists of gas gland cells. In *Perca*, *Gadus*, and many other species, gas gland cells are clustered together, forming a massive complex of several cell layers. A compact gas gland may also result from an extensive secondary folding of a single layer of epithelial cells (*Gobius*, *Syngnathus*). A characteristic of gas gland cells is its intimate contact with an extensive capillary vascular system.

Structure of Gas Gland Cells

Gas gland cells are cubical or cylindrical ranging in size from 10–25 μm to giant cells of 50–100 μm or even more. Gas gland cells are polarized with some small microvilli on the luminal side, while the basal side often is more densely vacuolated and shows a large number of infoldings (**Figure 3**) similar to other secretory or resorbing tissues. Gas gland cells are characterized by the presence of very few filamentous or elongated mitochondria with few tubular cristae.

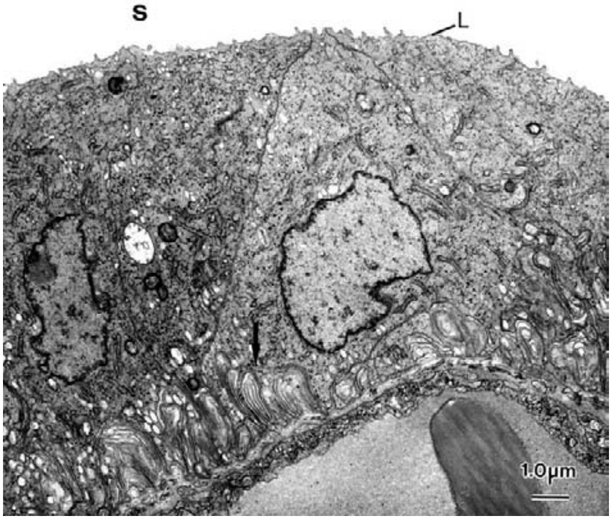

Figure 3 Histology of swimbladder gas gland cells of the European eel *Anguilla anguilla*. Extensive membrane foldings (indicated by an arrow) mark the contact site to blood vessels, while only a few small protrusions are seen at the swimbladder surface (S); L, luminal membrane. Metabolic Activity and the Single Concentrating Effect

Gas Secretion: A Diffusional Process

Although the term ‘gas secretion’ suggests that secretory events (exocytosis and adenosine triphosphate (ATP)-dependent gas movements) are required to fill the swimbladder, gas is transferred into the swimbladder lumen only by passive diffusion along a gas partial pressure gradient. The high gas partial pressure necessary to establish the diffusion gradients between the blood and the swimbladder lumen is established by two mechanisms, the reduction of the effective gas-carrying capacity of blood and subsequent countercurrent concentration of gases in a countercurrent system, the rete mirabile.

The Single Concentrating Effect

The reduction of the effective gas-carrying capacity of swimbladder blood is achieved by the metabolic activity of the epithelial gas gland cells. Although the swimbladder typically is exposed to a high P_{O_2}, gas gland cells produce acidic metabolites anaerobically and release these metabolites into the blood. Blood glucose is the main fuel; internal glycogen stores do not appear to be of major importance. Gas gland tissue of various species *in vitro* and *in vivo* has been shown to produce large amounts of lactate, even at hyperbaric oxygen pressures. A quantitative analysis of lactate and glucose metabolism of the active, gas-depositing swimbladder of the European eel revealed that about 75–80% of glucose taken up from the blood is converted into lactate.

The low mitochondrial density and comparatively low activities of enzymes of the citric acid cycle and of the respiratory chain suggest that aerobic glucose metabolism is of minor importance. A comparison of glucose metabolism and of O_2 and CO_2 exchange in the swimbladder of the European eel suggests that only 1% of the glucose removed from the blood is oxidized. Nevertheless, gas gland cells produce significant amounts of CO_2, but most of this CO_2 is formed by decarboxylation of glucose in the pentose phosphate shunt.

A summary of the metabolic pathways involved in glucose metabolism, based on results obtained from European and American eels, is shown in **Figure 4**. End products of glucose metabolism are lactic acid and CO_2, both of which are released into the blood. Due to the generation of significant amounts of CO_2 in gas gland cells, the P_{CO_2} in these cells is expected to exceed P_{CO_2} values in the blood and also in the swimbladder lumen. Therefore, CO_2 readily diffuses down its partial pressure gradient into the blood, lowering blood pH, and also into the swimbladder lumen, filling the swimbladder with CO_2.

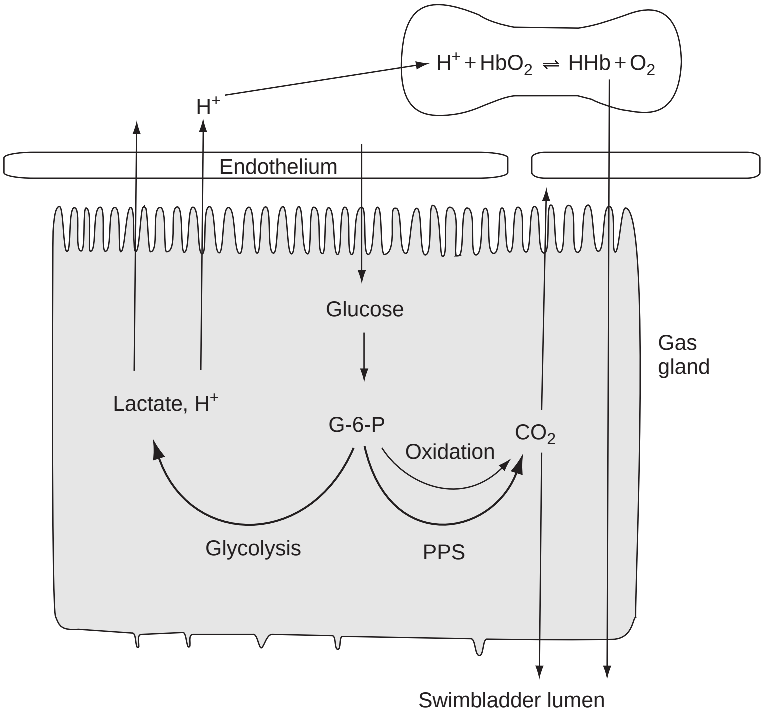

Figure 4 Present concept of glucose metabolism in swimbladder gas gland tissue. Glucose is taken up from the blood, and mainly converted into lactate, in spite of the fact that gas gland tissue typically is exposed to high oxygen partial pressures. A fraction of the glucose in converted to CO_2 in the pentose phosphate shunt. Only a very small fraction of the glucose is oxidized by aerobic metabolism. The CO_2 produced in the cell diffuses down the partial pressure gradient into the swimbladder lumen as well as into the blood, where it contributes to blood acidification. Protons are secreted into the blood, acidify the erythrocytes, and thus reduce the oxygen-carrying capacity of the hemoglobin. Oxygen is released from the hemoglobin and diffuses down the partial pressure gradient through the gas gland cells into the swimbladder lumen. Lactate is released into the blood and contributes to the salting-out effect. From Pelster B (2004) pH regulation and swimbladder function in fish. *Respiratory Physiology and Neurobiology* 144: 179–190.

Lactic acid enters the blood in the ionic state; lactate and protons are released separately. Pathways for the release of protons from gas gland cells include Na^+-dependent carriers, such as Na^+/H^+ exchange and Na^+-dependent anion exchange, and a proton ATPase, a V-ATPase (**Figure 5**).

Acidification of the blood via CO_2 and proton release from gas gland cells plus the increase in blood lactate concentration reduce the effective gas-carrying capacity of the blood perfusing the gas gland cells and thus induce an increase in gas partial pressures in the blood. This initial increase in gas partial pressures in the blood by acidification is called the single concentrating effect. The increase in blood lactate concentration causes a decrease in physical solubility of all gases due to the salting-out effect. Lactate release from gas gland cells is expected to be in the millimolar range, which decreases physical gas solubility no more than 1% or 2%, with a concomitant increase in gas partial pressures of the same magnitude. At present, this is the only way to induce an increase in gas partial pressures for inert gases such as nitrogen and argon.

A much larger increase in gas partial pressure can be expected for CO_2. The acidification of the blood during passage of the gas gland cells shifts the equilibrium of the HCO_3^-/CO_2 reaction toward formation of CO_2, and this reaction is speeded up by the activity of carbonic anhydrase within the red blood cells and within the gas gland cell membrane. A significant increase in P_{CO_2} has been recorded in swimbladder blood as it passes through the gas gland tissue in the European eel.

Oxygen, however, is expected to show the largest increase in gas partial pressure. The hemoglobin of many fishes is characterized by the presence of the Root effect, that is, by a decrease in hemoglobin oxygen-carrying capacity with decreasing pH (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect and Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). All types of hemoglobin have two stable states: a high affinity R-state and a low affinity T-state (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion and Red Blood Cell Function). The Root effect appears to be due to a number of amino acid substitutions destabilizing the oxygenated R-state or stabilizing the T-state of hemoglobin at low pH, so that it no longer binds oxygen even at very high oxygen partial pressures.

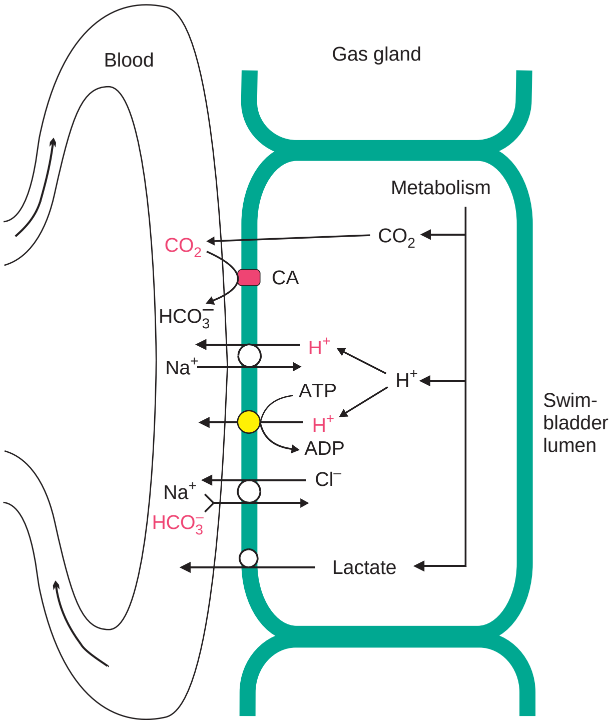

Figure 5 Hypothetical model showing the various proton translocating mechanisms identified so far in swimbladder gas gland cells of the European eel. Acidic metabolites (lactic acid (i.e., lactate and H^+) and CO_2) are produced in the glycolytic pathway and in the pentose phosphate shunt. The mechanisms of lactate transport have not yet been characterized in detail. CA, membrane bound carbonic anhydrase. Modified from Pelster B (2004) pH regulation and swimbladder function in fish. *Respiratory Physiology and Neurobiology* 144: 179–190.

Fishes that have a swimbladder usually also have Root-effect hemoglobin, and the acidification of the blood passing through the gas gland induces the transition from the oxygenated R-state to the deoxygenated T-state of their hemoglobin (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems). For the European eel, it has been estimated that about 40% of the hemoglobin can be deoxygenated in the swimbladder by acidification of the blood resulting in a large increase in P_{CO_2} in swimbladder blood.

The release of lactic acid and of CO_2 from gas gland cells thus causes an increase in the gas partial pressure of all gases in blood, and gases will diffuse into the swimbladder by diffusion following their partial pressure gradients. In addition, gas partial pressures in venous blood returning to the countercurrent system (rete mirabile) are higher than those in the arterial blood supplying the swimbladder epithelium. Thus, back-diffusion of gas from the venous to the arterial capillaries of the rete mirabile results in a countercurrent concentration (sometimes called countercurrent multiplier) of gases in the swimbladder.

Countercurrent Concentration

A countercurrent system is characterized by very close contact of arterial blood vessels, ideally capillaries, with venous vessels returning from the tissue. In a swimbladder rete mirabile, each arterial capillary is surrounded by several venous capillaries and vice versa. The diffusion distance between venous and arterial vessels is small (in the μm range), and the length of the vessels within the rete and the number of vessels determine total contact area. If the gas partial pressure in venous blood returning from the tissue to the heart is higher than in the arterial blood flowing to the tissue, gas molecules will diffuse back from the venous vessel to the arterial side, causing an increase in gas partial pressures on the arterial side of the rete and a decrease in gas partial pressures on the venous side. In a swimbladder with active, acid-secreting gas gland cells, the acidification of the blood will switch on the Root effect, causing a significant increase in blood P_{O_2}. Accordingly, oxygen will diffuse into the swimbladder, but the P_{O_2} in the venous blood returning to the rete mirabile will still be higher than in the arterial blood. Oxygen molecules will diffuse back along the partial pressure gradient from the venous to the arterial capillaries of the rete, causing an increase not only in P_{O_2} but also in the oxygen concentration in arterial blood. Thus, oxygen is concentrated at the swimbladder end of the rete mirabile by back-diffusion and countercurrent concentration. **Figure 6** illustrates the effect of proton and CO_2 release on oxygen and CO_2 concentrations as well as on P_{O_2} and P_{CO_2} in swimbladder capillaries. The resulting partial pressure gradients will drive subsequent countercurrent concentration of both gases in the rete mirabile.

On the other hand, if P_{O_2} is higher in the arterial inflow of the rete than in venous vessels, oxygen will diffuse from the arterial side to the venous vessels. In this case, oxygen would be shunted away from the swimbladder and immediately returned to the central circulatory system. A countercurrent system thus concentrates molecules at one end of the rete. This is the basic mechanism of countercurrent concentration, and it is not only useful for the concentration of gas molecules as discussed in the example above, but also useful for the countercurrent concentration of salts and metabolites in the kidney, or for the countercurrent concentration of heat (**see also Design and Physiology of Arteries and Veins**: The Retia).

Figure 7 shows a theoretical plot of the concentrating ability of a countercurrent system for an inert gas (i.e., without chemical binding of gas). The concentrating ability of a countercurrent system depends on the diffusing capacity of the barrier between venous and arterial capillaries in the rete mirabile and on blood perfusion. The diffusing capacity depends on the diffusion distance and

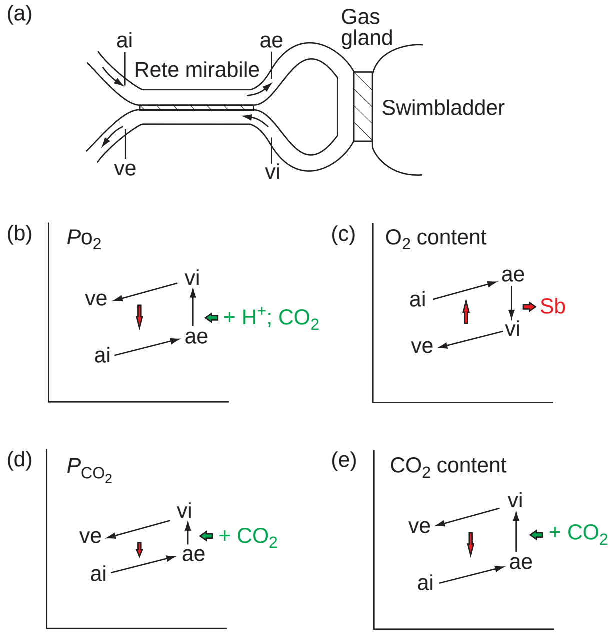

Figure 6 (a) Schematic drawing of a swimbladder with gas gland tissue and a rete mirabile. Secretion of protons and release of CO$_2$ from gas gland cells acidifies the blood, resulting in a switching on of the Root effect and an increase in blood P_{O_2} (b). The diffusion of oxygen into the swimbladder reduces oxygen content in swimbladder blood. Due to the elevated P_{O_2} in blood returning to the rete mirabile in the rete, oxygen diffuses back to the arterial side and is concentrated in the countercurrent system (c). Release of CO$_2$ from gas gland cells and acidification of the blood due to the release of protons increases blood P_{CO_2} (d), combined with an increase in CO$_2$ concentration (e). Due to the elevated P_{CO_2} in blood returning to the rete mirabile in the rete, CO$_2$ diffuses back to the arterial side and is concentrated in the countercurrent system (e).

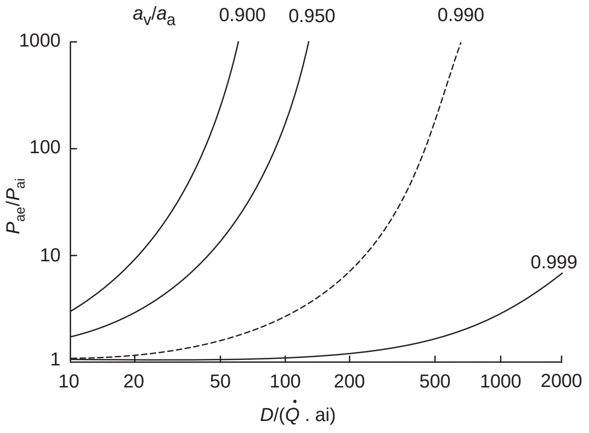

Figure 7 Efficiency of the rete in enhancing inert gas partial pressure, calculated as the ratio of partial pressure in the arterial efflux and influx (P_{ae}/P_{ai}). The efficiency is given by the conductance ratio ($D/Q{\cdot}\alpha$), the magnitude of the salting-out effect (α_v/α_a). For illustration a salting-out effect of up to 10% is assumed, although it can only be expected in the range of 1 or 2% according to our current knowledge. Adapted from Kobayashi H, Pelster B, and Scheid P (1989a) Solute back-diffusion raises the gas concentrating efficiency in counter-current flow. *Respiration Physiology* 78: 59–71.

the diffusivity or permeability, and on total contact area. Thus, a longer rete has a greater concentrating ability. Another crucial factor is the magnitude of the salting-out effect, that is, the change in physical solubility between venous and arterial blood. The higher the initial increase in gas partial pressure during passage of the gas gland cells, the higher the maximal gas partial pressures achieved in the rete.

For the swimbladder rete mirabile, it has been shown that the endothelial lining of the blood vessels is permeable not only to gases but also to metabolites, and that this permeability significantly augments countercurrent concentration. This is because solute back-diffusion in the rete initiates the salting-out effect in arterial capillaries and thereby causes an increase in gas partial pressure in addition to the increase induced by back-diffusion of gas molecules. Similarly, arterial PO$_2$ in the rete mirabile is enhanced not only by back-diffusion of oxygen, but also by back-diffusion of CO$_2$. Back-diffusion of CO$_2$ in the rete acidifies the arterial blood and increases arterial P_{O_2} by the Root effect. In an active, gas-depositing swimbladder, a P_{CO_2} gradient for back-diffusion of CO$_2$ inevitably exists, because CO$_2$ is produced as a byproduct of metabolism of gas gland cells. Thus, CO$_2$ production in the pentose phosphate shunt and CO$_2$ back-diffusion in the countercurrent system both appear to play pivotal roles in swimbladder function.

Based on lactate and acid secretion of the gas gland cells, the largest initial increase of gas partial pressures (single concentrating effect) in swimbladder blood vessels occurs with oxygen (due to the Root effect) and with CO$_2$ (due to the production of CO$_2$ in the pentose phosphate shunt and blood acidification). Accordingly, in the rete mirabile the highest gas partial pressures are achieved by these two gases, and oxygen and CO$_2$ are the main gases diffusing into and filling the swimbladder. Calculations using data collected from the European eel show that gas partial pressures of several hundred atmospheres can be achieved high enough to explain the occurrence of fish with a gas-filled swimbladder at depths of several thousand meters.

Compared with oxygen and inert gases, CO$_2$ has the highest diffusivity, and therefore diffusional loss out of the swimbladder is highest for CO$_2$, leaving behind oxygen and inert gases. Therefore, under steady-state conditions, the swimbladder contains mainly oxygen and inert gases.

Resorption of Gas

To reduce total gas volume in the swimbladder during ascent, gas has to be transferred from the secretory part of the swimbladder to the resorbing bladder or to the oval. In the resorbing section of the swimbladder, or in

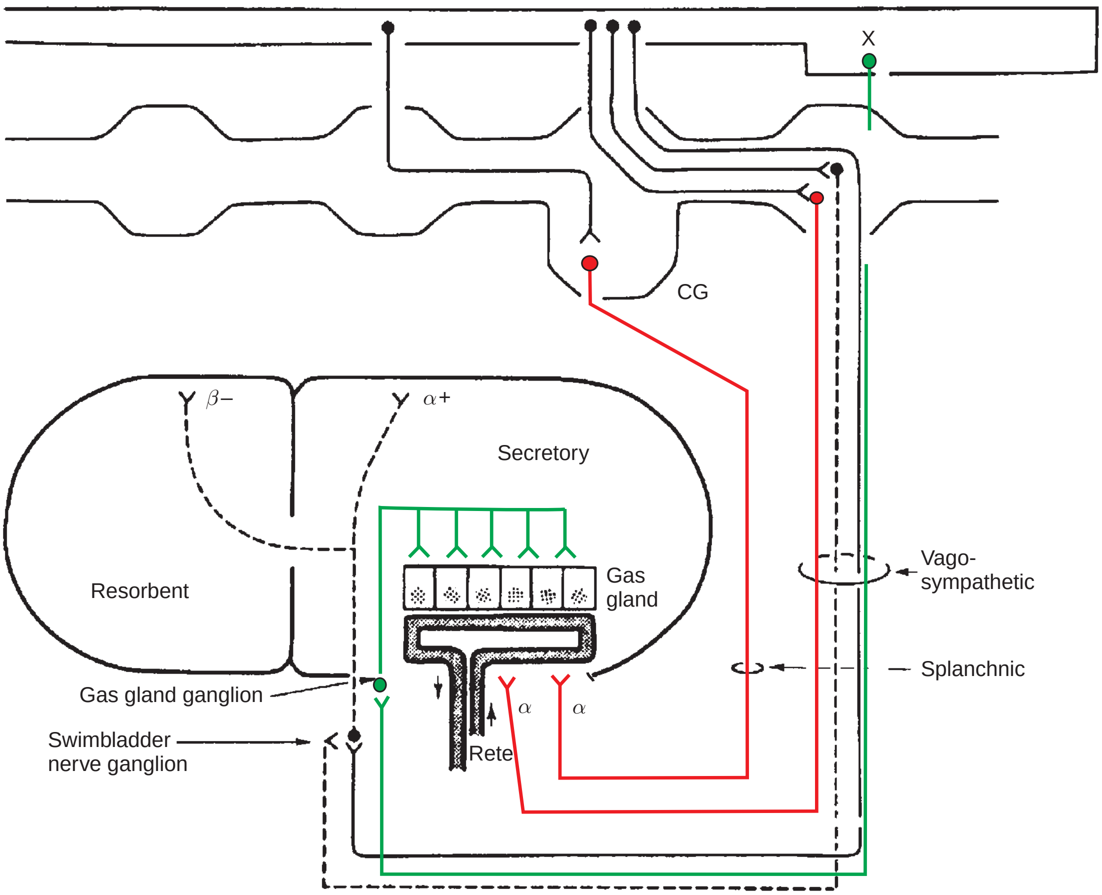

Figure 8 Schematic drawing summarizing our current knowledge of swimbladder innervation for a labrid swimbladder, which most likely can be transferred to other types like the eel swimbladder. α-Adrenergic innervation has been reported for the rete mirabile and for muscle cells in the secretory part of the bladder, while ß-adrenergic responsiveness has been observed in the resorbing section. Muscarinic cholinoceptors have been demonstrated in gas gland tissue. CG, coeliac ganglion. Modified from Nilsson S (2009) Nervous control of fish swimbladders. *Acta Histochemica* 111: 176–184.

the oval, gases are resorbed into the blood by diffusion along the partial pressure gradient. Total gas partial pressure in arterial blood after passing through the gills is close to ambient (i.e., close to or below 1 atm), and gas partial pressures in the swimbladder therefore are higher than in blood. In the oval or in the resorbing section of the swimbladder, gases diffuse into the richly vascularized epithelium lining this section of the bladder and into the blood. When the blood containing these resorbed gases enters the gills, the gases diffuse into ambient water.

However, different gas solubilities result in different rates of removal, and this not only applies to the leakage of gases through the swimbladder wall but also applies to the resorption of gases into the blood. As a result, the more soluble gases, mainly CO_2 and to some extent also O_2, are more rapidly resorbed, leaving behind the less-soluble inert gases. Consequently, CO_2 makes up some 20–30% of newly deposited gas, but, under steady-state conditions, contributes no more than 1% or 2% to swimbladder gas in the European eel.

Failure of Swimbladder Inflation

Failure to initially inflate the swimbladder can have a severe impact. In many species, there is a short time window during early development available for swimbladder inflation. If the initial filling does not occur within this window, the window is closed by atrophy of the pneumatic duct and/or of the swimbladder, or by further differentiation of the foregut. In fish farming, a malfunctioning swimbladder represents a serious problem, because it reduces growth rate and increases mortality. Lack of swimbladder inflation often is associated with a deformation of the spine (lordosis) and a decrease in viability of the larvae.

There may be several reasons for noninflation of the swimbladder. In fish farming, a thin oil or lipid film on the water surface, originating from lipid containing food, may not allow proper surfacing activity of the larvae, which is required for the initial filling of the swimbladder in some species. A bacterial infection or genetic defect may also be responsible for failure to inflate the swimbladder. Another potential reason could be the diet. For example, increasing the triiodothyronine level in female striped bass, *Morone saxatilis,* just prior to spawning increases swimbladder inflation and survival rates of the offspring.

Control of Swimbladder Inflation

With a flexible-walled swimbladder, the status of neutral buoyancy can only be maintained if swimbladder volume can be kept constant in the face of changing hydrostatic pressures. This means that during descent, gas must be deposited, and during ascent, gas must be resorbed. Accordingly, a sophisticated control system is required to adjust the swimbladder volume to the actual position and the swimming activity of the fish in the water column.

As already mentioned, two parameters appear to be crucial to adjust gas deposition: metabolic activity of the gas gland cells and blood flow through the swimbladder. The exchange characteristics of the rete mirabile and the hemoglobin oxygen-binding characteristics (e.g., the magnitude of the Root effect) are crucial for gas secretion. However, these parameters cannot be modified easily or rapidly and therefore cannot be changed in the short term. In addition, the process of gas resorption must be regulated by controlling the smooth muscle cells that guard the connection between the secretory and the resorbing parts of the swimbladder and thus control the transfer of gas from one part of the swimbladder to the other.

In adult fish, the swimbladder tissue is autonomically innervated, mainly by the splanchnic nerve, originating from the celiac ganglion, and the vagosympathetic trunk (**Figure 8**). Vagotomy or cholinergic blocking agents impair gas deposition. On the other hand, cholinergic stimulation increases lactate formation in gas gland cells, which enhances blood acidification and thus gas secretion. Adrenergic effects on gas gland cells have been postulated, but adrenergic nerves have not been demonstrated near gas gland cells. Thus, gas gland cells appear to be under cholinergic, parasympathetic control.

Adrenergic effects have been shown to be important for the control of blood flow to the secretory part of the bladder; α-adrenergic vasoconstriction significantly reduces blood flow to the rete mirabile. In addition, vasoactive intestinal polypeptide (VIP), nitric oxide, adenosine, and protons all exert some vascular control in the eel. In fact, several nonadrenergic, noncholinergic (NANC) mechanisms appear to contribute to the control of swimbladder vessels and the muscularis mucosae.

The swimbladder mucosa is under adrenergic control. There are α-adrenoceptors in the secretory muscularis mucosae and β-adrenoceptors in the resorbing parts of the bladder. In the eel, the secretory swimbladder contracts as a result of α-adrenoceptor activation, while the pneumatic duct, representing the resorbing section, relaxes on stimulation of the β-adrenoceptors. This suggests that during adrenergic stimulation, the swimbladder responds by decreasing secretory activity and shifting gas into the resorbing section of the bladder.

Glossary

Acceleration reaction A synonym for the added mass effect. See added mass.

Added mass The effect in which accelerating bodies in a fluid appear to have additional mass. It is also called the acceleration reaction. The body can be a solid immersed in the fluid, or a coherent region of the fluid itself (see Lagrangian coherent structure).

Added mass coefficient The amount of added mass relative to the body's own mass (units: dimensionless).

Circulation A measure of the total amount of vorticity in an area of fluid bounded by a loop (units: $m^2\ s^{-1}$).

Flow tunnel Also called a flume. A device that produces a constant, even fluid motion. It is often used for studying steady swimming in fishes, so that a fish can swim at a steady speed against the flow, but remain stationary relative to a camera or other measuring devices.

Impulse The total force applied over a time period. The integral of force with respect to time (units: $kg\ m\ s^{-1}$).

Kinematic viscosity The ratio of viscosity and density (μ/ρ) (units: $m^2\ s^{-1}$). At 20 °C, water's kinematic viscosity is $1.004 \times 10^{-6}\ m^2\ s^{-1}$.

Lagrangian coherent structure A region of fluid that tends to remain together. There may be fluid motion inside and outside of the region, but fluid moving inside the region tends to stay inside, while fluid outside tends to stay outside.

Laminar flow Flow in which parallel portions of the fluid (laminae) move steadily past each other. Laminar flow does not preclude the presence of vortices (see turbulent flow).

Particle image velocimetry A technique for revealing complex patterns of flow in a fluid by automatically tracking the motion of suspended particles.

Reynolds number The ratio of inertial to viscous forces in a flow.

Shear Differences in parallel flow velocity between two points. For example, if fluid is moving from left to right parallel to a wall at one speed and at a different speed (but still parallel to the wall) further from the wall, then there is shear between those two points.

Turbulent flow Complex, disordered flow that contains eddies or vortices of many different sizes and structures. Vortex flow is not necessarily turbulent (see laminar flow).

Viscosity The ease with which a liquid will flow under an applied pressure; molasses is more viscous than water.

Vortex A mass of fluid in whirling or circular motion. Vortices always appear where hydrodynamic lift is being generated.

Vortex filament An imaginary line around which fluid rotates, produced by tracing along the vorticity vector. Vortex filaments cannot have free ends; they must terminate on solid boundaries or loop around back onto themselves.

Vortex ring A three-dimensional fluid structure in which a vortex forms a loop.

Vorticity A point measure of how much the fluid at a point is rotating. In three dimensions, vorticity is a vector that defines the axis around which the fluid is rotating; the length of the vector is proportional to the angular velocity. Generally, vorticity is only produced when a force is applied to a fluid (units: s^{-1}).

Wake The moving fluid left behind after an object moves through a region of fluid. It is only present at high Reynolds number. Flow patterns in wakes can be used to estimate forces and power around an object.

Introduction

Fish physiologists use experimental hydrodynamics techniques to visualize and quantify the way water moves around swimming fishes. The water motion provides information about the forces that fishes generate as they interact with their environment, for instance, during locomotion (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming) and feeding (**see also Buoyancy, Locomotion, and Movement in**

Fishes: Feeding Mechanics). These flows and associated pressure waves also provide information to other aquatic animals (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays), and are therefore important for group behaviors such as schooling and for predator–prey interactions. Finally, environmental flows, such as eddies in a stream or wave motions around reefs, also produce forces to which fishes must adjust, either compensating for them or, in some cases, extracting energy from them (**see also Buoyancy, Locomotion, and Movement in Fishes**: Stability and Turbulence). This article introduces basic principles of fluid dynamics, some standard techniques for measuring fluid flows, and several methods for interpreting flow fields (**See also Buoyancy, Locomotion, and Movement in Fishes:** Buoyancy, Locomotion, and Movement in Fishes: An Introduction).

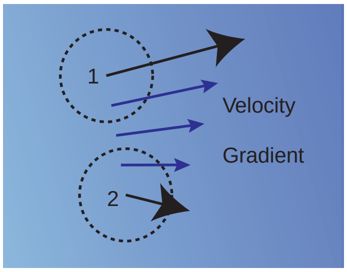

Figure 2 Definition of Reynolds number. Two blobs of fluid with different velocities (black arrows labeled 1 and 2). Viscosity will tend to equalize the velocity gradient between them (blue arrows), while the blobs' inertia will tend to keep their velocities different. Reynolds number is the ratio of inertial forces to viscous forces.

Basic Fluid Dynamic Principles

A fluid is different than a solid because it has no defined shape. Consider a block of rubber. If the bottom was fixed and a force was applied parallel to the top (called shearing the block), the block would resist the force, and the force would be proportional to how far you sheared it (θ in **Figure 1(a)**). Now imagine doing the same thing to a block of fluid. The fluid can be deformed forever, so the amount of shear is irrelevant, but the speed at which you shear the block matters. The fluid velocity would vary throughout the block from 0 at the bottom to V at the top (**Figure 1(b)**). The amount a fluid resists shear rate is called its viscosity, denoted μ. Fluids such as honey and motor oil are highly viscous, while water and alcohol are less viscous.

Thus, viscosity tends to make fluids stick together. If two blobs of fluid (1 and 2 in **Figure 2**) are moving at different speeds, viscosity will resist the shear between them and tend to equalize their speeds. The opposite effect is inertia, the mass of the blobs of fluid. If the blobs are relatively large or moving quickly, then the viscous forces on them will have a small effect, and they will carry on moving at their separate velocities. The relative importance of inertia and viscosity is called the Reynolds number *Re* (the symbols used in this article are explained in **Table 1**):

$$Re = \frac{\rho l U}{\mu} \tag{1}$$

where ρ is the density of the fluid, l a length, and U a velocity. The length and velocity are intentionally vague. The proper choice depends on the specific situation, but, in general, high Reynolds number ($Re >> 1$, which, in practice, means greater than 100 or so) means that viscosity is not very important. Reynolds number is also often written using the kinematic viscosity ν as

$$Re = \frac{lU}{\nu} \tag{2}$$

Re is only useful as an order of magnitude. One must choose an approximate length l and velocity U that are representative of lengths and velocities of interest. For instance, for a 10-cm fish swimming at 1 body length (L) per second, the scale of fluid motions is approximately the length of the fish and velocities are near the swimming speed. *Re* is thus $[(1000\ \mathrm{kg\ m}^{-3}) \times (0.1\ \mathrm{m}) \times (0.1\ \mathrm{m}^{-1}\ \mathrm{s})]/(1 \times 10^{-3}\ \mathrm{Pa\ s}) = 10\ 000$. If the fish were swimming at $1.5\ L\ \mathrm{s}^{-1}$, it would not be much more informative to write $Re = 15\ 000$, because the order of magnitude is still the same.

High Reynolds number flow has several important consequences, listed as follows:

1. Fluid motions persist for some time. If a force starts a blob of fluid moving, then the inertia of the blob will keep it moving for a while, even after the force has stopped. Thus, at high *Re*, one can learn about forces on

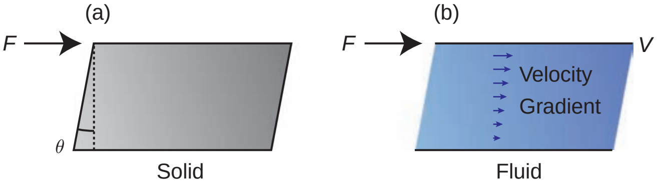

Figure 1 Differences between solids and fluids. Solids resist the amount of shear (θ), while fluids resist the shear rate ($\dot{\theta}$), which sets up a velocity gradient between the top and bottom.

Table 1 Symbols used in the article

Γ,	Circulation
δ,	Spacing between fluid velocity measurements
μ,	Viscosity
ρ,	Density
Σ,	A surface in a fluid
ω,	Vorticity vector
ω_z,	Component of the vorticity vector in the *z*-direction
a,	The thickness of a vortex ring along its central axis
A,	An area, usually the wetted surface area or the cross-sectional area
C,	A contour surrounding a vortex along which velocity is integrated to calculate circulation
d,	Diameter of a vortex loop in the horizontal plane
$\mathbf{C}_A$,	Added mass coefficient tensor
C_A,	Added mass coefficient for acceleration and force along the same axis
C_F,	Force coefficient. Normalized force relative to the swimming speed and body size
$\mathbf{I}$,	Impulse vector
$\mathbf{F}$,	Force vector
$\mathbf{F}_{\text{mean}}$,	Mean force vector
h,	Height of a vortex loop or a wake in the vertical plane
l,	Length (generally body length)
l,	Tangent vector along the contour *C*
L,	Body length of a fish
P_{thrust},	Thrust power
P_{wake},	Wake power; change in kinetic energy in the wake
Re,	Reynolds number
S,	Volume of an LCS
T,	Time period, usually half the tail beat period
$\mathbf{u}$,	Velocity vector
U,	Speed (generally swimming speed)
U_V,	Velocity of an LCS as a group
u,	Component of the velocity vector in the *x*-direction
v,	Component of the velocity vector in the *y*-direction
w,	Component of the velocity vector in the *z*-direction
Wa,	Wake vortex ratio; ratio of unsteady effects to steady forces for an LCS

a body, such as a fish, by studying its wake, the moving fluid left behind after the body has moved past. In contrast, at low *Re*, any fluid motion requires force, and as soon as the force stops, the fluid stops too.

2. Vortices may be present. A vortex is a rotating piece of fluid that usually places shear stress on the fluid. Vortices are directly related to force in a fluid, and, at the limit of infinitely high *Re*, they persist forever. Thus, they are useful for studying forces produced in a fluid.
3. Flow may be turbulent. Turbulence is a poorly understood phenomenon in which flow becomes complex and irregular. Turbulence changes many of the standard rules of thumb of fluid dynamics, such as drag and lift coefficients, so one must be careful when studying turbulent flows.

Vorticity

Vorticity is a measure of how much a very small blob of fluid is rotating. Rotation is important because it is strongly related to force. In general, a force must be applied to a fluid to produce vorticity.

Vorticity is a point measure. Imagine putting a very thin rod into a fluid, and consider whether it will rotate, independently of its translational motion. Vorticity is non-intuitive: a vortex usually, but not always, has vorticity, and vorticity may be present in flow that does not appear to be rotating, such as a shear flow (**Figure 3**). Mathematically, vorticity ω is the curl of the velocity field:

$$\omega = \nabla \times \mathbf{u} \tag{3a}$$

$$= \left(\frac{\partial u_z}{\partial y} - \frac{\partial u_y}{\partial z}, \frac{\partial u_x}{\partial z} - \frac{\partial u_z}{\partial x}, \frac{\partial u_y}{\partial x} - \frac{\partial u_x}{\partial y} \right) \tag{3b}$$

written concisely using the curl operator in eqn (3a), or explicitly in eqn (3b). Vorticity ω is itself a vector, and defines the axis around which fluid is rotating, according to the right-hand rule. For example, the vorticity vector in **Figure 3(a)** is pointing out of the page toward the reader, while the vector in **Figure 3(c)** is pointing into the page away from the reader. For two-dimensional (2D) flows, such as those pictured in **Figure 3**, the first two components of ω are 0; figures therefore often depict only the z-component as a contour map.

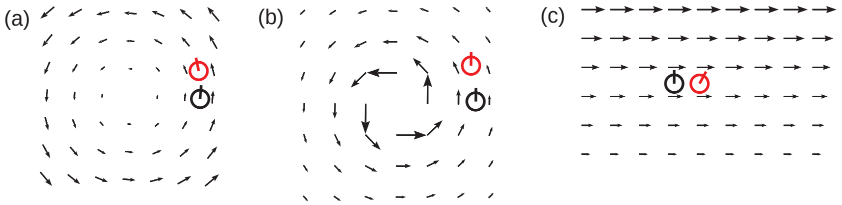

Figure 3 Examples of flow patterns with and without vorticity. In each case, the black circle represents an imaginary rod inserted into the **flow**, and the red circle indicates its position and orientation after some time has passed. (a) Swirling flow with vorticity. The red circle is rotated relative to the black circle. (b) Swirling flow without vorticity. The flow velocities decrease with radius so that the imaginary rod translates around, but does not rotate. Vorticity is zero at all points in this flow except for single point at the center. (c) Shear flow with vorticity. The imaginary rod translates and rotates, indicating vorticity.

One must remember, though, that real vorticity is 3D. In particular, if one follows the vorticity vectors, they define a vortex filament – a line around which fluid rotates. Vortex filaments cannot have free ends; they must either loop back on themselves or end at a solid boundary. The most common real 3D vortex structure, therefore, is a vortex ring, a circular vortex filament (**Figure 4**).

Added Mass

Fluids have one more strange effect that is prominent at high *Re*: the phenomenon of added mass, also termed the acceleration reaction. Accelerating bodies in a fluid behave as if they have some additional mass. In essence, added mass is the consequence of the fact that the fluid itself has mass. Accelerating a body in a fluid requires force to accelerate the body, and also some additional force to accelerate some fluid that surrounds the body. The acceleration reaction does not only affect solid bodies; it can also become important in unsteady flows without any solid bodies. If a blob of fluid accelerates, it also has added mass, which must be accounted for if one wants to estimate the force required to accelerate the blob.

Measuring Fluid Velocities

At any point in a moving fluid, the fluid has a speed and a direction in three dimensions. Generally, the motion at that point is represented by a vector (u, v, w), where u, v, and w are the speeds of the motion along the x, y, and z axes, respectively. The (u, v, w) vector is defined at every (x, y, z) coordinate in the fluid; therefore, the flow velocity is called a vector field. The magnitude of the vector $\left(\sqrt{(u^2 + v^2 + w^2)}\right)$ is the flow speed.

Techniques used for experimental hydrodynamics experiments fall into several classes, based on whether they make measurements at a single point or at many points in a plane or a volume, and what they measure at the point or points (i.e., the speed of the flow, or two or three components of the velocity vector). 1D techniques include hot wire anemometry and acoustic Doppler velocimetry, but neither of these are commonly used for studying fish. The most common technique is particle image velocimetry (PIV), a planar (2D) technique. Several fully volumetric (3D) methods are becoming more common.

Once velocities are estimated, derivative quantities such as vorticity can be estimated using standard

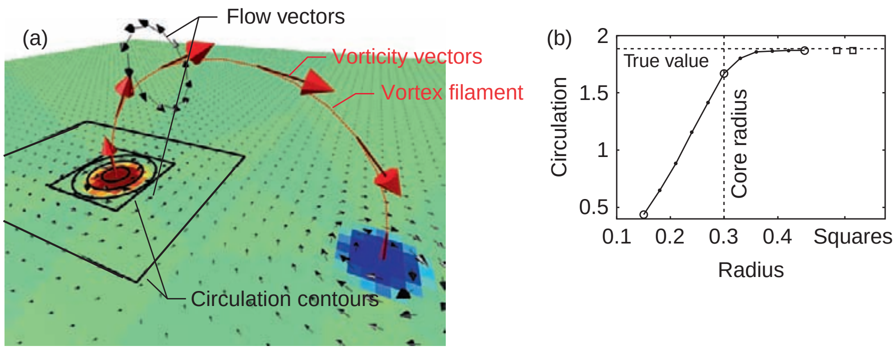

Figure 4 (a) 3D view of a vortex ring. Velocity vectors are shown in black and vorticity vectors are shown in red. Velocity vectors are shown only in the horizontal plane and in one example loop. The horizontal colored plane shows the z-component of the vorticity vector ω; red and blue indicate positive and negative values for ω_z, respectively. The central vortex filament is a red dashed line and it continues in a loop around under the horizontal plane. Several contours for estimating circulation are shown with thick black lines. (b) Circulation calculations. Circles show estimates for increasingly large circular contours, while squares indicate square contours. Open symbols indicate contours shown in (a).

numerical techniques. For planar measurements, such as PIV, with evenly spaced measurements of u and v on a grid with spacing δ between the measurements, out-of-plane vorticity can be approximated using a standard central difference technique as

$$\omega_z^{i,j} = \frac{1}{2\delta}\left[\left(v^{i,j+1} - v^{i,j-1}\right) - \left(u^{i+1,j} - u^{i-1,j}\right)\right] \qquad (4)$$

where $\omega_z^{i,j}$ is the z-component of vorticity at point (i, j), with i being the index that varies over the y values and j being the index that varies over the x values.

Particle Image Velocimetry

The technique called PIV is the most important experimental technique used for hydrodynamic measurements. It is a planar (2D) technique that can resolve the two components of the velocity vector that are in the plane. An important extension of the technique, called stereo PIV, can resolve all three velocity components but is still restricted to a planar measurement region.

Figure 5 shows a drawing of a typical PIV configuration. The water is seeded with small, reflective particles, and a strong light source, usually a laser, is used to illuminate a plane. A laser beam can be spread out to produce a plane using a cylindrical lens (shaped like half a cylinder) or a Powell lens (shaped like a house). One or more cameras are used to film the motion of the particles, and a computer algorithm is used to estimate the distance the particles have moved between two frames of the video.

For PIV to estimate fluid velocities accurately, the particles must not move too little or too much between frames. For a given average flow velocity, there are two main methods to ensure that the particle displacement is appropriate.

1. Use a continuous laser and adjust the frame rate of the camera (**Figure 6**(**a**)). Often this method requires a high-speed camera to achieve high-enough frame rates so that the particles do not move too far between frames. Because of the constant laser illumination, particle images may blur if the camera exposure time is too long. This is the most common method used for biological flows.
2. Use a pulsed laser and adjust the time between pulses (**Figure 6**(**b**)). Many of these systems use a double-pulsed laser, which can emit two pulses in rapid succession, but then have a relatively long delay before the next pair of pulses can be emitted. Pulsed lasers can often deliver large amounts of light in short amounts of time, which can be helpful to prevent particle blur. This method is more often used in engineering situations in which the flow is highly repeatable.

In recent years, a new generation of high-speed pulsed lasers have been developed, which combine the advantages of the two types of PIV systems.

Once the images are acquired, they must be processed to estimate the vector fields. The PIV algorithm does not track individual particles, because there are typically too many particles to identify specific ones reliably. Instead, it uses a technique called cross-correlation to estimate the average displacement of groups of particles (**Figure 7**). Each image is divided up into a grid of many small interrogation windows, and those windows are compared between two frames. The cross-correlation matrix indicates how well the images in the two windows match up when there is a slight offset between them (**Figure 7**(**b**)). The offset with the strongest correlation represents the

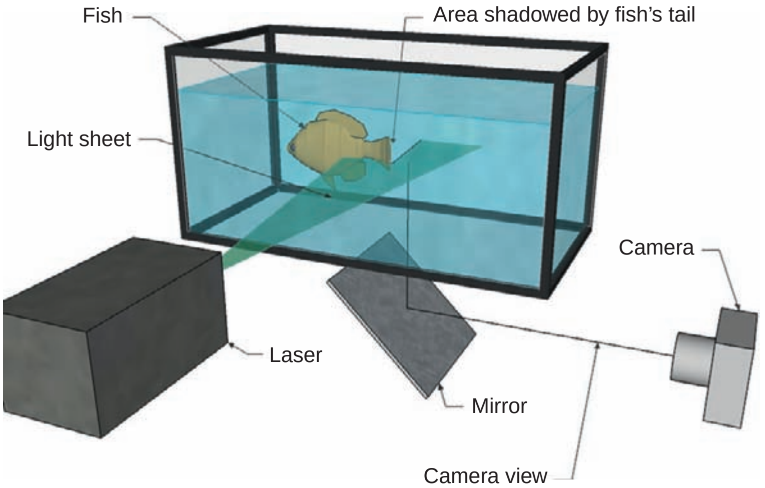

Figure 5 Schematic of a typical particle image velocimetry setup. A laser produces a horizontal light sheet, and a camera films the light sheet and fish from below. When the fish's tail is in the light sheet, it results in a shadow. These experiments are often performed in a flow tunnel, so that the fish swims against a flow (from left to right in this image), maintaining position in the laboratory frame of reference.

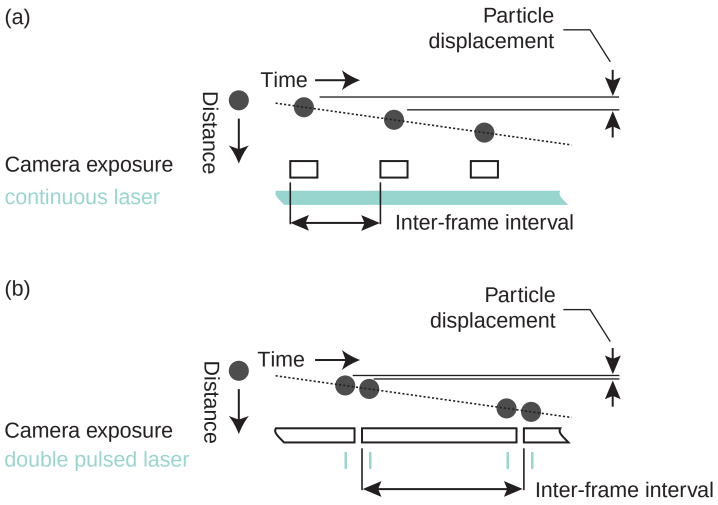

Figure 6 Schematic of the timing for two different PIV configurations. Panels show a particle (gray circle) as it moves over time along the dotted line. The open boxes indicate the camera exposure and the green bars indicate when the laser is on. Particles are shown only when the camera shutter is open and the laser is on. (a) With a high-speed camera and a continuous laser, the particle displacement may be relatively large, but the time between frames (inter-frame interval) is short. (b) With a normal camera and a double-pulsed laser, the particle displacement can be very small, but the inter-frame interval is often large.

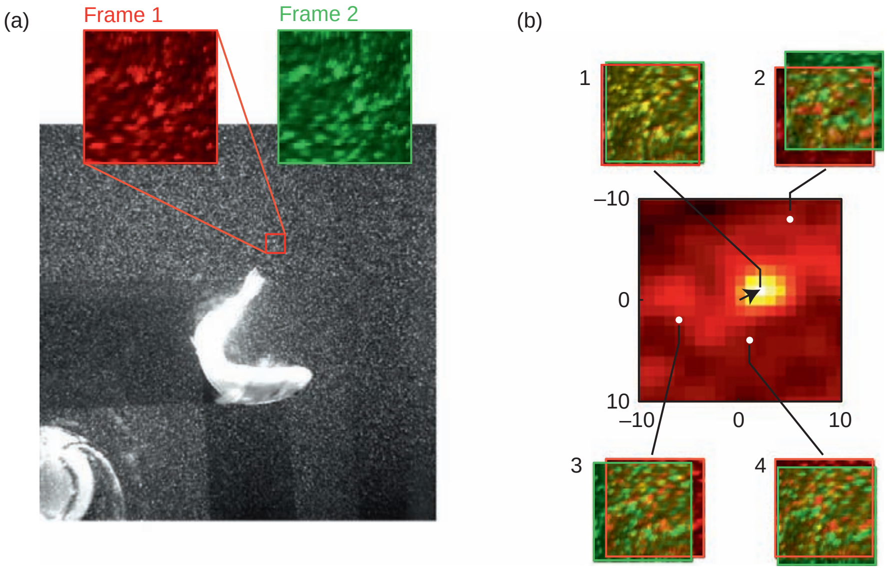

Figure 7 Example of the cross-correlation technique used to estimate velocity vectors for PIV. (a) Typical PIV image, with an interrogation window identified in red. The same window from the next frame is shown in green. (b) Example cross-correlation of the two windows. The center image shows the cross-correlation matrix, where hotter colors indicate greater correlation. The peak correlation is offset from the center by 3 pixels right and 2 pixels up, which is the best estimate of the average motion of particles in that window between frames. Around the cross-correlation are examples of the overlap between the two interrogation windows at different offsets. The windows are again in red and green, and regions where they overlap well show up as yellow.

average displacement of the particles (**Figure** 7(**b**1)). Most modern PIV systems now use a technique called super-resolution PIV, in which the cross-correlation technique runs several times, starting first with a fairly coarse grid, then repeating the algorithm with a finer grid that uses the previous results as a starting estimate. In this manner, very large numbers of vectors can be estimated.

An extension to the standard PIV technique is stereo-PIV, which uses two cameras at an angle to the light sheet to estimate the two in-plane velocity components, as well as the through-plane component. Besides the fact that it produces 3D velocity estimates, stereo-PIV has several other advantages. First, it is often able to correct errors better than normal PIV. Second, stereo-PIV calibration usually implicitly corrects lens distortion from the cameras.

Because fluid moves in three dimensions, planar PIV techniques require measurements in multiple planes or assumptions about the flow structure to generate 3D approximations of the flow. For example, counter-rotating vortex pairs are often assumed to be parts of the same vortex ring (**Figure 4**). **Figure 8** shows two examples of horizontal planes behind a swimming American eel (*Anguilla rostrata*) and a bluegill sunfish (*Lepomis macrochirus*), along with the simplest possible 3D reconstruction. Wakes of American eels are consistent with two unlinked vortex rings shed per tail beat (Fig. 8C), while the wakes of bluegill sunfish appear to have two linked loops per tail beat (Fig. 8D). One must be careful about these simple reconstructions. The bluegill sunfish's wake does have two linked vortex loops, as hypothesized in Fig. 8D, but the loops are not circular, and they interact in a complex way with vortices shed off the dorsal and anal fins. **Figure 9** shows a reconstruction of the bluegill sunfish's wake based on measurements made in multiple transverse planes.

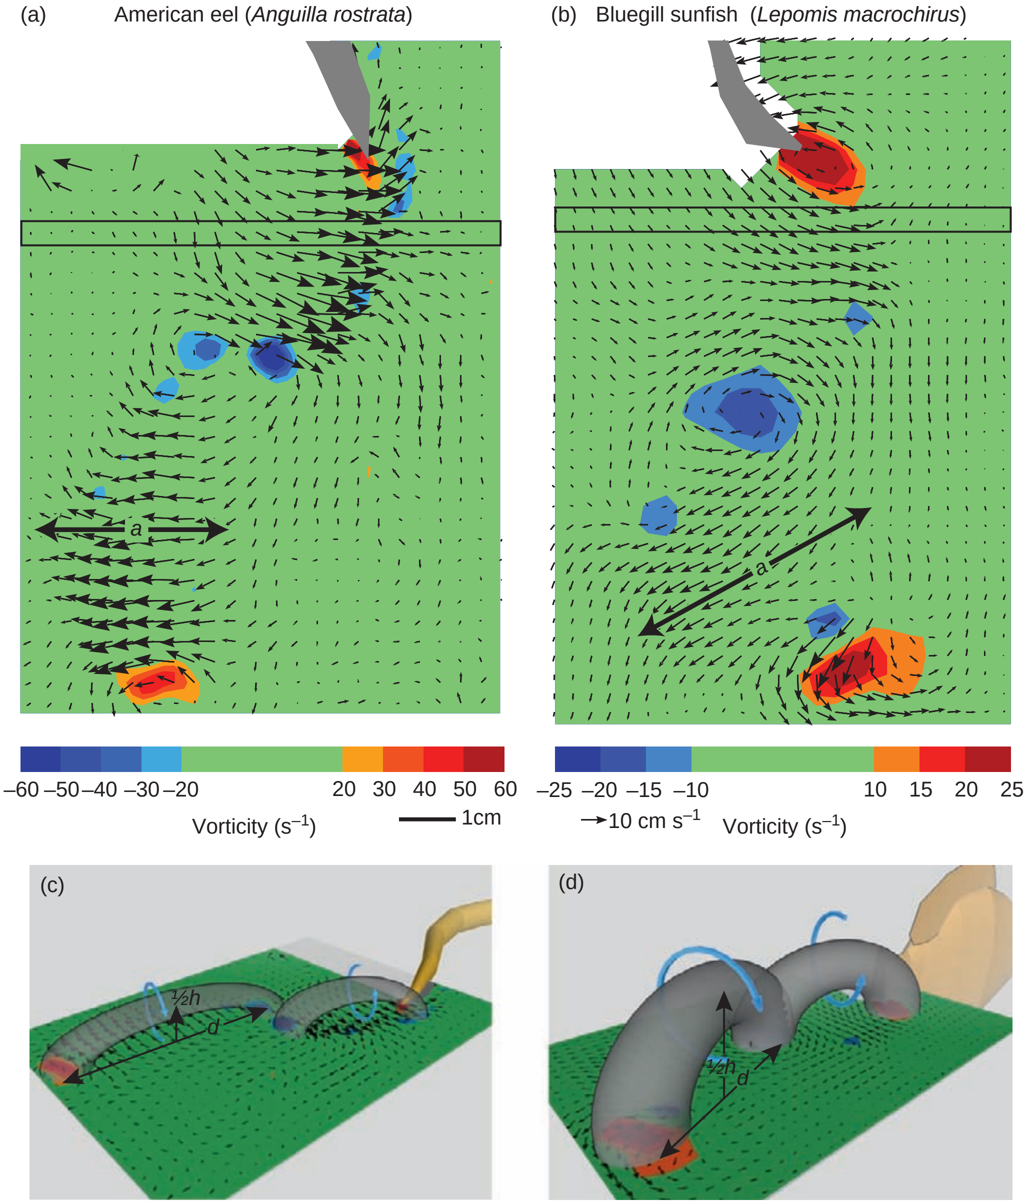

Figure 8 Examples of wake flow in horizontal planes behind an American eel and a bluegill sunfish, each swimming at approximately 1.9 Ls^{-1}. (a, b) Flow patterns near the end of a tail beat cycle. Velocities are given with black arrows, and vorticity is shown in color. Note that length and vector scales are the same, but the vorticity scales are different. The black box indicates the region used for power calculations. (c, d) Simplest 3D flow structure consistent with the wakes shown. Transparent gray tubes indicate vortex loops, and light blue arrows show 3D flow. Thick arrows show the diameter and half height of the vortex loops. (a, b) Modified from Tytell ED (2007) Do trout swim better than eels? Challenges for estimating performance based on the wake of self-propelled bodies. *Experiments in Fluids* 43(5): 701–712.

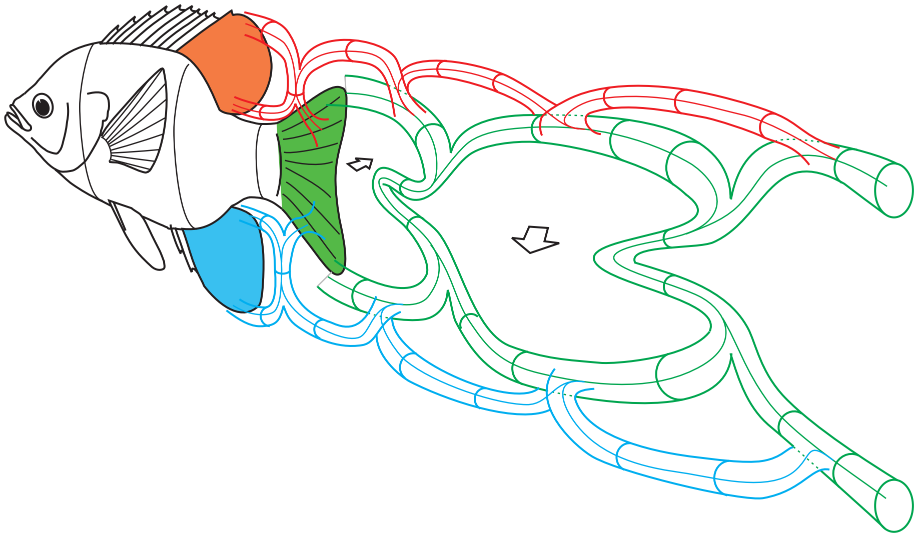

Figure 9 Schematic of 3D flow in the wake behind a bluegill sunfish, while the fish is swimming at 1.2 Ls^{-1}. Green loops show vortices shed off the caudal fin, while red and blue show those shed off the dorsal and anal fins, respectively. Note that the green loops are not circular. Modified from Tytell E (2006) Median fin function in bluegill sunfish. *Lepomis macrochirus*: Streamwise vortex structure during steady swimming. *Journal of Experimental Biology* 209: 1516–1534.

Volumetric Techniques

The oldest technique, dye flow visualization, is a volumetric technique, meaning that it resolves flow structures in a volume. Dye is injected into the flow and filmed as it follows the local fluid motion. Generally, dye tends to become concentrated near the center of vortices, but not always, which means that results need to be interpreted carefully. Dye images provide qualitative results about flow structure; for quantitative measurements of flow velocity, one must use other techniques. In addition, the fact that dye can move in three dimensions throughout a volume can make it challenging to interpret the images, particularly if only one camera is used. Some groups have used a planar light source, like those used for PIV, to illuminate a single plane of dye, which simplifies interpretation, but means that measurements are only available in that plane. Despite these limitations, dye can be quite useful for identifying the general structure of a flow or showing how two regions of flow mix.

Recently, two quantitative volumetric techniques, holographic PIV and defocusing PIV, have become feasible for biological fluid dynamics. Both of these techniques require a laser or lasers to illuminate a volume brightly and evenly. Holographic PIV relies on the interference between two beams of light to reconstruct 3D images of particles or bodies in the fluid. From these images, flow velocities can be estimated in a variety of ways. One method is to use computational techniques to estimate planar slices of the volume, which can then be analyzed using similar methods as 2D PIV. One form of defocusing PIV uses a single camera with a special lens with three apertures aligned in a triangle. A single particle thus produces three images in a triangle; the center of the triangle represents the position of the particle parallel to the camera, and the size of the triangle represents the particles distance away from the camera. The equipment and software necessary to implement defocusing PIV is now available commercially.

Interpreting Flow Fields

Force

In most cases related to fish locomotion, researchers who study fluid flow are interested in using their measurements to estimate forces on the fish's body. There are two general ways to estimate forces in a fluid, one based on fluid momentum that is best suited to rapidly changing or unsteady flows, and one based on fluid vorticity that is best for steady flows and time-averaged forces.

In both cases, one first estimates impulse **I**, the integral of force **F** applied to the fluid over time, or, more usefully, the mean force $\mathbf{F}_{\text{mean}}$ applied to the fluid multiplied by the total time T over which it was applied:

$$\mathbf{I} = \int_0^t \mathbf{F}\,\mathrm{d}t \tag{5}$$

$$= \mathbf{F}_{\text{mean}} T \tag{6}$$

One can then divide **I** by T to obtain mean force, or take the derivative to estimate instantaneous force:

$$\mathbf{F} = \partial \mathbf{I}/\partial t \tag{7}$$

Forces can be compared across different size or shape animals by estimating a force coefficient C_{F}:

$$C_F = F/[\frac{1}{2}\rho AU^2] \tag{8}$$

where A is the area of the body, usually either the wetted surface area or the cross-sectional area, and U the swimming speed. This normalization takes into account the fact that larger or faster animals generally produce more force, and allows one to ask the question, "If the body shapes and swimming speeds were the same, would these two animals produce the same forces?"

Vortex analysis

The amount of vorticity in an animal's wake is also related to the impulse on the animal. To estimate impulse, researchers often do not use vorticity directly, but use circulation, another measure of rotation strength. It is the total vorticity within an area circumscribed by a closed loop, such as the black loops shown in **Figure 4**.

For a steadily moving vortex ring, the procedure to estimate the force that generated it is quite straightforward. Any sufficiently large loop that passes through the center of a vortex ring has a constant circulation (**Figure 4(b)**) that is proportional to the force required to generate the ring:

$$F_{\text{mean}} = \frac{1}{4}\frac{\pi\rho\Gamma d h}{T} \tag{9}$$

where ρ is the density of the fluid, Γ the circulation, d the distance between the two vortex centers in the plane, and h an estimate of the out-of-plane height of the loop (see **Figure 8** for examples of h and d). For example, a good rough estimate for h for a ring shed by the caudal fin is the height of the fin itself. T is the time over which the two counter-rotating vortices were shed, generally half of the tail or fin beat cycle. Mathematically, circulation Γ can be written in two equivalent ways:

$$\Gamma = \int_{\Sigma} \omega \cdot \mathrm{d}\Sigma \tag{10}$$

$$= \oint_C \mathbf{u} \cdot \mathbf{dl} \tag{11}$$

where $\sum$ is a surface in the fluid, C the closed contour around the edge of the surface (thick black lines in Fig. 4), and l the tangent vector along the contour. The second form of the expression for circulation is important experimentally, because it allows one to estimate circulation without taking any derivatives of the velocity field. Taking derivatives tends to introduce numerical error, so the second form (eqn (11)) is often more accurate.

Momentum analysis

Newton's laws tells us that force is equivalent to change in momentum, and that, for any force on the body, there is an equal and opposite force on the fluid. Thus, in principle, one could simply measure the change in momentum in the fluid, which should be equal and opposite to the force on the animal.

For a solid body whose mass is not changing, this procedure is the familiar $F = ma$. In a fluid though, the volume of fluid affected may change, and thus m is not constant. To estimate change in fluid momentum, therefore, one must use three steps: (1) determine the volume of fluid affected by the force, (2) find the mean fluid velocity in that volume, and (3) include the effect of added mass.

1. Determine the volume. Some analyses have performed this step manually, but recently, a technique has been developed to identify what are called Lagrangian coherent structures (LCSs): volumes of fluid that tend to stay together. For example, if a fish's fin accelerated some fluid, one can track the volume of accelerated fluid as it grows and moves over time by using an LCS analysis.
2. Mean LCS velocity. Once the volume **S** has been determined, estimate the velocity U_v that the LCS itself is moving. Note that this velocity is not necessarily equal to the mean velocity of the fluid in the volume.
3. Added mass. Estimate the added mass coefficient tensor $\mathrm{C_A}$ for the volume, which will depend on the shape of the fluid volume, but not its velocity. For linear forces, the added mass tensor is a 3 × 3 matrix giving the added mass effect along each axis for acceleration along the same or a different axis. For complex bodies, the acceleration reaction may produce counter-intuitive forces, not necessarily parallel to the acceleration itself. However, we will simplify and consider only force and acceleration along the same axis, giving a scalar added mass coefficient C_A. For symmetric bodies or volumes of fluid, this approximation is appropriate.

The force on the animal corresponding to the changing fluid momentum is thus the opposite of the time derivative of the impulse required to produce the motion of the volume S:

$$F = -\frac{\partial}{\partial t}[\rho S(1 + C_A)U_V] \tag{12}$$

Figure 10 shows an example of this force calculation. The LCS around the bluegill sunfish's pectoral fin is estimated during one fin beat (**Figure 10(a)**). The vertical (lift) force is estimated, and the relative importance of the changes in velocity, volume, and added mass of the LCS are given (**Figure 10(b)**). Early in the cycle, changes in U_v are the dominant effect, while later in the cycle, the added mass coefficient C_A decreases, reducing the force.

Choosing vortex or momentum analyses

Since the tail and fins move back and forth, swimming is inherently unsteady; nevertheless, for swimming at a

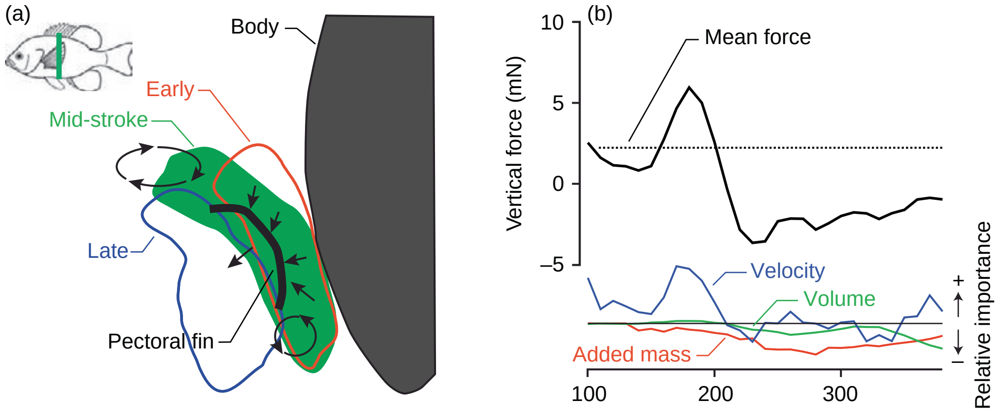

Figure 10 Example of a momentum analysis for the bluegill sunfish's pectoral fin beat. (a) Cross section through the fish body and pectoral fin. Schematics of the fin and flow are shown at mid-stroke with a thick black line and black arrows, respectively. The volume of fluid affected by the fin is shown in green for mid-stroke (same time as the fin and flow schematic), red for early in the stroke, and blue for late. Inset shows the position of the cross section. (b) Force estimates. Top panel shows the instantaneous force estimate based on the LCS calculations in (a), along with a mean force estimate (dotted line). Bottom panel gives the relative importance of the changes in LCS velocity, volume, and added mass to the force estimate. Early in the stroke, changes in velocity are the most substantial effect, contributing to positive force, whereas later in the stroke, changes in added mass become more influential, decreasing the total force. Modified from Peng J, Dabiri JO, Madden PG, and Lauder GV (2007) Non-invasive measurement of instantaneous forces during aquatic locomotion: A case study of the bluegill sunfish pectoral fin. *Journal of Experimental Biology* 210(4): 685–698 and Drucker EG and Lauder G (1999) Locomotor forces on a swimming fish: Three-dimensional vortex wake dynamics quantified using digital particle image velocimetry. *Journal of Experimental Biology* 202: 2393–2412.

steady average velocity, the vortex analysis described above is often sufficient and is much simpler to apply. For instance, in **Figure 10(b)** the time-averaged mean force matches the vortex analysis.

The relative importance of unsteady effects can be determined by the wake vortex ratio Wa as described by Dabiri:

$$Wa = \frac{C_A S U_V}{\Gamma} \tag{13}$$

which relates the observed vortex motion to the motion that one would expect if there were no unsteady forces. When Wa is very large or very small, the added mass forces are either speeding up or slowing down the vortex and an unsteady, momentum-based analysis is best. When Wa is near a critical value, either approach is correct, but the time-averaged vortex analysis may be simplest. For a vortex analysis (eqn. (9)) to be valid, the following condition serves as a rule of thumb:

$$Wa_{\text{crit}} = \frac{C_A}{1 + C_A} \tag{14}$$

If Wa is substantially above or below Wa_{crit}, then the momentum-based analysis is most appropriate.

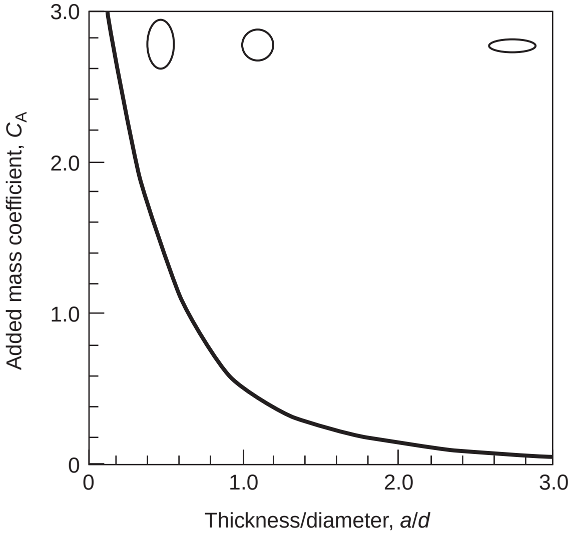

Figure 11 Theoretical added mass coefficients as a function of the thickness/diameter ratio of prolate spheroids, which approximate those of the LCS surrounding a vortex ring. Thickness *a* is the axis parallel to the motion of the ring, while diameter *d* is the largest diameter between vortex cores. Reproduced form Daniel TL (1984) Unsteady aspects of aquatic locomotion. *American Zodogist* 24: 121–134.

For the purposes of estimating Wa, the added mass of a vortex ring can be approximated by that of a solid prolate spheroid. Choose the largest diameter d_{max} (b or d in **Figure 8**, whichever is larger) and estimate the thickness of the loop (a in **Figure 8**). **Figure 11** shows added mass as a function of the thickness/diameter ratio a/d_{max}. Then estimate the mean circulation of the two vortex cores and the speed U_v that the whole loop is moving along its axis and use eqns (13) and (14) to determine the importance of unsteady effects. For example, in **Figure 10**. *Wa* is between 0.2 and 0.4, while $C_A/(1+C_A)$ is about 0.4. Thus, the vortex analysis is appropriate.

Power

Another useful metric for analyzing a wake is the hydrodynamic power contained in the wake, P_{wake}. This power is one component of the total propulsive power, $P_{\text{total}} = P_{\text{thrust}} + P_{\text{wake}}$. A perfectly efficient swimmer would somehow manage to devote all of its power to thrust and would leave no wake. Real swimmers are not perfectly efficient, and therefore they leave a wake. The thrust power P_{thrust} is difficult to estimate, particularly for steadily swimming fishes, but P_{wake}, which can be quantified in a fairly straightforward manner, can be used as a proxy measure for inefficiency. Higher P_{wake} values are indicative of low efficiency, though they are not conclusive.

Because power is change in kinetic energy; wake power is estimated by adding up the kinetic energy of the fluid that enters and leaves a volume that surrounds the fish. For a wake measurement, such as those in **Figure 8**, one must have a sufficiently wide cross section across the wake that the fluid momentum added by the animal decreases to zero at the edges. The large width means that we can assume that there is no flow through planes parallel to the swimming direction of the fish. Ideally, one would also have a cross section upstream of the fish, although this can usually be estimated from the mean swimming speed (equal to the flow speed in a flow tunnel). The planes form a control volume. The net power that the fish adds to the fluid is the rate kinetic energy enters the upstream cross section, minus the rate it leaves the downstream cross section.

$$P_{\text{wake}} = \frac{1}{2}\rho h U \int (2Uu + u^2 + v^2)\,\mathrm{d}y \qquad (15)$$

where h is the approximate height of the wake (usually equal to the height of a fin or the body), U the mean swimming speed or mean flow speed, u and v the fluid velocities added by the fish in the x and y directions, and where it is assumed that the upstream flow has a constant velocity U. Power can be normalized in a similar way as force (eqn (8)):

$$C_P = P/[\tfrac{1}{2}\rho A U^3] \qquad (16)$$

Figure 12 shows an example comparing wake power coefficients for American eels, rainbow trout (*Oncorhynchus mykiss*), and bluegill sunfish. Note that sunfish have the most costly wake, suggesting low swimming efficiency compared with American eels swimming slowly (0.5 Ls^{-1}) or rainbow trout swimming rapidly (~2 Ls^{-1}).

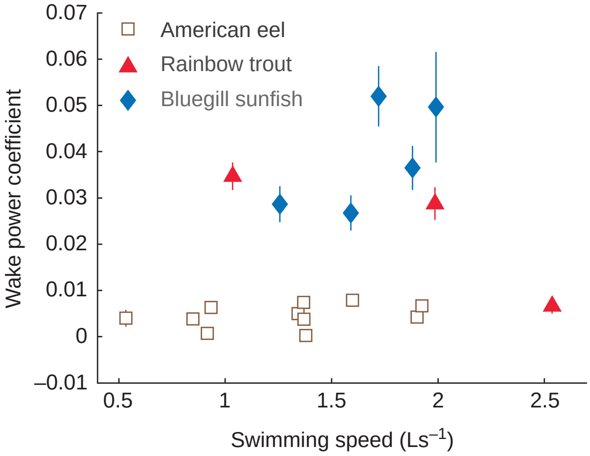

Figure 12 Wake power coefficients plotted against swimming speed for American eels, rainbow trout, and bluegill sunfish. Error bars indicate standard error; where they are not visible the symbol is larger than the error range. Modified from Tytell ED (2007) Do trout swim better than eels? Challenges for estimating performance based on the wake of self-propelled bodies. *Experiments in Fluids* 43(5): 701–712.

Future Developments

Much of this article has dealt with 2D flow fields, because these are currently the most common and easiest to measure. In the future, 3D measurements will become more common. Techniques such as defocusing PIV and holographic PIV are starting to be available commercially. In interpreting 3D flow fields is substantially more difficult than 2D fields. Nevertheless, the force and power analyses detailed above are applicable to 3D flows. In some ways, they are simpler to apply with 3D data, because one does not need to make assumptions about the 3D structure of the flow (e.g., the wake height h). At the same time, the flow data become much harder to visualize and understand. To help with this problem, it is likely that a class of techniques called dimensionality reduction methods will become much more important. These include principal orthogonal decomposition (POD) and biorthogonal decomposition (BOD), both of which are similar to principal components analysis, a technique commonly used to compare many different morphological measurements across fish species. Both techniques produce estimates of flow patterns that are the most coherent and energetically strongest. Then understanding the flow becomes easier, in that one can examine just these coherent modes.

Glossary

Electromyography A technique for measuring the electrical activity associated with muscle contraction. Sensing electrodes implanted in the muscle tissue detect timing of muscle action as a high-frequency burst of voltage spikes.

Kinematic analysis Quantification and analysis of body movements.

Myoseptum The collagenous connective tissue forming the boundary between successive myotomal muscle blocks. In addition to forming the origins and insertions of myotomal muscle fibers, the myosepta are typically anchored to the skin and axial skeleton. Regions of the myotome that act as primary routes of force transmission are reinforced to form tendon-like structures.

Myotome A block of segmental muscle tissue. In fish, these consist of short (typically in the order of a few mm to a few cm) muscle fibers stretched between sheets of connective tissue, the myosepta, that separate adjacent muscle blocks.

Muscle action potential The wave of electrical depolarization that spreads across a muscle cell membrane in response to a stimulus from a motoneuron.

Sonomicrometry A technique that uses transmitted ultrasound as the basis for measuring length changes in muscle tissue. Pairs of ultrasound transducers are implanted parallel to the muscle fibers in the myotomal muscle. As the muscle tissue cyclically lengthens and shortens with each tail beat, this length change is indicated by the change in ultrasound transit time between the transducers.

Work loop A plot of muscle force production against muscle length. During contractions with a regular length-change cycle, the plot forms a closed loop. The area within the loop has units of work and represents the net work done by the muscle.

Introduction

All swimming animals move by transferring mechanical power generated by their muscles to the surrounding water. This accelerates the water, increases its kinetic energy and momentum, and creates a wake around and behind the animal. Through the conservation of momentum, transfer of power to the wake creates reaction forces that are the basis for movement through the water (**see also Buoyancy, Locomotion, and Movement in Fishes**: Experimental Hydrodynamics). Many swimming animals transfer momentum using rostrocaudal waves of curvature that pass along their body axis. This article will focus on how body undulations of this type are generated in fish by contraction of the segmented myotomal musculature and the transfer of muscle force to the axial skeleton.

Undulatory Swimming Modes

Fish adopt a wide variety of swimming styles, utilizing fins and/or body movements to transfer muscle mechanical power to the water. Within the broader diversity of swimming styles, there are many species that swim using lateral undulations of their body axis. These body undulations, and the lateral movements of the caudal and unpaired dorsal and ventral fins they create, accelerate the surrounding water, generating lift, thrust, and stabilizing forces.

Undulatory swimmers are phylogenetically diverse. This swimming style is exhibited by petromyzontids, myxinids, and gnathostomes. Most of the data concerning kinematics and muscle dynamics have been obtained from gnathostomes. Within this group, the vast majority of data are from teleosts, with a relative handful of studies focusing on elasmobranch swimming. Undulatory swimmers also span a size range encompassing larval fish a few millimeters in length and whale sharks with body lengths in excess of 10 m. Despite this, the basic mechanics of swimming are similar in most undulatory swimmers. Lateral undulations are generated by sequential contraction of the segmented, myotomal muscle created by motor outputs from the spinal cord. Waves of muscle contraction pass along the body axis from anterior to posterior creating a wave of local muscle shortening and lateral bending of the body axis (**Figure 1**). The timing of the waves is offset between opposite sides of the body, resulting in an alternating wave of curvature moving along the body axis from anterior to posterior.

Undulatory swimmers have typically been broken down into a series of categories based on the two-dimensional kinematics of their midline during steady swimming. Categories are defined based on the number of waves of curvature present on the body and the proportion of the body axis that undulates (**Figure 2**). Under this scheme, the modes are named for genera that typify a particular swimming style. At one extreme, the anguilliform swimmers undulate the majority of their body axis. Subcarangiform and carangiform swimmers undulate progressively less of their body axis and have increasingly long mechanical wavelengths (so a smaller portion of a complete waveform is present on the body axis). Thunniform swimmers have a uniquely specialized muscle and connective tissue anatomy that sets them apart from the majority of other swimmers that transfer momentum to the water using axial movements. These result in the confinement of lateral movement to the caudal region rather than a clear axial progression of lateral undulation *per se.* In light of these differences, discussion is largely confined to more typical anatomies and the modes of undulatory swimming they generate.

Recent kinematic, morphological, and hydrodynamic analyses suggest that a kinematics-based scheme may have limitations in terms of clearly distinguishing between swimming modes. Amplitudes of undulation are actually quite similar in species typically separated into anguilliform and subcarangiform modes. Species in these groups also share a similar myotomal muscle and connective tissue anatomy that is distinct from the pattern seen in some carangiform swimmers. In contrast, visualization of wake structure has revealed an anguilliform wake pattern distinct from that shared by subcarangiform and carangiform swimmers. A comprehensive classification scheme will likely need to integrate kinematic, morphological, physiological, and hydrodynamic data. Unfortunately, at present, data from all these categories are available for very few species and a kinematics-based scheme remains the best available option for describing swimming modes.

Regardless of size, anatomical variation, hydrodynamic factors, phylogenetic affinities, or body midline kinematics, all undulatory swimmers are alike in one respect: the relationship between tail-beat frequency and

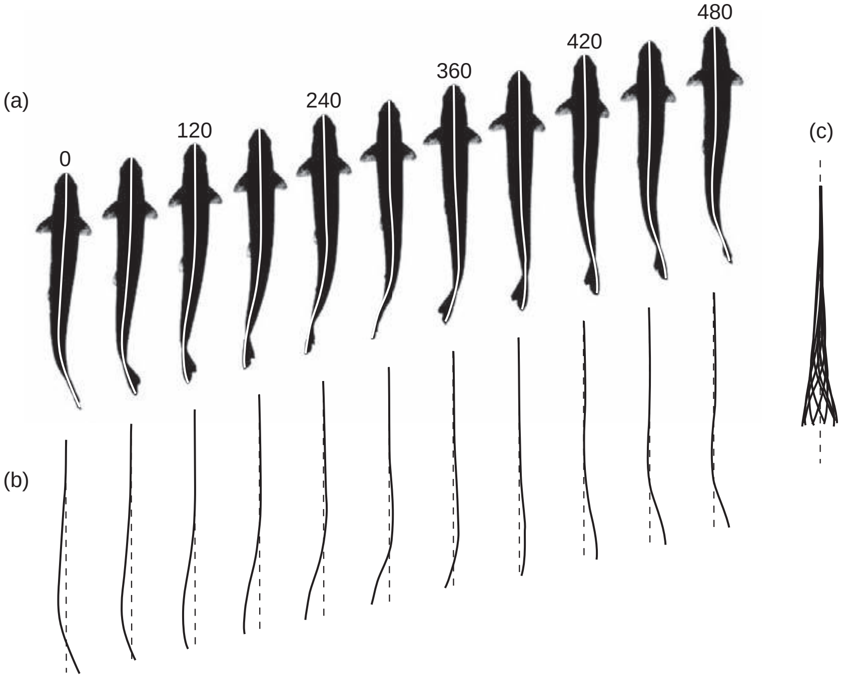

Figure 1 Axial undulations in a gnathostome fish. (a) Sequential images during a single tail beat. Numbers denote time in milliseconds. Axial midline is highlighted in white. Figure 3 Relationships between undulatory swimming speed and tail-beat frequency. Representative data are presented for species spanning the range of swimming modes defined by midline kinematics. The data presented are as follows: black, American eel, *Anguilla rostrata*, anguilliform; blue, rainbow trout, *Oncorhynchus mykiss*, subcarangiform; red, bonito, *Sarda chiliensis*, carangiform. American eel: from Gillis GB (1998) Environmental effects on undulatory locomotion in the American eel *Anguilla rostrata*: Kinematics in water and on land. *Journal of Experimental Biology* 201: 949–961. Rainbow trout: from Webb PW (1988) 'Steady' swimming kinematics of tiger musky, an esociform accelerator, and rainbow trout, a generalist cruiser. *Journal of Experimental Biology* 138: 51–69. Bonito: from Dowis HJ, Sepulveda CA, Graham JB, and Dickson KA (2003) Swimming performance studies on the eastern Pacific bonito *Sarda chiliensis*, a close relative of the tunas (family Scombridae): II. Kinematics. *Journal of Experimental Biology* 206: 2749–2758.

swimming speed is approximately linear (**Figure 3**). That is, it can be described by a simple linear equation in the form, $U = fS + I$, where U is the swimming speed, f the tail-beat frequency, S the gradient or slope of the linear relationship, and I the zero speed intercept. The absence of a zero intercept for the relationships is unexpected, and appears to be due to modulation of undulatory kinematics at low speeds, particularly with regard to tail-beat amplitude. Despite this, for most of the speed range, speed control is primarily achieved via alteration of the tail-beat frequency. The gradient, S, is a useful measure of performance, as it represents a 'stride length', the distance traveled per tail-beat cycle.

The precise pattern of axial undulation is dictated by complex interactions between active and passive components of the musculoskeletal system, overall body shape, fin morphology and mechanical properties, and external hydrodynamic forces. This complexity, coupled with a tendency for any given study of undulatory swimming to focus on a subset of the system components, means that the mechanics of axial undulation are not fully understood. An increasing focus on integrating physiological, anatomical, mechanical, and hydrodynamic data, however, is leading to improved understanding of how muscle activity is translated into axial bending and ultimately the transfer of momentum to the surrounding water.

Myotomal Muscle Anatomy

The mechanical power for undulatory swimming is produced by the segmented, myotomal muscles that constitute a large portion of the total skeletal muscle mass in myxinids, petromyzontids, and gnathostomes. The myotomes are a series of blocks of muscle tissue separated by connective tissue, the myosepta (**Figure 4**). The myotomes are most easily visible as the flakes in a cooked fish filet when heat breaks down the connective tissue, allowing separation of the muscle blocks. Each myotome consists of many short muscle fibers that run between successive myosepta. The three-dimensional shape as well as the arrangement of the muscle fibers within a myotome are complex. The basic structure in most gnathostomes and myxinids consists of a series of nested cones of muscle tissue. In a cross section of a fish these are visible as a series of concentric circles of muscle alternating with connective tissue (**Figure 4**). A series of anterior-pointing cones are located dorsal and ventral to the midline of the fish. Dorsal and ventral to these are a series of posterior-pointing cones and at the dorsal and ventral extremes of the myotomes are a series of anterior-pointing arms of muscle tissue. Moving axially from the rostral to caudal myotomes, there is a trend for increased elongation of the cones and arms. Few of the muscle fibers, except for those in the most superficial and laterally placed muscle, are arranged in parallel with the long axis of the fish. Fiber angles change markedly with position within the myotomes. In the anterior myotomes of

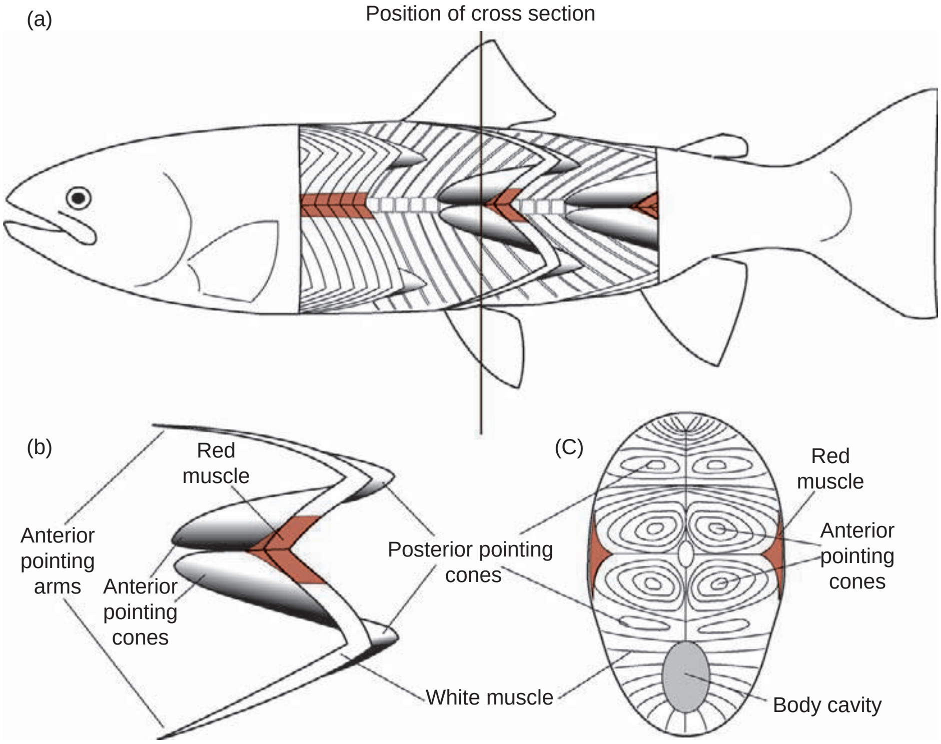

Figure 4 Myotomal muscle anatomy. (a) Lateral view of a typical gnathostome. A single myotome at the midpoint of the body axis is shown *in situ* with adjacent tissue removed to reveal its three-dimensional structure. (b) Component parts of a myotome. (c) Body cross section to reveal distribution of muscle fiber types and myosepta. Pink muscle is not shown as this typically represents a minimal component of the total muscle cross section.

gnathostome fish, arched trajectories of fibers spanning several myotomes have been identified. Starting anteriorly, close to the vertebral column, exterior arches run laterally outward from the midline of the body before curving back to the midline posterodorsally. Additional interior arches run under the midpoint of the outer arches, possibly having a supportive, pulley-like role during contraction of the fibers in the outer arches. The arrangement of these helix-like muscle trajectories and their associated connective tissue strongly suggests that adjacent myotomes interact in producing axial bending.

Muscle Fiber Types

The skeletal muscles of many vertebrates contain a mixture of muscle fiber types. These differ in terms of their mechanical performance and the metabolic pathways by which they obtain metabolic energy. Fish myotomal muscle is unusual in that different fiber types are anatomically separated. In most fish, the myotomal muscle contains three types of muscle fiber: red, pink, and white, named for their superficial appearance. White muscle accounts for the majority (typically >90%) of the myotomal muscle mass. Red muscle accounts for the most of the remainder. In most fish, red muscle is located laterally and has a wedge-shaped cross section (**Figure 4**). Pink muscle, if present, forms a thin layer between the red and white fibers. The color differences reflect underlying differences in their structure, biochemistry, and, as a consequence of these, their mechanical performance.

Regional Variation in Myotomal Muscle Properties

Myotomal muscle contractile properties vary between fiber types, with position on the body axis and among developmental stages. Force production and shortening by skeletal muscle are caused by myosin cross-bridge cycling. This requires adenosine triphosphate (ATP) energy and the binding and release of Ca^{2+} from troponin C, a protein component of thick myosin filament. Muscle shortening velocities decrease in the order white > pink > red in concert with a decreasing myosin-ATPase content. Factors affecting the Ca^{2+} occupancy of troponin-binding sites and the rates of cross-bridge attachment and detachment change the rates of muscle activation, shortening, and relaxation. Differences in the rates of activation, shortening, and relaxation can occur independently as they are influenced by separate muscle proteins.

Both red and white muscle fibers in a number of teleost species have slower rates of activation and/or relaxation moving along the body axis from anterior to posterior.

These differences have been correlated with longitudinal changes in the expression of three muscle proteins: parvalbumin, troponin T, and the myosin light chain (MLC; specifically MLC2 the regulatory light chain). Regional differences have been found in the relative amount of these proteins and/or in the relative proportions of alternate protein isoforms:

- Binding of Ca^{2+} to troponin C is an essential step in triggering cross-bridge cycling and muscle contraction. Parvalbumin binds free Ca^{2+} in the myoplasm, competing with troponin C. Parvalbumin, therefore, influences muscle relaxation by reducing the concentration of free Ca^{2+} in the myoplasm. High parvalbumin concentrations should be associated with rapid muscle relaxation. Parvalbumin content declines from anterior to posterior in trout (*Oncorhynchus mykiss*), sheepshead (*Archosargus probatocephalus*), and kingfish (*Menticirrhus americanus*) red band white muscle, and in cod (*Gadus morhua*) and largemouth bass (*Micropterus salmoides*) white muscle, likely being a factor in increased relaxation times moving from anterior to posterior in these species.
- Troponin T is a component of muscle thin filaments (**see also Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element). It is thought to affect the rate at which Ca^{2+} dissociates from troponin C, and therefore the rate at which muscle relaxes. The relative proportions of two troponin T isoforms shift from anterior to posterior in cod (*G. morhua*) and largemouth bass (*M. salmoides*), with the dominant anterior form likely having faster kinetics than the alternate isoform.
- MLC2 is a thick filament component that may modulate cross-bridge kinetics by controlling sensitivity to Ca^{2+}. The amounts of the slow MLC2 isoform increase, moving from anterior to posterior in both the slow and fast muscle of rainbow trout (*O. mykiss*).

The list of regionally variable proteins that influence myotomal muscle contractile properties is likely to grow as more data become available. Fewer data are available for elasmobranchs, but similar regional differences in contractile properties have not yet been detected.

In addition to regional mechanical differences, there is also variation in the extent to which fish muscle fibers rely on either aerobic or anaerobic metabolic pathways to supply energy for contraction. The volume fraction of red fibers occupied by mitochondria is typically greater than 25% compared with less than 10% in white muscle. Accordingly, the activities of mitochondrial enzymes associated with aerobic metabolism, such as cytochrome oxidase and citrate synthase, are higher in red than in white muscle. Pink muscle shows an intermediate level of activity for these enzymes. White muscle relies primarily on anaerobic glycolysis for its energy supply, as indicated by higher levels of glycolytic enzymes, such as phosphofructokinase, than found in red or pink muscle.

Muscle Length Change and Activity

The interaction between mechanical properties and the metabolic pathways that fuel this performance dictates the speed and sustainability of the movements that a particular muscle type can power. Steady, sustained, undulatory swimming is powered by the red, aerobic muscle fibers. Pink fibers supply additional mechanical power at the upper end of the aerobically supported speed range. The anaerobic white muscle has limited involvement in undulatory swimming in most species, except during brief, rapid sprints. These fibers are primarily active during rapid, asymmetrical, maneuvers used to capture prey and avoid predators. Accordingly, the majority of data for muscle function during undulatory swimming have been obtained from red and pink muscle.

The relationship between force production and length change is the major determinant of muscle mechanical performance. Direct recordings of muscle activity and length change patterns have been made in a number of fish species during undulatory swimming (**Figure 5**). These have been obtained using two techniques: electromyography and sonomicrometry. Force production by skeletal muscle is triggered by a series of chemical and electrical signals. A key step is the generation of a muscle action potential (MAP). This is a wave of electrical depolarization propagated along the cell membrane of muscle cells that is generated by changes in membrane permeability, primarily to sodium ions. Electromyography uses recording electrodes adjacent to muscle cells to detect the MAP.

Body undulations are driven by waves of muscle activity and contraction proceeding sequentially through the myotomes from anterior to posterior (**Figure 6**). In most species, activity coincides with local shortening of the myotomal muscle. This creates curvature of the body axis of the fish with the active muscle on the inside of the curve. The timing of the waves of activity on opposite sides of the body is offset. Muscle contralateral to the active muscle is inactive and being lengthened by the active muscle tissue. This throws the body axis into a series of curves that proceed along the body from anterior to posterior along the body.

These recordings reveal a number of similarities, irrespective of differences in swimming mode or taxonomic group:

- The muscle length change pattern is an approximately sinusoidal wave form.
- Muscle activity starts just before peak muscle length.
- Muscle activity persists during the majority of the shortening phase.

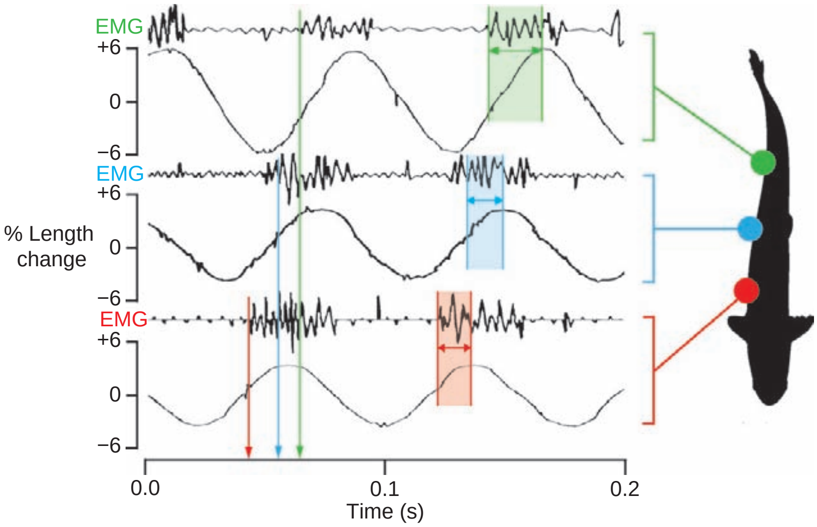

Figure 5 Myotomal muscle activity and length change at three points along the body axis. Vertical arrows show the relative timing of EMG onset at the three points. Shaded areas and horizontal arrows show the shift in EMG onset relative to peak muscle length. Adapted with permission from Ellerby DJ and Altringham JD (2001) Spatial variation in the fast muscle of rainbow trout *Oncorhynchus mykiss* during fast starts and sprinting. *Journal of Experimental Biology* 204: 2239–2250.

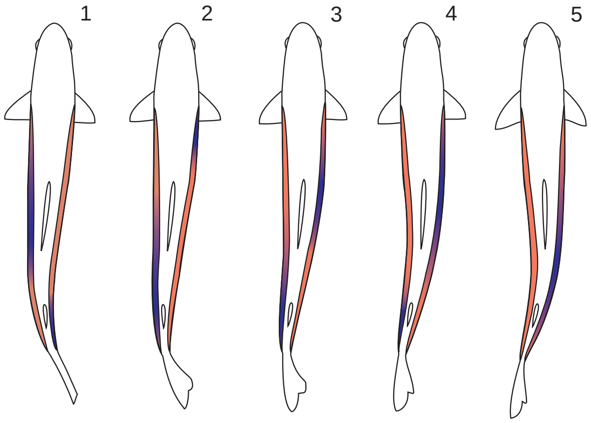

Figure 6 Timing of muscle activity along the body axis. Dark shading denotes the presence of EMG activity. Numbers show a sequential progression through the tail beat.

There are also a number of trends within teleost undulatory swimmers that are increasingly apparent as the mechanical wavelength of the axial undulations increases; that is, they are more marked in carangiform, than in subcarangiform or anguilliform swimmers:

- The amplitude of muscle fiber length change increases moving from anterior to posterior myotomes.
- The timing of muscle activity relative to the length change cycle shifts earlier, moving from the anterior to posterior myotomes.
- The relative duration of muscle activity decreases moving from anterior to posterior myotomes.
- The speed of axial progression of the electromyogram (EMG) activity increases from anterior to posterior.

As for muscle contractile properties, fewer data are available for undulatory elasmobranchs, but shifts in the relative timing of muscle activity have yet to be detected.

Muscle Mechanical Performance

EMGs are useful as indirect indicators of muscle force production. There are, however, limits to what can be learnt from EMG data for two reasons: first, there is a time lag between EMG activity and muscle force production and this is likely to change along the body axis due to regional differences in contractile properties; and, second, the EMG signal cannot indicate the magnitude of the force produced. Therefore, in the absence of direct measures of muscle force, EMG and sonomicrometry data alone cannot supply information about muscle work and power output.

The complexity of the myotomal anatomy means that direct measurements of myotomal muscle force are not possible in a swimming fish. Muscle force and work output can be measured in muscle fibers removed from the myotomes and maintained *in vitro* in oxygenated, physiological saline. Muscle work and power have been determined in this way for a number of species using the work loop technique (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops).

Applying this technique, patterns of length change and activation measured *in vivo* using sonomicrometry and electromyography are played back to the *in vitro* muscle fibers by an ergometer and the resulting force, work, and power outputs measured. For a muscle to do mechanical work on its surroundings, it must exert force primarily while shortening. As undulatory swimming requires work to be done on the surrounding water by the myotomal muscle then the majority of the active muscle mass should operate in this mode. This has generally been found to be the case; with the majority of force production is confined to the shortening phase of the length change cycle. A limitation in interpreting data from work loop experiments is that the muscle fibers are no longer connected to the connective tissue that transmit force and power to the axial skeleton.

Force and Power Transmission

In order to create axial undulations and ultimately to transfer power to the water, muscle force and power must be transmitted to the axial skeleton of the fish. There are a number of potential routes for force transmission from myotomal muscle via connective tissue and skeletal elements. Recently, detailed anatomical investigations of the myoseptal anatomy have led to a reevaluation of how they transmit force. These structures were typically viewed as relatively homogenous sheets of connective tissue. It is now clear that within the overall structure there are reinforced regions of connective tissue with a tendon-like structure. The orientation of these structures with regard to the muscle fascicles and axial skeleton strongly suggests that they are playing a major role in force transmission during undulatory swimming. In many teleosts, this force transmitting capacity is enhanced by ossification of the tendons to form the epineural and epipleural bones. The primary role of these tendons is the posterior transmission of forces from anterior muscle (**see also The Skeleton**: Bony Fish Skeleton).

In gnathostomes and myxinids, myoseptal connective tissue is also directly linked to the stratum compactum, a fibrous layer of connective tissue in the skin (**see also The Skin**: The Many Functions of Fish Integument). This layer is a likely route for transmission of force directly from superficial myotomal muscle fibers, and indirectly from muscle inserting on the myosepta.

Roles of Myotomal Muscle in Addition to Power Production

Power Transmission

The typical onset of muscle activity during muscle lengthening means that for part of the length change cycle myotomal muscle is stretched by adjacent muscle while exerting force. This means that the muscle is not a pure producer of work and power. In addition to doing work on the water, work also must be done on the muscle to stretch it while active. This has two mechanical consequences: first, the active prestretch enhances force production and power output during the subsequent shortening phase of the cycle; and, second, muscle that is stretched while active has high stiffness (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops). On this basis, it has been hypothesized that the muscle tissue itself could act as a transmitter of force and power from adjacent muscle tissue in addition to doing positive work later in its length change cycle. The trend for increasingly early onset of activity moving from anterior to posterior along the body axis means that this later role is likely to be more pronounced in the posterior myotomes. In some species, peak positive power production in the anterior myotomes also appears to coincide with high stiffness in the poster myotomes. Given the robustness of the tendon-like myoseptal structures in many species, however, the role of muscle as power transmitter is likely to be of limited importance.

Stability Control

Work loop experiments suggest that the power output from anterior red myotomal muscle is suboptimal under *in vivo* conditions (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops). In addition, at low swimming speeds in particular, the anterior myotomal muscle is intermittently active. This is a surprising operating mode for a power producing muscle. At a constant swimming speed, a power producing muscle would be expected to show a relatively constant level of activity and produce power at a near optimal level. Intermittent, suboptimal contractions suggest an alternate role. A likely explanation is that the anterior muscle is assisting in making small stabilizing and maneuvering corrections to control the heading of the fish (**see also Buoyancy, Locomotion, and Movement in Fishes**: Stability and Turbulence).

Modulation of Body Stiffness

It has been hypothesized that fish dynamically alter their body stiffness in order to match the natural frequency of the body axis to their tail-beat frequency. This may potentially reduce the mechanical work required to undulate the body axis. Stiffness modulation could be achieved by the action of muscle on the stratum compactum of the skin placing the connective tissue fibers in this layer in tension. Stiffness may also be affected by changes in intramuscular pressure during myotomal muscle contraction. Unconstrained muscle undergoes radial expansion as it shortens during contraction. Resistance of radial expansion by myoseptal connective tissue would increase intramuscular pressure and axial stiffness.

In summary, carefully timed activation of blocks of muscle on either side of the body plus having different muscle blocks contracting and relaxing at different rates results in waves of contraction or undulation of the body and ultimately forward swimming.

Glossary

Cycle frequency The number of complete strain cycles imposed on the muscle per second (Hz), often analogous to the tail-beat frequency of a swimming fish.

Duty cycle The fraction of the strain cycle period during which the muscle is activated. It is a measure of the duration of stimulation of the muscle relative to the strain cycle duration.

Lengthening work Sometimes referred to as negative work, it is the work required to lengthen a muscle and is energy absorbed by the muscle. While negative work *per se* is not defined (and is thus, perhaps, not the best choice of terminology), the negative notation arises from the calculation of work in work-loop analysis, where an increase in muscle length results in a negative value when calculated as initial length minus final length. It is equally acceptable to express lengthening work as a positive or negative value, because it is understood that the absolute value represents the energy required to lengthen the muscle.

Net work The mathematical difference between shortening and lengthening work, typically calculated over a complete cycle of shortening and lengthening. In this calculation, the lengthening work is subtracted from shortening work when both are assigned positive values alternatively, if lengthening work is defined as a negative quantity, then net work is the sum of shortening and lengthening work. A positive value of net work denotes the muscle doing more work while shortening than it absorbs while being lengthened. A negative value denotes more work being required to lengthen the muscle than it produces while shortening.

Phase A particular reference point or segment during an oscillation.

Power The rate of doing work (watts = joules per second). In work-loop analysis, it is usually calculated as the work (J) done during one complete cycle, multiplied by the cycle frequency (Hz).

Shortening work Sometimes referred to as positive work, is the work done by a muscle as it shortens, and is energy exerted by the muscle on the external world.

Stimulus frequency or pulse frequency The rate (Hz) at which stimulus pulses are applied to the muscle or nerve to cause muscle contraction.

Strain cycle In work-loop analysis, this refers to the pattern of length change imposed on the muscle, typically sinusoidal, but not necessarily, and sometimes called the strain trajectory, or excursion in earlier literature.

Strain or strain amplitude The magnitude of change in muscle length expressed as a fraction or percent of the resting or average length. It is referred to as excursion or excursion amplitude in earlier literature. Strain may be expressed as peak-to-peak amplitude or only peak; refer to the specific study for details.

Work A measure of mechanical energy (joules), calculated as the integral of force with respect to muscle-length change in work-loop analysis.

Work loop A plot of muscle force production against muscle length. During contractions with a regular length-change cycle, the plot forms a closed loop. The area within the loop has units of work and represents the net work done by the muscle.

Work, Swimming, and Muscles

Swimming requires work. For a fish, it requires a good deal of energy to move through the water, more so for some than others. Most fishes are neutrally buoyant or nearly so; thus, relatively little energy need be expended to support their body weight (**see also Buoyancy, Locomotion, and Movement in Fishes:** Buoyancy in Fishes). For what, then, is the energy required? At a minimum, a mass of water must be accelerated backward to propel the fish forward. Water is dense and viscous relative to air; thus, as the fish moves through water, considerable energy is required to push water out of the way and to escape its grip on the body surface. Energy is also needed to accelerate the body itself, both forward and laterally. Subtle and not-so-subtle changes in body shape, attitude in the water column, vortices, and turbulence, all require energy to create, whether intentional or not. All these considered, swimming requires work.

In fishes, like most multicellular animals, work for locomotion comes from skeletal muscles that transduce chemical energy from adenosine triphosphate into mechanical work. During relatively slow and sustained swimming, the slow, red myotomal muscles are active, while during rapid movements, the fast, white muscles carry the load (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming). What is it about these muscles that makes them suitable under the circumstances in which they are used? How can we understand the abilities of different muscles to power various aspects of swimming and the effects of swim speed, temperature, oxygen availability, etc., on the ability of muscle to power movement? Mechanical work of muscle has been measured historically using relatively simple contractions from fully activated muscle at constant velocity of muscle shortening, or working against a constant load such as lifting a weight off the ground. However, this does not mimic how muscles function in living, moving animals. In 1985, Robert Josephson reported successful adaptation of a technique allowing measurements from muscles working much as they do in moving animals, and we have since gained many new insights into how muscles are used by animals to move. This is the work-loop technique.

Before discussing what work loops tell us about muscles and swimming, a brief introduction to some terminology is needed. Proper terminology should be understood and abided by, as casual use will cause confusion and have one appear as blissfully uninformed as advertisers touting powerful whiteners in their toothpaste and efficiency in their software solutions. This will not be dealt with in detail. Work, with units of joules (newton meters, Nm), is a measure of mechanical energy, an important energy currency in the world of physical movement. Mathematically, work done on an object is the product of the net force (*N*) exerted on the object (or load) and its displacement (*m*); that is, how hard something is pushed multiplied by how far it moves. The relevant force in calculating work is the vector acting in parallel with the vector of movement, and because force need not be steady while the object moves, it can be stated more generally that work is the dot product integral of force with respect to displacement. In practice, we will see that all or most force acts in parallel with the load in typical work-loop studies, and so, work is calculated simply by summing the products of average forces and displacements over many small intervals. Therefore, for those anxious about integral calculus and vector algebra, if one can, or a calculator can, multiply two numbers together, then one can do work-loop analysis.

As a product of force and displacement, work is a linear function of their magnitude. Moving a given load a given distance would require the same work as moving double the load over half the distance, etc. Further, if a large force is exerted against an object that does not move, or if an object moves steadily without any force being applied to it (coasting through space), then no work is done on the object; anything multiplied by zero is zero.

Power is the rate of doing work, expressed as joules of work done per second (watts, W). Moving a given load a given distance will require a given amount of work. Doing it faster requires the same amount of work (all else being equal), but the work is done over a shorter period of time, and so the power is greater. A bulldozer and a person will do the same amount of work in moving a load of earth (in simple terms), but the bulldozer can do it much faster than a human, because it is more powerful. As for toothpaste whiteners being powerful, well, that it is a load of another sort! The work done by fish muscle per cycle of shortening/lengthening is a useful measure of the energy made available during each tail beat to propel the fish forward. Power, as a measure of how fast that work is done, is a useful gauge of how fast a fish might swim; bearing in mind that swimming speed is not a linear function of power.

Measures of work incorporate both the ability to produce force and the ability to shorten while producing force, making work-loop analysis all the more informative. Isometric force is not always a good predictor of the ability of a muscle to do work, and sometimes is a dismal predictor. Further, movement of muscle has a marked effect on force, and thus on work, including classical force–velocity and length–tension properties of muscle, the poorly understood effects of stretch and shortening on cross bridges, effects of muscle length on titin, activation, calcium sensitivity and release, and perhaps other passive force-generating elements in muscle, and the effects of stretch and shortening on the time course of force generation and relaxation. All of these are important in influencing how much work is produced during muscle contraction, and all are accounted for only during contractions where the muscle moves similar to how it would in a living, moving animal. Alternatively, none of these is accounted for during isometric contractions, and isotonic or isovelocity shortening do not account for the important effects of stretch on muscle work and energy available for locomotion, nor do they usually allow relatively realistic patterns of muscle activation, making work-loop analysis all the more valuable as a tool to understand muscle function in moving animals.

Measuring Work

Ideally, we would measure work directly from muscle in a swimming fish. However, it is not yet technically feasible to measure simultaneously the force and strain of

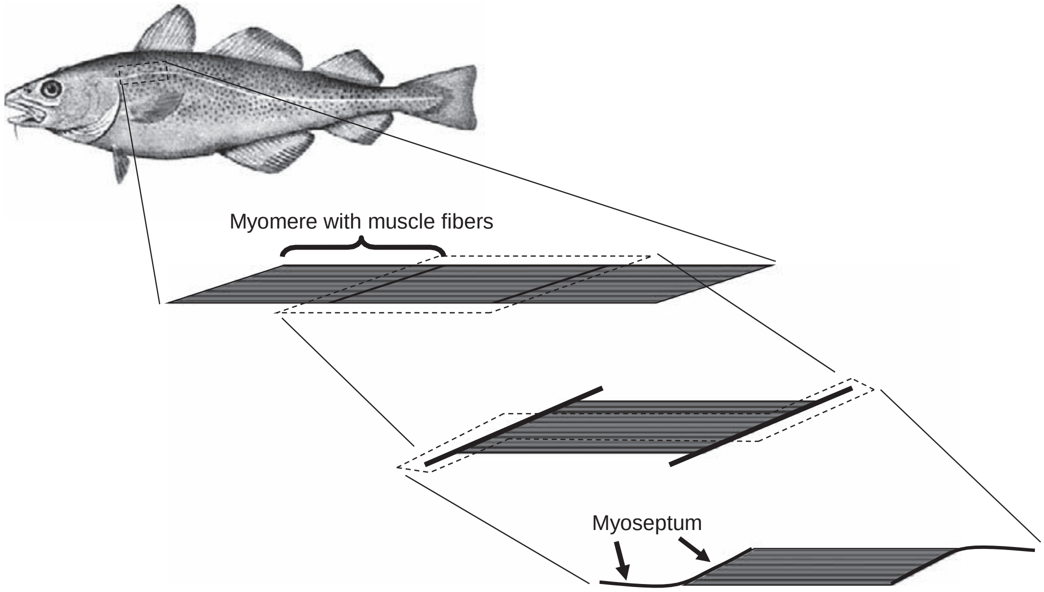

Figure 1 Isolation of a muscle preparation for work-loop experiments. In this example, a block of myotomal red muscle is first removed from the fish, typically directly beneath the lateral line. In this sketch, the muscle fibers are shown running horizontally, with dark myosepta separating the myomeres at an oblique angle. The initial block of tissue is several myomeres in length. This is then dissected to a preparation that is a single myomere in length with myosepta at either end, and finally pared down to the final preparation, which is relatively narrow in cross section and has segments of myoseptum extending from either end. These loose ends of the myosepta are secured to the apparatus (see **Figure 2**).

myotomal muscle in a swimming fish. The preparation of necessity is thus isolated muscle (**Figure 1**). For myotomal preparations, a small segment of muscle, usually several myotomes in length and several millimeters in width, is removed from a freshly killed fish and placed in cold physiological saline. The sample is then pared down via dissection, leaving normally one myotome in length and a width that is convenient for the experimenter's needs, ranging from a single fiber to about 1 mm in width. Short segments of myoseptum are left attached to either end of the preparation and used to secure it in the experimental apparatus. One end of the preparation is attached to the moveable arm of a servomotor, which is used to manipulate the length of the muscle. The other end is attached to a force transducer (**Figure 2**). In some instances, one end of the muscle is simply fixed to an immovable object and the other end to an ergometer, a device that can measure both muscle length and force, and thus work. It is named after the erg, a unit of energy ($\mathrm{g\,cm^2\,s^{-2}}$) equivalent to 100 nJ that is rarely, if ever, used today.

The preparation is immersed in physiological saline, usually with a means to maintain the pH, oxygen saturation, and temperature. As it is usually not practical or possible to maintain innervation of fish myotomal muscle, a pair of stimulating electrodes is placed alongside the muscle to activate the muscle directly.

The length of the muscle is oscillated by the servomotor with a trajectory that (usually) mimics that in a swimming fish. This strain trajectory is normally sinusoidal, as has been found to be a good approximation of how muscles stretch/shorten in swimming fish. Strain patterns other than symmetrical sine waves have been employed, including saw-tooth and modified sine waves, but the results do not differ greatly. The rate of cycling of the muscle length (cycle frequency) is set either to match the tail-beat frequency of the fish of interest, or a range of frequencies that can be explored to investigate the effects of cycling frequency on work and power output. The amplitude of the length change (strain) is likewise set to match some estimate in swimming fish or varied according to the experimenter's needs.

The final piece of the puzzle is muscle activation – precisely when (phase) and for how long (duration or duty cycle) the muscle is activated during each cycle of length change. Electromyogram (EMG) analysis along with measures of muscle strain in swimming fish have been used extensively to measure the phase and duration of muscle activation (**see also Buoyancy, Locomotion, and Movement in Fishes:** Undulatory Swimming). If known, these can be applied in work-loop analysis to obtain measures of work production that mimic those from a swimming fish (with due acknowledgment that muscles in swimming fish are activated via a complex barrage of synaptic depolarizations dispersed among the muscle fibers, not synchronously and maximally by a pulse of current from electrodes alongside the muscle). If such measures of EMG in swimming fish are not available, then the most common approach, and the one on

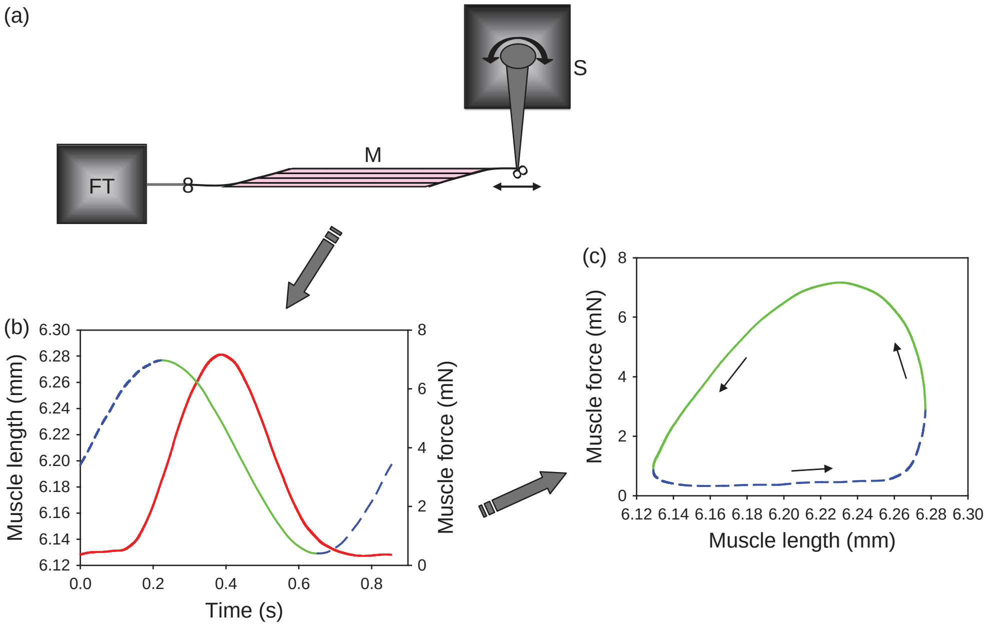

Figure 2 Work-loop experiments. (a) The loose myosepta of the muscle preparation (M) are typically tied to the arm of a servomotor (S) and force transducer (FT). The servomotor is used to impose cycles of oscillatory strain (length change) on the muscle fibers, and the force produced by the muscle is recorded with the force transducer. (b) In this example, a strain cycle with a sinusoidal trajectory has been imposed on the muscle (broken blue line is muscle lengthening and solid green line is muscle shortening). The resting or average length of the muscle was 6.2 mm, and the peak-to-peak strain amplitude was 2.4%. The muscle was stimulated near the point where force rises rapidly (about 0.1s), resulting in a transient rise and fall in force (red line). In this example, the stimulus phase was set to 10% of the sine cycle, or 36°, such that the majority of force occurred during the shortening portion of the strain cycle. (c) A work loop, formed by plotting muscle force against muscle length. Shortening (solid green line) and lengthening (broken blue line) segments of the loop are indicated, with the loop being traversed in a counterclockwise direction such that force during shortening is greater than force while lengthening. Work required to lengthen the muscle (lengthening or negative work) is the area beneath the lengthening portion of the loop, and work done by the muscle while shortening (shortening or positive work) is the area beneath the shortening portion of the loop. The net work, which is the difference between shortening and lengthening work, is the area within the loop, and would be considered a positive value in this example because more shortening work was done than lengthening work (i.e., the loop is counterclockwise, not clockwise).

which the vast majority of the literature is based, is simply to alter the stimulus phase and duration until net work output from the muscle is maximized.

The muscle's length is so oscillated and it is so stimulated, while length and force production are measured (**Figure 2**). A work loop is a graphical representation of the force–length relationship of the muscle during a complete cycle of lengthening and shortening. The trajectory of such a plot forms a closed loop. Work, being the integral of force with respect to muscle length, is readily gleaned from a force–length plot as the area beneath the curve. For lengthening work, it is the area beneath the lengthening arm of the loop (usually the lower arm), while for shortening work, it is the area beneath the shortening arm. The net work then, which is the difference between the shortening and lengthening segments, is the area inside the closed work loop. For a loop that is traversed in a counterclockwise direction, the area beneath the upper arm (shortening) is greater than the area beneath the lower arm (lengthening). Thus, more work is done by the muscle while it shortens than is required to lengthen the muscle and the net work would be a positive number. For a loop that is traversed in a clockwise direction, where force during lengthening is greater than the force during shortening, the net value is negative; the muscle absorbs more work in being lengthened than it produces while shortening.

Power, the rate of doing work, is typically calculated as the product of the work done during a single cycle and cycle frequency. Be mindful that this yields power averaged across the entire cycle, which includes the period when the muscle is being lengthened such that energy is being absorbed rather than produced. Thus, power from work-loop analysis will be considerably lower than the instantaneous, maximal power that might be measured using other techniques; but in the end, power from work-loop analysis best reflects the power available to swim.

The loop is an extremely useful and informative visualization of how the muscle behaves when working. If the phase and duration are adjusted to maximize net work output, the loop will typically be traversed in a counterclockwise direction. If phase and duration are not adjusted accordingly, the loops will have a different trajectory; they may run clockwise and may even form complex figure-eight patterns where one loop of the pair will have a net positive value and the other net negative, with the overall net work depending on the balance. Once experience is gained in understanding and interpreting the loops, one will know at a glance from the shape of the loops what the muscle is doing in terms of work output, activation, and even function in the swimming fish. It is a remarkably informative (though not powerful) construct.

What We Have Learned Using Work-Loop Analysis

Some of the first questions asked by physiologists studying work output of fish muscle included (1) how do strain (analogous to tail-beat amplitude in swimming fish) and cycle frequency (analogous to tail-beat frequency in swimming fish) impact the ability of muscles to produce work and power, (2) how do the abilities of the slower, oxidative red muscles differ from the faster, glycolytic white muscles, (3) what are the effects of temperature on work output, and (4) what are the functional roles of myotomal muscles in swimming fish? We will briefly consider what we have learned about each using work-loop analysis.

Effects of Strain and Cycle Frequency on Work and Power

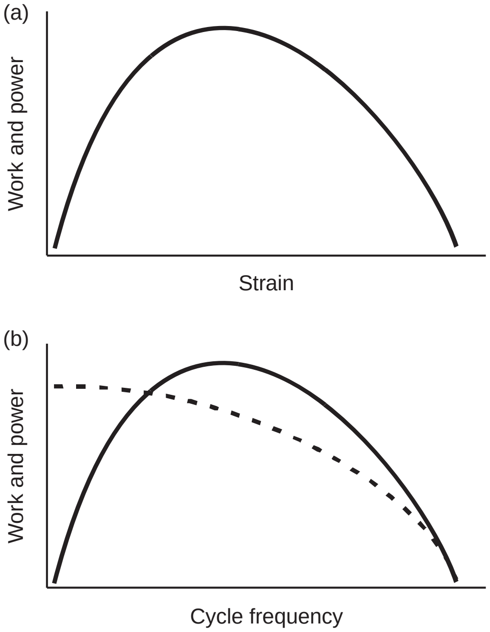

Figure 3 (a) Both net work and power show the same bell-shaped relationship with the amplitude of muscle strain. While the units of work and power differ, power is simply a scalar of work done per cycle. (b) Net work done per cycle (broken line) declines with increasing cycle frequency. Power, which is the product of work done per cycle and cycle frequency, shows a bell-shaped relationship with cycle frequency.

An increase in strain amplitude indicates that the muscle shortens and lengthens a greater distance. As work is the integral of force with respect to length change, we anticipate an increase in work with increased strain amplitude (**Figure 3**(**a**)). But this is true only up to a limit. All else remaining equal, the muscle must also move at a higher velocity (both peak and average) with increased strain amplitude. Force–velocity properties of muscle dictate that the faster a muscle shortens, the less force it is capable of producing. This limits the force and thus work done while shortening with increased strain amplitude, so that at relatively large strains, shortening and net work actually decline with further increases in strain amplitude. Changes in strain amplitude also influence the portion of the length–tension relationship over which the muscle operates, which may further impair force and thus work production at large strains. Other less-known impacts of stretch and shortening on force, activation, relaxation, etc., will also impact force and work done with changes in strain amplitude. The result is a bell-shaped relationship between net work done per cycle and strain amplitude, with work being maximized at some intermediate strain and falling as strain amplitude is either increased or reduced from this value. At zero strain (isometric contraction), work is zero, and at some large strain, net work would also be zero as the muscle shortens so fast that it can produce little to no force. In practice, muscles would likely be damaged before they reached strain amplitudes of this magnitude and in life would be restricted by the skeleton from experiencing such large extensions. The strain amplitude at which (net) work is maximized is in the neighborhood of 15% peak to peak (i.e., a 7.5% stretch above resting length and a 7.5% shortening below resting length). However, this value can vary considerably depending on the preparation, and factors such as temperature and cycle frequency. The relationship between power and strain amplitude is qualitatively identical to that for work, because power is simply a scalar of work (work per cycle × cycle frequency). Thus, there exists a tail-beat amplitude at which muscles would produce the most net work per cycle and power for swimming under a given regimen of temperature and tail-beat frequency. Do fish swim with these tail-beat amplitudes? Sometimes yes, and sometimes not. Should we expect them to? This is a fruitful area for further study.

It can be noticed that the word net is often sneaked in before the term work. This is to distinguish the relationship of net work with strain from those of shortening and lengthening work. In addition to force generated by cross bridges, work has components associated with elastic recoil and viscous resistance. Like stretching an elastic band and pulling on a fluid-filled plunger, lengthening work will rise monotonically with increasing strain in a relaxed muscle, and reach a maximum only as a result of damage at unphysiologically large strains. Shortening work will normally show a relationship with strain much like net work (bell-shaped), although not identical. The precise relationship between strain and net work is, of course, a function of the difference between the relationships between shortening and lengthening work with strain.

Cycle frequency, analogous to tail-beat frequency in a swimming fish, is the number of stretch/shorten cycles the muscle undergoes in a given period of time (usually per second, hertz). As the muscle shortens faster with increased cycle frequency, it will produce less force and thus tend to do less work during each cycle. Hence, at a given strain amplitude, shortening and net work per cycle decline with increasing cycle frequency (**Figure 3**(**b**), also see **Figure 5**). Net work per cycle is, in theory, maximal at a cycle frequency that approaches zero. In reality, such a slow tail-beat frequency would not be effective for swimming (as when moving a canoe paddle as slowly as possible through the water); so, the cycle frequency at which work is maximized is not particularly interesting to consider. Net work per cycle falls with increased cycle frequency, reaching zero near the frequency at which the muscle is moving so fast that it cannot produce force. Why is it near that frequency and not at it? Since we are talking about net work, the amount of work required to lengthen the muscle will also limit net work output. Force due to viscous resistance during lengthening increases with increasing cycle frequency. Further, at high cycle frequencies, the muscle typically does not relax fully between contractions, and so the muscle resists lengthening more and more as cycle frequency rises. Thus, it is not only the inability of the muscle to produce force while shortening at high cycle frequencies that limits net work output, but also the ever-rising work required to lengthen the muscle. A faster muscle, in terms of its ability to generate force and then relax, is able to cycle at higher frequencies while still producing positive net work. This can be seen later when we consider different types of muscle.

The relationship between power and cycle frequency is quite different from the relationship between work and cycle frequency (**Figure 3**(**b**)). Power is the product of work done per cycle and cycle frequency, the former which decreases and the latter which increases with increasing cycle frequency. The resulting power versus cycle frequency relationship is bell shaped, with power being zero at zero cycle frequency (even though work would theoretically be maximal), reaching a maximum at some intermediate frequency, and then falling at higher frequencies where the decrease in work per cycle exceeds the increase in cycle frequency. The power versus cycle frequency relationship has been used to predict the tail-beat frequency resulting in maximal power output for swimming, and would depend on the muscle, strain, temperature, etc.

Differences between Red and White Muscle

Simply put, red muscles tend to produce less power and operate at slower frequencies than white muscles. How much lesser? In the neighborhood of one quarter, but this can vary considerably. Why is this less? Not because red muscles lack the inherent ability to generate high forces, but because they cannot sustain high forces and hence high power at high shortening velocities, and they are not capable of rapid relaxation, which limits their ability to function at high cycle frequencies (**Figure 4**). As such, red muscles are typically used to power relatively slow, sustained, cruise swimming (**see also Buoyancy, Locomotion, and Movement in Fishes:** Undulatory Swimming). They possess characteristics that suit these activities, including a rich blood supply and high levels of myoglobin, relatively slow relaxation (slow rates of calcium uptake into the sarcoplasmic reticulum and slow rates of cross-bridge detachment), and they produce substantial amounts of force and power only when shortening at relatively slow velocities. Their power versus cycle frequency relationship thus has a peak in power at modest cycle frequencies (**Figure 4**), which tend to correspond with the tail-beat frequencies observed in a number of species of fishes swimming at their cruise speeds. Red muscles contribute little power if used at high tail-beat frequencies.

Conversely, the fast, white muscles have force–velocity characteristics that allow them to produce substantial amounts of force and hence power when shortening at relatively high speeds, and they relax rapidly (fast rates of calcium uptake into the sarcoplasmic reticulum, as well as high concentrations of calcium-binding proteins in the cytoplasm). Thus, their power versus cycle frequency relationship has a peak at high cycle frequencies (**Figure 4**), considerably faster than the tail-beat frequencies used by cruising fish. As fish tend not to swim steadily at high speeds, but rather burst and glide or only sprint for short periods, it is challenging to measure such behaviors in fish and to define clear relationships between muscle performance and swimming ability. Nonetheless, during high-speed movements, the white muscles shorten at velocities at which work-loop analysis clearly shows they can make substantial contributions to power.

Results from EMG studies convincingly show that red muscles are the only muscles recruited to power swimming at slower, cruise speeds. Available evidence suggests red muscles are either not used or make a limited contribution as swim speed increases toward burst and sprint speeds, or during escape maneuvers, and are then

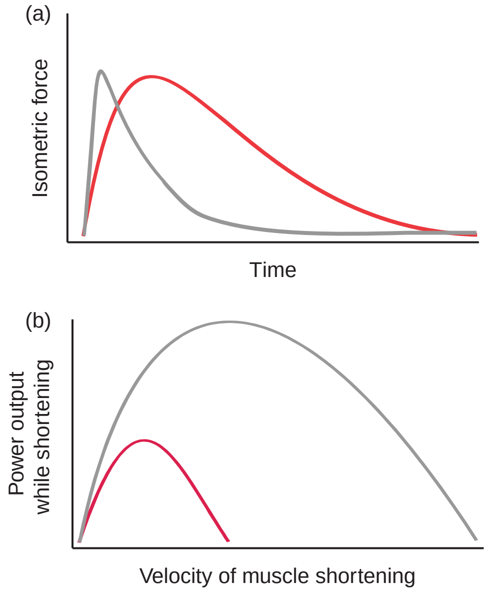

Figure 4 Other contractile properties of muscle can be used to estimate their ability to produce cyclic work and power. (a) Illustration of force produced during isometric twitches of red muscle (red trace) and white muscle (gray trace). The rates of force generation and relaxation are faster in white than red muscle. The shorter duration of the twitches in white muscle qualitatively predicts that the white muscle can endure faster rates of cycling during cyclic work activity than can red. (b) Illustration of the power output of fully activated muscle during steady shortening shows a bell-shaped relationship with the velocity of muscle shortening. This is the instantaneous power output of the muscle while shortening, and has both a higher maximum and faster velocity at that maximum for white muscle than red muscle. Such values of power can be used to predict qualitatively that white muscle will produce more power than red muscle during cyclic contractions, and sustain power output at higher cycle frequencies. However, the values of power obtained from such plots will differ considerably from those obtained during cyclic contractions (see text).

obviously supported by faster pink and white muscles. While EMG studies confirm which muscles are being recruited at different swim speeds, and while force–velocity, power–velocity, and twitch characteristics allow us to infer in a semiquantitative manner that red muscles should suffice to power slow movements while only white muscles would excel at powering fast movements, only measures of cyclic work using work-loop analysis have allowed us to confirm the real limits of their contributions to such movements. The as-yet poorly understood effects of stretch and shortening on the time course and extent of force production can only be fully accounted for on muscles that are activated and moving as they do in swimming fish.

If fast muscles can produce high power and continue to produce power at high cycle frequencies, why bother having the slow, red muscle at all? While there is likely more to answering this question than first meets the eye, measures of muscle work allow us to reason that differences in contractile properties and anatomical position of red and white muscle may result in white muscle moving so slowly at cruise swim speeds that they cannot produce enough power to sustain even slow swimming. Further, the slower red muscles are more efficient at producing work than the faster white muscles (i.e., red muscles tend to use less energy to perform a given amount of work than white muscles). For slow and sustained swimming, the economy of movement is likely an important consideration in recruiting a slower, less powerful muscle. Conversely, the faster, more powerful white muscles are recruited for rapid bursts and escape maneuvers, where performance is paramount and energy savings are not.

Effects of Temperature

In terms of the ability of fish muscles to produce work and power, cold muscles do not perform as well as warm muscles (**Figure 5**). With cooling, the rates of force generation and relaxation slow and the ability to sustain force production while shortening is reduced. These lead to less work done per cycle, reduced power output, and a slowing of the cycle frequencies at which power is maximal and at which the muscle can continue to produce work and power. The Q_{10} for these responses typically ranges from 2 to 3. For the fish, this means they must swim more slowly as temperature decreases and/or recruit more of their muscle or faster muscles to swim at a given speed in the cold. Yet, not all fish are equal in this regard, and the sensitivity to temperature depends heavily on whether the cold exposure is acute or long term. Fish that live in cold environments tend to possess muscles that are adapted to working in the cold. They produce more power and can function at higher cycle frequencies at a given, cool temperature than fish that live in warmer water and are acutely exposed to a cool temperature. This is true not only when comparing across species that inhabit arctic/temperate/tropical habitats, but likewise in fish acclimated to different temperatures. When exposed to cool temperatures, the muscles of a cold-acclimated fish can perform faster and with more power than the muscles of a warm-acclimated fish. There is thus a degree of compensation. However, the compensation is not complete. Cold-adapted or cold-acclimated muscles working in the cold still cannot produce as much power as warm muscles can.

So there might be an advantage in maintaining warm muscles when living in cold water, versus simply possessing cold adapted/acclimated muscles. A number of fish warm their muscles up, including tunas, the lamnid sharks, and some thresher sharks (**see also Design and Physiology of Arteries and Veins**: The Retia and **Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks). Work-loop studies suggest the warmer muscles

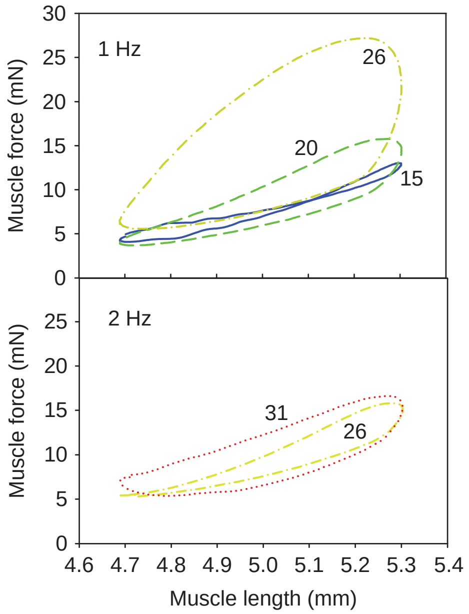

Figure 5 Work loops from salmon shark red muscle obtained at two different cycle frequencies (1 Hz upper panel and 2 Hz lower panel), and four different temperatures (15 °C solid blue, 20 °C broken green, 26 °C broken-dotted yellow, and 31 °C dotted red). Loops are traversed in a counterclockwise direction, except the 15 °C loop which has both clockwise and counterclockwise components. The area of the work loop (the net work done per cycle) increases with increasing temperature in salmon shark red muscle, which normally operates at warm temperatures. The net work done per cycle decreases with increasing cycle frequency (compare loops in upper and lower panels). Note that at 15 °C, the coolest temperature tested, the muscle is just capable of producing a small amount of net positive work at a 1-Hz cycle frequency, and that at the faster 2-Hz cycle frequency, only loops at 26 and 31 °C are shown because this warm-adapted muscle was not capable of producing net positive work at cooler temperatures. This highlights the temperature sensitivity of muscle contractile properties and the limitations imposed on the ability to produce work at different temperatures.

do very well if kept warm, but would do very poorly if these endothermic fish allowed their muscles to cool down, notably worse than cold-adapted muscles. We do not yet know much about these fishes, and research is underway to understand the costs and benefits of such strategies (**see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks).

Functions of Muscle during Swimming

How might we tell what a specific muscle is doing in a swimming fish? As noted earlier, for the most part, it is technically beyond our means to measure this directly. However, we can infer it with work-loop analysis. It is possible to measure the strain patterns of muscle in swimming fish, via either video analysis or sonomicrometry, and to measure electrical activity of muscles using EMG, which reflects muscle activity. Combining these two measures, we can quantify the strain amplitude and cycle frequency of the muscle and the phase and duration of muscle activation, all the ingredients required to perform work-loop analysis. The results of such experiments will approximate muscle performance in a swimming fish. This has now been accomplished in a number of species, and the results unearth a remarkable diversity in function and strategy (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming). Such studies confirm that slow muscles tend to be used to power slow, sustained swimming and that they cannot power sprint swimming, while fast muscles power fast, burst swimming, and likely supplement swimming in the cold. Providing even greater insight into muscle function, we can compare the work loops from muscles when used as they are in a swimming fish with results where work is maximized by optimizing parameters such as stimulus phase and duration in work-loop analysis. With this approach, we can begin to understand what the function of the muscles might be in contributing to movement (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming). We have learned that some fishes appear to use muscles in the anterior region to produce power, while the more posterior muscles act as active struts to transmit this energy toward the tail. Conversely, some fishes use the more posterior muscles to produce power, with anterior muscles showing work that is highly variable from tail-beat to tail-beat, perhaps belying a role in steering and stabilizing the fish. Some fishes, such as eels, seem to use muscles along the entire length of the body to produce power for swimming. These are only examples of fishes that bend their bodies to swim. We have barely begun to explore the functions of muscles in labriform (pectoral fin)-based swimmers (**see also Buoyancy, Locomotion, and Movement in Fishes**: Paired Fin Swimming).

An obvious hypothesis is that fish might be expected to use their muscles in a manner that allows them to produce maximal power for swimming. Work-loop analysis has allowed us to test this otherwise intractable hypothesis. In some instances, it seems to be supported, at least approximately, including slow swimming in carp, cruising in tunas, and, in some instances, in white muscle during fast starts. In cold-acclimated fish, there are changes in both the muscle and recruitment patterns that result in substantial improvements in power output over what would occur if such changes were not effected; a two- to ninefold increase has been reported in scup. However, a number of examples cast doubt on the notion of maximizing power output as a universal objective of muscle during swimming, including in red muscle during sustained swimming and in white muscle during fast swimming. Further, in acutely cooled fish, the recruitment patterns used by the fish (phase and duration of activation) do not change in the manner required to maximize power output and there is a marked reduction in power as a result. Indeed, in some instances, fish appear to recruit the faster pink muscle simply to sustain cruise swimming in the cold, not so much because the red muscles are incapable of producing enough power, but because they are not activated appropriately by the nervous system. Similarly, as noted above, even during swimming at normal temperatures, there are a number of reports suggesting the fish are not simply attempting to maximize power from their muscles. Other demands, such as stability, agility, and economy may well be dominant functions of muscle during cruise swimming. There remains much room for discovery.

Glossary

Angle of attack The angle made between the chord length of the fin and the direction of incident flow the fin encounters.

Aspect ratio The square of the fin span divided by the fin area.

Balistiform swimming Aquatic propulsion by means of undulatory movements of the dorsal and anal median fins.

Center of buoyancy The center of gravity of the volume of water which the animal's air-filled spaces or tissues of lower density than water displaces.

Center of mass The point in a body where the gravitational force may be taken to act.

Contralateral On the other or opposite side.

Labriform swimming Aquatic propulsion by means of beating the pectoral fins to produce lift and thrust.

How fishes use their fins for propulsion and maneuvering has become the focus of biomechanical study. Because up to 20% of living fishes rely on pectoral fin swimming as their primary mode of propulsion and all fish use these fins for stability and maneuverability, the majority of work has been done on paired pectoral fins. Only recently have the pelvic fins become the focus of study.

Diversity of Paired fins

Fish fins are folds of skin supported by skeletal elements controlled by fin musculature. Fins may be used for locomotion, reproduction, display, or protection. Generally, fish have two sets of paired fins and three median fins. The dorsal, anal, and caudal median fins are not paired and attach on the dorsal, ventral, and posterior aspects of the fish, respectively. Paired fins consist of the pectoral and pelvic fins, and attach to the fish's pectoral and pelvic girdles. The bony rays that support the fin membrane are made of either segmented (soft ray) or fused (spiny ray) bone.

Large variation exists in the size, shape, and location of paired fins among fishes. In extreme cases, some fish species have reduced or lost their paired fins entirely. A broad taxonomic review of the ray-finned fishes shows two trends in paired fin orientation and location:

1. pectoral fins in basal fishes lie ventral and with a near-horizontal attachment site, while in more derived fishes pectoral fins lie mid-dorsal with a vertical attachment site; and
2. pelvic fins in basal fishes are posterior of the fish's center of mass, while in more derived species they lie directly below or even in front of the center of mass (**Figure 1**).

The change in location and orientation of paired fins through fish evolution has changed fin function. Where fins are located relative to the fish's center of mass and center of buoyancy, the forces and torques each fin can produce will change (**Figure 2**).

Anatomy of Paired Fins

Generally, each set of paired fins is composed of a bony girdle that anchors the fin muscles within the fish's body and supports the fin. The external fin surface is made of a series of bony rays joined by a tissue membrane. For more information on musculo-skeletal anatomy and development, the reader is referred to **Brain and Nervous System**: Motor Control Systems of Fish, **The Skeleton**: Bony Fish Skeleton, and Cartilaginous Fish Skeletal Anatomy.

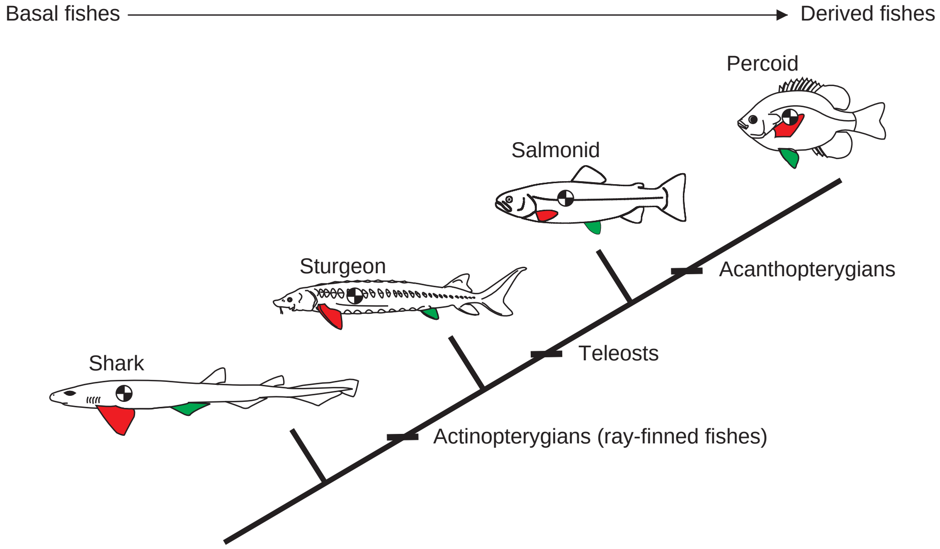

Figure 1 Paired fin position throughout fish evolution. A representative cladogram of selected fish groups. Black and white circles represent estimated location of fish centre of mass. From Standen EM (2008) Pelvic fin locomotor function in fishes: Three-dimensional kinematics in rainbow trout (*Oncorhynchus mykiss*). *Journal of Experimental Biology* 211: 2931–2942.

Each fin ray, called a lepidotrich, is composed of two halves called hemitrichia that are fused at their tip. Along their length, these two halves can slide relative to each other allowing the ray to bend. All bending of the rays is controlled by musculature attached to the hemitrichia on either side of the fin base (**Figure 3**).

Pectoral Fins

The pectoral girdle is homologous to the shoulder girdle and is composed of several bones (**Figure 4**). The fin skeleton consists of radials, located at the fin base and supporting the more distal fin rays. A cartilaginous pad at the end of the radials acts as a focal point for fin ray rotation. The first ray is generally thicker and shorter than the rest and joins with the scapula of the girdle. The rest of the rays are embedded into the cartilage and generally tend to be longer antero-dorsally and shorter ventrally.

The generalized teleost muscle morphology consists of pairs of muscles on either side of the pectoral girdle (**Figure 4**). Large arrectors, dorsal and ventral, attach to the marginal fin ray. Adductors, superficial and deep, attach to the rest of the fin rays in a sheet. Abductors, superficial and deep, lie to the lateral or ventro-lateral side of the pectoral girdle (see **Table 1** for detailed muscle origin and insertion points).

Pelvic Fins

The pelvic girdle is homologous to the pelvis and is composed of two plates that are thickened and fused together by a cartilaginous joint at their anterior most end (**Figure 5**). The thickening of the anterior plate provides a joint surface around which the fin ray bases can rotate. The lateral-most ray is often shorter than those adjacent to it and the base of the dorsal most hemitrich may be anchored into the body and skin of the fish.

The generalized teleost pelvic fin has six muscles associated with it, three on each side (**Figure 5**). Arrectors, dorsal and ventral, are not always present in more basal fishes. Adductors, superficial and deep, attach to the dorsal hemitrichia of each ray. Abductors, superficial and deep, attach to the ventral hemitrichia of each ray (see **Table 1** for detailed muscle origin and insertion points).

Fin Motion

Pectoral Fins

The diversity in pectoral fin morphology has led to diversity in how different fish use their fins for swimming. Fish can use their pectoral fins as nonoscillating passive control surfaces where fins are held stiff against oncoming flow. Pectoral fins may also be undulated or oscillated to actively produce forces. When a fin undulates a wave is passed from fin base to fin tip and usually there are multiple waves on the fin surface. When a fin oscillates waves are passed from fin base to fin tip but there is only one wave on the fin surface at a time; in this way, the fin appears to act as a solid plate. Oscillated fins can work like paddles producing drag-based propulsion, or they can work like flapping wings producing lift-based propulsion.

Passive control surfaces

Nonoscillating fins are found in sturgeons *(Acipenseridae)* and sharks *(Elasmobranchii)*. These fins have limited

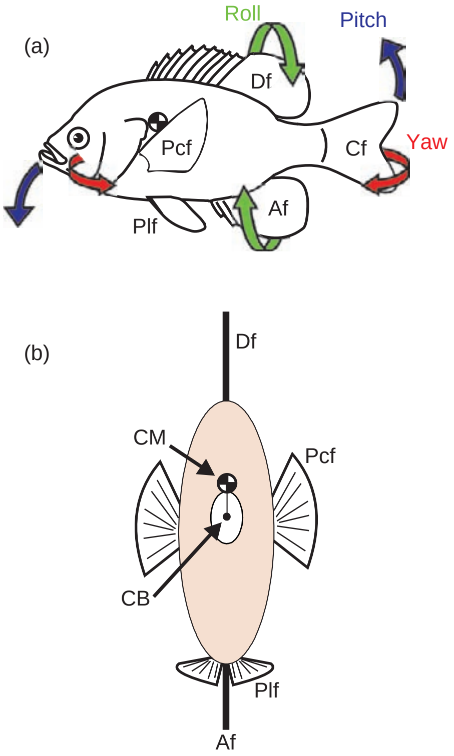

Figure 2 (a) Fins and axes of instability in bluegill sunfish *(Lepomis macrochirus)*. Paired fins in bluegill are represented by the pectoral (Pcf) and pelvic fins (Plf). Dorsal (Df), anal (Af), and caudal (Cf) fins are median fins. Fins work to control the forces that act on the fish in three major axes: pitch (head up and down movement), roll (body rotating along its longitudinal axis) and yaw (head side to side movement). (b) Schematic cross section showing center of mass (CM), center of buoyancy (CB) and fin placement. The white oval in the center of the fish represents the swimbladder cavity of the animal. The area of the fin surface as well as its location relative to the fish's center of mass and center of buoyancy will determine the amount of torque a fin can impose on the body at a given velocity. Modified from Standen EM and Lauder GV (2005) Dorsal and anal fin function in bluegill sunfish *Lepomis macrochirus*: Three-dimensional kinematics during propulsion and maneuvering. *Journal of Experimental Biology* 208: 2753–2763.

flexibility and they act as hydrofoils affecting lift and pitch during swimming.

Undulating fish fins

Animals that undulate their fins have three primary gait parameters that vary between species and swimming speed: undulatory wave frequency, wave speed, and length-standardized wavelength (essentially wavelength/chordlength). For example, as swimming speed increases in spotted stingrays (*Taeniura lymma*), the frequency and wave speed of undulatory waves on the pectoral fin increase, but their amplitude remains constant. Skates and rays *(Batoidea)* pass an undulatory wave rearward along their fin at twice the speed of their forward locomotion. The wings of skates closely approach the shape predicted by theoretical models to minimize cost of transport during swimming. Diversity among the batoid fishes (skates and rays) shows a continuum of locomotory motion of the pectoral fins from undulatory to oscillatory.

Fish such as the puffer fishes and burrfishes *(Tetraodontiformes)* also use undulatory pectoral fin motion to locomote. During fin abduction, an undulatory wave is passed from the anterior-most fin edge to the posterior edge. Left and right pectoral fins beat 180° out of phase in a contralateral oscillation so that when one fin is fully abducted the other is fully adducted. Puffer fish swim exclusively with their pectoral fins accompanied by dorsal and anal fin oscillation up to speeds of 3.0 BL s^{-1}, at which point they begin to beat their tails as well. Burrfishes appear to oscillate and undulate their fins and the undulation is hypothesized to function during maneuvers and slow-speed swimming rather than adding significantly to forward thrust production at higher-speed swimming.

Oscillating fish fins

Much work has been done to quantify and model forces produced by fin oscillations. Moving through three-dimensional space, there are three main planes in which a fin can be moved: the sagittal plane (paddling, where the fin attachment is ventral and the fin oscillates under the fish's body), the frontal plane (rowing, where the fin hinges more or less vertically and swings horizontally beside the body), or the transverse plane (flapping, where the fin is more or less horizontally hinged and swings vertically up and down beside the body; **Figure 6**).

Basal fishes, including some teleosts, demonstrate paddling fin motions. Rowing and flapping motions are seen throughout teleost evolution, and flapping appears to be derived from more basal paddling and rowing. Flapping is also seen in ratfish *(Chimaeriformes)* and batoids; the latter often combine flapping with undulation. Paddling and rowing fins have a distinct power and recovery portion to the stroke, whereas flapping fins are moved at angles that affect force production at all points in the stroke, eliminating the need for a distinct power and recovery portion of the stroke.

Gait transitions

Gait transitions occur when a fish changes its style of swimming to account for increasing or decreasing speed. In most acanthomorph fishes, slow-speed swimming is accomplished using pectoral fins only. As swimming speed increases, a transition speed is met where both pectoral fins and body caudal fin undulation contribute to thrust production. Finally, at the fastest speeds, the pectoral fins are tucked against the body to reduce drag and all thrust is produced by body caudal fin undulation.

Fin-beat frequency, fin-beat amplitude, and stroke plane can be measured during different speeds of swimming to quantify how fish change their fin motion to account for changing swimming speed. The swimming

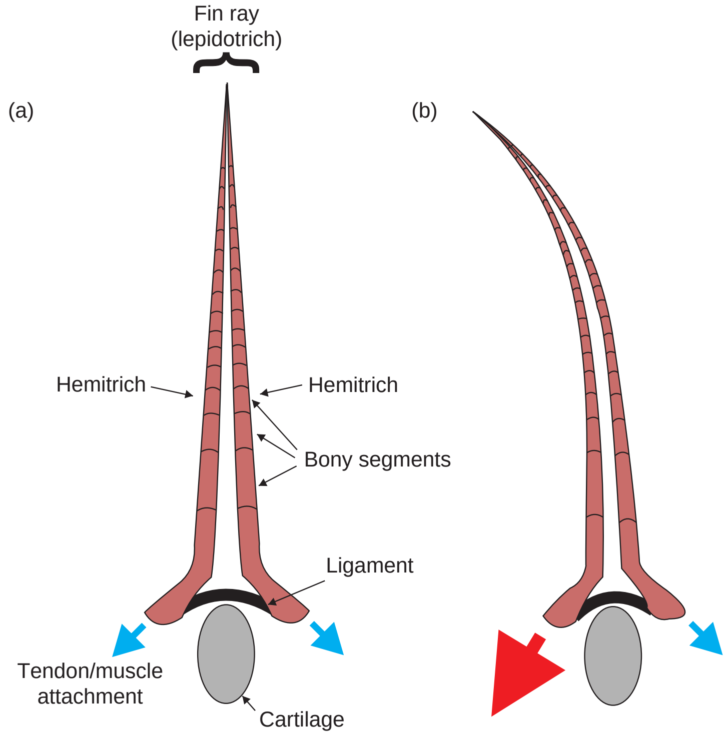

Figure 3 Fin ray structure. (a) Side view of one fin ray composed of two hemitrichia. Each hemitrich is made of bony segments. (b) Muscles attach to tendons at the base of each hemitrich and exert forces on each hemitrich, facilitating ray stiffening (symmetrical forces (a)) and bending (asymmetrical forces (b)). Modified from Figure 1d in Alben S, Madden P, and Lauder GV (2007) The mechanics of active fin-shape control in ray-finned fishes. *Journal of the Royal Society Interface* 4: 243–256.

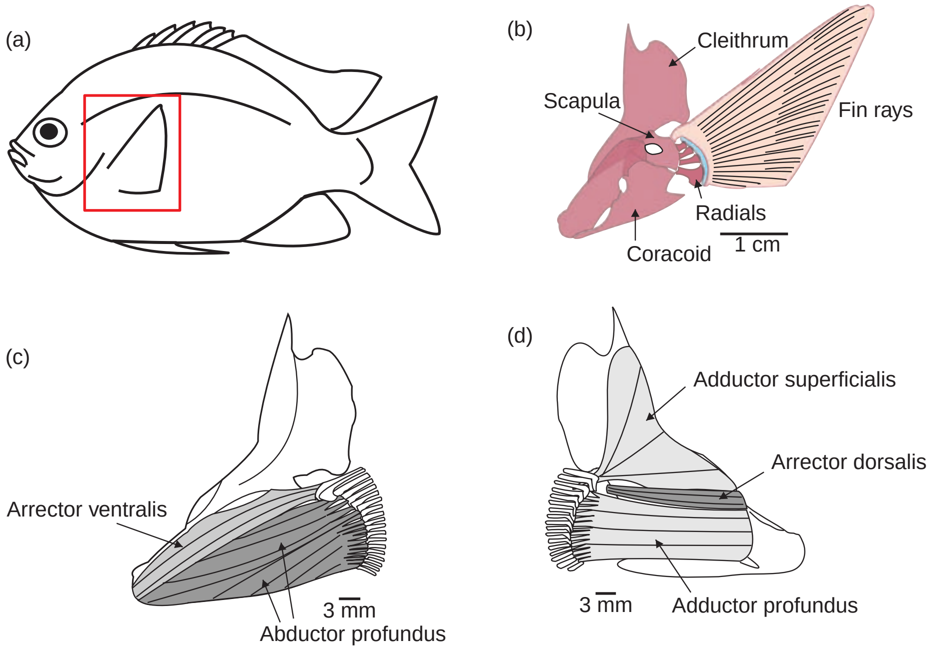

Figure 4 Pectoral fin anatomy. (a) The lateral view of labriform swimmer. (b) Skeletal anatomy of the pectoral girdle and fin. The cleithrum, coracoid, and scapula form the pectoral girdle supporting the radials. A cartilage pad (blue) rests at the distal end of the radials forming a surface for rotation for the fin rays. (c) Latero-medial view of the pectoral fin musculature. The abductor superficialis is removed from this image. (d) Medio-lateral view of the pectoral fin musculature showing the arrector dorsalis, adductor superficialis, and the adductor profundus. Modified from Figures 2a and 4a in Thorsen DH and Westneat MW (2005) Diversity of pectoral fin structure and function in fishes with labriform propulsion. *Journal of Morphology* 263: 133–150.

Table 1 Paired fin muscle location

Fin	*Muscle*	*Location*	*Origin*	*Insertion*
Pectoral	Abductor superficialis	Lateral or ventro-lateral of the pectoral girdle	Cleithrum (sometimes coracoid or even radials)	Diffuse or onto tendons attaching to anterior bases of fin rays
Pectoral	Abductor profundus	Lateral of the pectoral girdle but medial of superficialis	Lateral face of the coracoid (sometimes cleithrum and scapula)	Tendinous on the posterio-ventral flanges of fin rays
Pectoral	Arrector Ventralis	Well-developed lateral of most pectoral fin muscles	Anterolateral cleithrum (may include lateral faces of coracoid and scapula, inner face of cleithrum)	Tendinously on antero-medial base of medial half of marginal (first) fin ray
Pectoral	Adductor superficialis	Dorsomedial muscle mass located on the medial face of the pectoral girdle	Dorsomedial face of cleithrum (sometimes scapula, coracoid, or meso coracoid	By way of tendons attaching to the antero-dorsomedial faces of the fin rays distal to their bases and does not attach to the first fin ray
Pectoral	Adductor Profundus	Sometimes not entirely separate from superficialis lies medial of the pectoral girdle but lateral to the superficialis	Coracoid and postero-ventral portion of the cleithrum (sometimes scapula, radial, and mesocoracoid)	Tendinous on the postero-ventral flanges at the bases of all but the first fin ray
Pectoral	Arrector dorsalis	Dorsomedial of the pectoral fin musculature	Postero-ventromedial face of the cleithrum and adjoining coracoid (also scapula)	Tendinous on the base of the medial half of the first fin ray
Pectoral	Other muscles that may be present in the pectoral fin of fishes are the coracoradialis, adductor medialis, adductor radialis, and the interradialis pectoralis			
Pelvic	Abductor superficialis	Lies ventrally and medially	The ventral region of the pelvis or median septum between pelvic basals	Anterior (medial) rays but may serve all
Pelvic	Abductor profundus		Ventral face of the pelvis and the medial septum	Broadly on the bases of the soft fin rays
Pelvic	Arrector ventralis pelvicus		Ventrolateral face of the pelvis	Ventrolateral face of the pelvic spine or first pelvic ray, can be absent or not separate from other ventral pelvic musculature
Pelvic	Adductor superficialis pelvicus	Lies on the dorsal surface of the pelvis immediately above the profundus	Lateral surface of a median dorsal ridge on the pelvis or a midline fascia or the infracarinalis tendon	Fin rays distal of their bases
Pelvic	Adductor profundus pelvicus	Lies immediately above the pelvis	Dorsal side of pelvis	Anterolateral bases of fin rays
Pelvic	Arrector dorsalis pelvicus		Dorsolateral face of the pelvis	Dorsolateral surface of medial half of the first fin ray or pelvic spine when present
Pelvic	Extensor proprius	Dorsal most muscle of the pelvic musculature, lies above the adductor superficialis	Anterolateral surface of the dorsal part of the pelvis	Posteromedially to variable number of inner pelvic fin rays, when present.
Pelvic	Other muscles present in some teleosts are radialis ventralis, abductor accessorius, and arrector tertius			

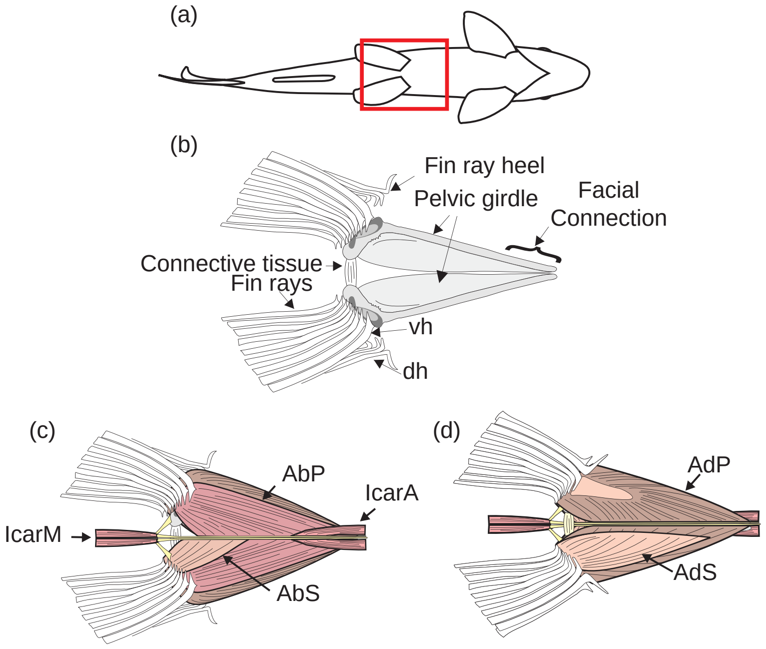

Figure 5 Pelvic fin anatomy. (a) Ventral view of trout. (b) The bony structure of the pelvic girdle. Ventral hemitrichia (vh) and dorsal hemitrichia (dh) make up the lepidotrichia of the fin rays. (c) Infracarinalis (Icar) muscles run midline along the ventral surface of the body attaching to the pelvic girdle and the infracarinalis anterior (IcarA). The abductor superficialis (AbS) and abductor profundus (AbP) muscles originate along the midline fascia and tendon of the Icar muscles and the pelvic girdle. The AbP attaches to the heel of the processes of all vh and the AbS attaches to the tips of the processes. (d) The adductor profundus (AdP) originates across the dorsal side of the pelvic girdle and along the midline fascia. This muscle is thicker on its medial and lateral edges. The adductor superficialis (AdS) lies in the cavity of the adductor profundus made by the thinning of the profundus muscle. The AbS originates on the pelvic girdle through the AdP muscle. Both adductor muscles insert on the processes of the dh. Modified from Standen EM (2010) Muscle activity and hydrodynamic function of pelvic fins in trout *(Oncorhynchus mykiss)*. *Journal of Experimental Biology* 213: 831–841.

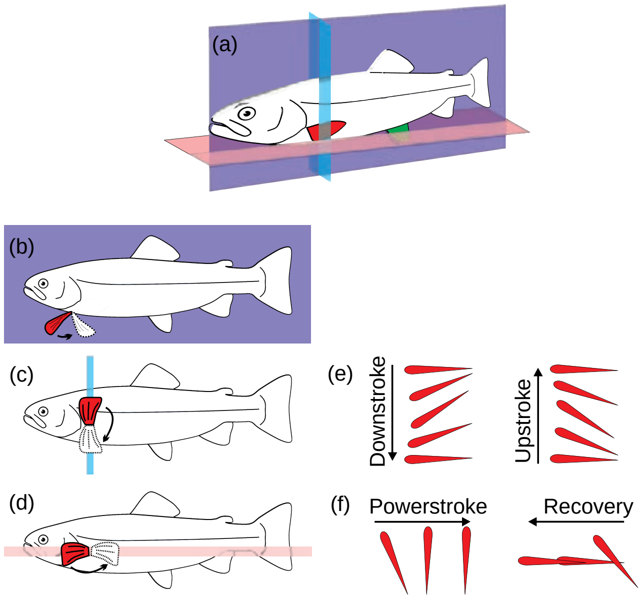

Figure 6 (a) Fish fin motion in three planes. Purple represents the fish's sagittal plane; (b) motion in this plane is considered paddling where the fin pivots under the body of the fish. Cyan represents the fish's transverse plane; (c) motion in this plane is considered flapping where the fin moves up and down at the side of the fish. Pink represents the fish's frontal plane; (d) motion in this plan is considered rowing where the fin moves back and forth at the side of the fish. (e) Subtle angle changes in the fin surface are present during flapping so that lift is created on both up- and downstrokes. (f) Rowing fins have a distinct power stroke where the fin is held perpendicular to the flow to maximize thrust and then feathered during recovery to minimize drag. Modified from Standen EM (2008) Pelvic fin locomotor function in fishes: Three-dimensional kinematics in rainbow trout (*Oncorhynchus mykiss*). *Journal of Experimental Biology* 211: 2931–2942.

speed at which an animal transitions from pectoral fin swimming to body caudal fin swimming is called $U_{\text{p-crit}}$ and can be used to compare swimming speeds among species of animals that have clear gait transitions. $U_{\text{p-crit}}$ varies among fish species and increases with body size.

Fin-beat frequency increases exponentially as speeds increase, peaking at gait transition. Some fish, such as the surfperch (*Embiotoca lateralis*), have a gait with a break between fin beats; fins produce thrust and then the fish glides for a portion of the stroke. In many fish studied, fin amplitude increases slowly at slow and intermediate speeds and plateaus at high speeds.

The stroke plane is the plane in which a fin moves during oscillation. Different species of fish tend to swim with different stroke-plane angles. A steep downstroke for thrust production has a large vertical force component. Shifts in stroke angle from negative angles of attack produce a downward backward force, while shifts toward a positive angle of attack create an upward forward force. Swimmers that combine flapping and rowing can decrease or increase the steepness of their stroke plane as swimming speed increases. Research on extreme flappers (*Gomphosus varius*) and extreme rowers (*Gasterosteus aculeatus*) has shown that stroke angle does not change with speed.

Switching gaits is useful to fish. It allows them to swim at different speeds by utilizing different types of muscle fibers, which makes swimming speed faster but not necessarily more efficient (reducing the amount of energy the fish uses to swim). Different fish species have different combinations of muscle fiber types in their pectoral fins: red fibers that are slow oxidative fibers, pink intermediate fibers, and white fast glycolitic fibers. Generally, slow oxidative fibers operate aerobically using less energy and can be used for endurance swimming. Fast-glycolitic fibers operate anaerobically, use a great deal of energy and give large amounts of power for very short bursts of speed; however, they quickly run out of energy and require rest periods.

Muscle fiber types in fish fins have not been extensively studied, but it appears that fish that swim with primarily a pectoral fin gait have pectoral fins made up of mostly red slow oxidative muscle fibers. In contrast to species of fish that swim aerobically using a body caudal fin gait, some labriform swimmers have only fast-glycolitic body musculature. Thus, when they change from a pectoral fin gait to a body caudal fin gait, they are also switching to swimming anaerobically and therefore cannot sustain this gait for a long time.

So, if one is a labriform swimmer and uses less energy to swim with aerobic muscle fibers only, why switch to body caudal fin swimming? Aerobic muscles (pectoral fin or otherwise) have a limit to the speed that they can lessen with peak mechanical output. This means that at a certain contraction speed the muscles do not provide enough force and the body muscle (usually in the form of white glycolitic fibers) needs to be recruited to swim faster. Work on parrot fish (*Scarus schlegeli*) shows that using body musculature gives them the power they need but it is more costly than if they could use their pectoral fins. A similar pattern is seen in bluegill sunfish (*Lepomis macrochirus*), where the maximum power output of the pectoral fin muscles occurs at the gait transition from pectoral fin swimming to body caudal fin swimming. Cost of transport, measured using respirometry, increases when bluegill switch from pectoral fin swimming to body caudal fin swimming. This suggests that using body caudal fin swimming is not more efficient but is simply required to reach maximum speeds.

Pectoral fins can also be used to aid in terrestrial locomotion of fishes. Tropical catfishes (e.g., *Clarias batrachus*) can use their pectoral fins to walk on land, a feat refined in the running behavior of mudskippers (*Gobiidae, Oxudercinae*) over mangrove flats during low tide.

Pelvic Fins

Pelvic fins, although little studied, are of great interest as they are one of the most morphologically plastic structures within the fishes. The function of the pelvic fins is as variable as their morphology between fish. They are used in swimming as an aerofoil, brake, propulsor, and rudder, for ground walking, and for hovering. At the same time, pelvic fins can be spined and used for protection, contain gases, and be used for floatation, sensory perception, camouflage, a holdfast organ, and for reproduction.

Although early studies that amputated pelvic fins and recorded no change in swimming ability concluded that pelvic fins had limited or no locomotory function, recent work has suggested otherwise. Slow-speed swimming experiments have shown that trout actively oscillate their fins in a contralateral pattern. This oscillation alters the flow conditions along the ventral aspect of the fish, possibly acting to stabilize the fish and influence the hydrodynamic function of downstream fins. Pelvic fins are also active during yawing maneuvers in trout species.

Like pectoral fins, pelvic fins are often tucked against the body during moderate- and high-speed steady swimming to reduce drag, possibly leading to their earlier reputation of having little to no locomotory function.

In some highly derived species, pelvic fins have developed into locomotory structures for punting along the ocean floor (skates and rays), walking on the substrate (epaulette sharks (*Hemiscyllium ocellatum*) frog and toad fishes (*Lophiiformes, Antennariidae*)), and slow-speed hovering oscillations (coelacanth), to name a few.

Maneuvering

Pectoral and pelvic fins are used by both cartilaginous and bony fishes for all types of maneuvers: yawing, pitching, acceleration, braking, backward swimming, and hovering. The versatility of paired fins becomes evident in the diversity and complexity of motion that these fins may undergo. Most of our understanding is of pectoral fins; however, recent work has given us new insight into pelvic fin motion as well.

Yawing

There are different turning strategies among fishes. Some fish (balistiform swimmers) suspend pectoral fin motion on the inside of the turn while continuing to steadily swim with the opposite side pectoral fin. Axial undulating fishes such as tetraodontiformes suspend the pectoral fin motion on the outside of the turn and hold the inside pectoral fin abducted for a pivot. Labriform, coelacanthiform, and ostraciiform swimmers move both pectoral fins, but in a distinct way compared with steady swimming. Rainbow trout (*Oncorhynchus mykiss*) initiate a turn by a series of rapid pectoral fin abductions and elevations on the inside of the turn followed by a similar but slower motion of the opposite fin to help complete the turn. Their pelvic fins also help control body position during yawing; the inside fin abducting and acting as an initial pivot to help turn the body with a later outside fin abduction to help realign the body with the flow.

Hovering

Fish have to balance forces during hovering; they must produce lift to stay elevated in the water column and balance fore and aft forces. During hovering, rainbow trout use an out-of-phase sculling pattern of both pectoral and pelvic fins to keep their body stationary. Both sets of paired fins contralaterally oscillate by adducting fins on one side and then the other. In addition, fish time the oscillation of fin pairs such that when the left pectoral fin is adducted, the right pelvic is adducting and vice versa. This somewhat synchronous motion appears to balance forces produced on either side of the body contributing to stability. Similarly, bass (*Centrarchidae*) and other acanthomorph fishes counter-oscillate pectoral fins for hovering. Balistiform swimmers use a dorso-ventral propagation of waves along the pectoral fins and this balances lift force and aft forces during hovering.

Braking

During braking, rainbow trout and more derived teleosts upturn the posterior edge of both pectoral fins simultaneously. This simultaneous motion maximizes drag and slows the forward progress of the animal without inducing a yawing moment; pitching moments tend to be counteracted by flaring of the pelvic fins. Although both pectoral fins abduct at the same time shorter fish tend to make symmetrical fin motions, while longer fish have asymmetrical fin motions. Both the rate of pectoral fin protraction and area of the fins have considerable impact on the braking performance of a fish. Fishes with partially ablated pectoral fins simply protract their fins faster to obtain a comparable level of performance, highlighting the importance of both behavior and morphology of the fins.

Fin Control

The muscles that control the fins are very diverse between species and only a fraction of fish species have been thoroughly described. Generally, adductors and abductors are used to affect the upstroke and downstroke of pectoral fins, respectively. Adductors and abductors not only have similar function on the pelvic fins, but also act in combination to produce a flaring of the fin. Fin muscle mass is proportional to force generation ability, and the ratio of muscle mass between adductors and abductors varies between species and changes the way the fins are used to produce forces.

Muscle motor activity of adductors and abductors in pectoral fins suggests that these muscles act antagonistically and alternate their activity through the stroke cycle (**Figure 7**). Pelvic fin adductor and abductor muscles are active in slowly swimming trout driving a contralateral fin oscillation. Interestingly, contrary to the antagonistic muscle action of the pectoral fins, the adductors and abductors of the pelvic fins are active at the same time, affecting fin abduction and arrection during the cycle (**Figure 7**).

Hydrodynamics

Thrust can be generated in many ways during swimming. Viscous stresses, bound circulation, flow separation, fin–vortex interaction, acceleration–reaction forces, and jet-like squeezing forces, all can produce thrust forces. Visualizing flow helps quantify and define forces produced by fins (**see also Buoyancy, Locomotion, and Movement in Fishes**: Experimental Hydrodynamics, Maneuverability, Stability and Turbulence, and Undulatory Swimming).

Fins that are long from base to tip and narrow crosswise have a high aspect ratio and are effective at producing lift. Fins that are shorter from base to tip and wide crosswise have a lower aspect ratio and tend to be used for drag-based propulsion.

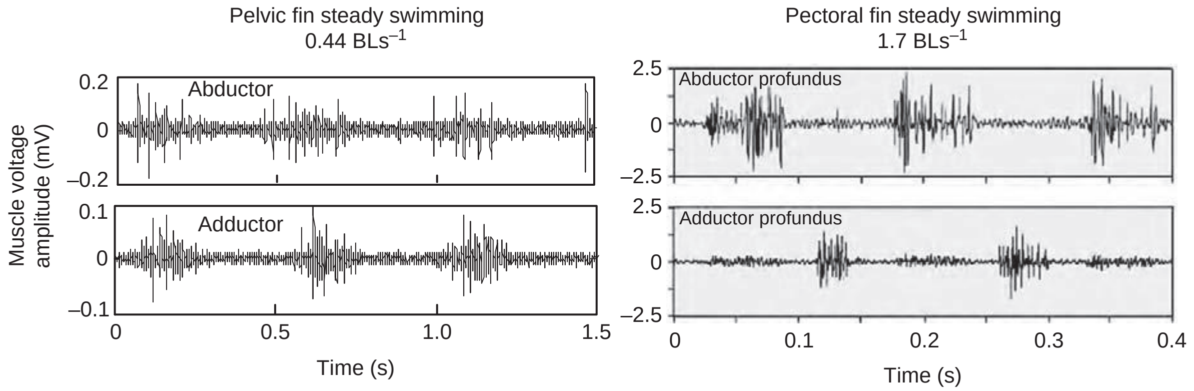

Figure 7 Paired fin muscle activity patterns. Pelvic fin abductors and adductors contract at the same time acting to abduct and arrect the fin during the oscillation cycle. This activation pattern suggests that adductor and abductor muscles work together to produce unique fin motion. In paired pectoral fins, the adductor and abductor operate one after the other, contributing to a clear adduction and abduction. Pelvic fin data from trout (*Oncorhynchus mykiss*) swimming at 0.44 BL s^{-1}, modified from Standen EM (2010) Muscle activity and hydrodynamic function of pelvic fins in trout (*Oncorhynchus mykiss*). *Journal of Experimental Biology* 213: 831–841; pectoral fin data from the bird wrasse (*Gomphosus varius*), adapted with permission from Westneat MW and Walker JA (1997) Motor patterns of labriform locomotion: Kinematic and electromyographic analysis of pectoral fin swimming in the labrid fish *Gomphosus varius*. *Journal of Experimental Biology* 200: 1881–1893 (www.jeb.biologists.org).

Sharks and sturgeons have relatively passive pectoral fins that produce vortical wake structures from their trailing edges. Sharks can change the angle of their pectoral fins relative to the oncoming flow, thus changing the fin's angle of attack and the resulting fin wake structures. Because the pectoral fins are located in front of the center of mass, lift and drag forces produced by the fins result in pitching moments. Positive angles of attack result in an upward pitch in the water column and negative angles result in a downward pitch. If opposite fins are held with opposite angles of attack, the shark induces a rolling instability, facilitating a turning moment.

Rowing fins move in the sagittal plane and have a distinct thrust phase where the fin is held perpendicular to the water and adducted against the water (this is a drag-based method of producing thrust). The thrust phase is followed by a recovery stroke where the fin is abducted back to the initial position. Flapping fins move in the transverse plane and, by angling the fin relative to the flow, use lift to produce thrust in both the up- and downstrokes. Although it is useful to categorize motion in terms of rowing and flapping, the fish world does not have exclusively rowers or flappers; fish use both lift and drag (a combination of flapping and rowing) to produce forces during swimming. The relative contributions of lift and drag can change between species and within species depending on swimming speed.

In bluegill sunfish, a labriform swimmer, paired pectoral fin downstroke produces a wake structure composed of a vortex ring with a central jet pointing both laterally and downstream (**Figure 8**). As swimming

Figure 8 Pectoral fin wake of bluegill sunfish (*Lepomis macrochirus*) reconstructed using quantitative flow visualization. (a) At low swimming speeds (e.g., 0.5 body length (L) per second), the pectoral fin wake consists of a single vortex ring produced per fin beat cycle. (b) At higher speeds, the wake is composed of one complete vortex ring generated on the downstroke of the pectoral fin and a linked vortex filament produced by the upstroke, which terminates on the flank of the fish to form a second, incomplete ring attached to the body. In these schematic reconstructions of wake morphology, curved red arrows represent centers of vorticity observed in perpendicular flow fields, and straight red arrows indicate the direction of jet flow through the center of each vortex ring. Locomotor forces (shown per fin) derived from wake momentum flux are resolved into thrust, lift, and laterally directed components. From figure 10.12 in Drucker E, Walker JA, and Westneat MW (2006) Mechanics of pectoral fin swimming in fishes. In: Shadwick RE and Lauder GV (eds.) *Fish Biomechanics*, vol. 23, pp. 369–424. London: Elsevier Academic Press.

speed increases, both downstroke and upstroke have associated jets (linked vortex rings). Wake size and vorticity strength increase with swimming speed in these labriform swimmers. These jets produce forces which counteract the drag associated with swimming at higher speeds. There are interspecies variations in wake structure as would be expected. Bluegills have a single vortex ring at 50% U_{pcrit} and as speed increases the jet orients more laterally. In contrast, *Embiotoca* sp. has two linked vortex rings and as speed increases they direct their jets downstream. To learn more about how modeling of hydrodynamics has helped design robotic fish fins, the reader is referred to **Buoyancy, Locomotion, and Movement in Fishes:** Biomimetics: Robotics Based on Fish Swimming.

Maneuvering Hydrodynamics

Fish have to balance three-dimensional hydrodynamic forces to control their body position. Depending on the location of the fish's center of mass relative to its center of buoyancy (**Figure 2**; **see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes and Swimbladder Function and Buoyancy Control in Fishes) different fish will experience different instabilities. Differences in the location of fins on a fish's body will determine how forces produced by those fins affect the fish's body.

Yawing

Lateral yawing turns are elicited by an asymmetrical production of forces around the fish's center of mass. Generally, greater thrust force is produced by the fin on the outside of the turn, while a braking force is produced by the fin on the inside of the turn. Depending on the species of fish, this combination of forces can pivot the animal in a very tight turn or a more gradual cruising turn. Studies have shown that fish with vertical pectoral fin placement produce greater lateral forces for turning than fish with ventrally located pectoral fins. For example, during slow turning, vertically oriented bluegill fins produce greater lateral yawing forces per unit of fin area compared with the horizontally oriented fins of rainbow trout.

Forces produced by fins during yawing are also greater than during steady swimming. The fin on the outside of the turn in yawing acanthomorph fishes produces 4 times greater lateral forces than during steady swimming and the inside fin generates posteriorly oriented vortex rings with a thrust force 9 times greater than steady swimming. This combination of forces pivots the fish and translates the fish toward the inside of the turn.

Hovering

Trout station hold by altering anterior–posterior directed wake flows. The forces cancel out over the cycle.

Braking

Both trout and bluegill produce anterior force during braking; the trout's line of action falls below the center of mass causing a downward pitching action, while the bluegill's braking line of action goes through the center of mass so there is little to no pitch destabilization.

Glossary

Agility The rate of maneuver.

Gait Combinations of swimming motions and muscle-usage characteristic of swimming at various speeds.

Gait transitions The change from one swimming gait to another over a narrow range of speeds.

Heave A vertical movement.

Maneuvers Intentional changes in body posture and/or swimming trajectory controlled by a fish.

Minimum turning radius The smallest radius at which a fish can turn during a maneuver.

Pitch Vertical, head up/down rotation.

Reynolds number The ratio of inertial to viscous forces in a flow.

Roll Rotation about the head-to-tail longitudinal axis.

Routine or volitional swimming Locomotor behavior during normal activity in the absence of imposed controlling conditions.

Slip A lateral movement.

Speed–maneuver limit A boundary at which the mechanical energy for locomotion in a gait reaches a maximum, at which changes in speed and maneuvering must be inversely related.

Stability The control of posture and/or trajectory.

State The description of a system, here a fish, at some instant in terms of its position and velocity.

Surge An anterior–posterior movement.

Translational maneuver A maneuver involving change in speed without change in direction.

Yaw Left/right lateral rotation.

Introduction

The survival, growth, and reproductive success of fishes all hinge on successful interactions with a myriad of internal and external stimuli (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy, Locomotion, and Movement in Fishes: An Introduction). Responses to such stimuli usually involve some locomotor component, expressed in a variety of motions generally recognized as maneuvers. Turning maneuvers are common, and obviously essential, in spite of being energetically expensive, increasing swimming costs by over an order of magnitude compared with those for rectilinear swimming at the same average speed.

Studying maneuvers has proved to be challenging. Among ≈30 000 species of fishes, there is a wide range of maneuvers, many of which can be executed with different combinations of body and fin motions while swimming over a wide range of speeds. Recording maneuvers under controlled conditions is problematic. Consequently, information is incomplete and ideas on factors affecting maneuverability are often speculative.

Definitions of Maneuvers and Agility

Maneuvers are volitional whole-body changes in state. State is defined in terms of velocity. Changes in state result from combinations of rotational, linear, and centripetal accelerations, leading to one or more changes in posture, speed, or direction. Maneuvers are the opposite of stability. The same principles apply to both, with the difference that maneuvers are induced displacements while stability requires the correction of involuntary displacements (**see also Buoyancy, Locomotion, and Movement in Fishes**: Stability and Turbulence).

Changes in state are resolved about the center of mass with components for three rotational axes and for three translational planes (**Figure 1**). Rotational changes are pitch (vertical, head up/down rotation), yaw (left/right lateral rotation), and roll (rotation about the head-to-tail longitudinal axis). Translational changes in state are heave (vertical displacement), slip (lateral displacement), and surge (anterior–posterior displacement). Rotation results in changes in body posture, which, when combined

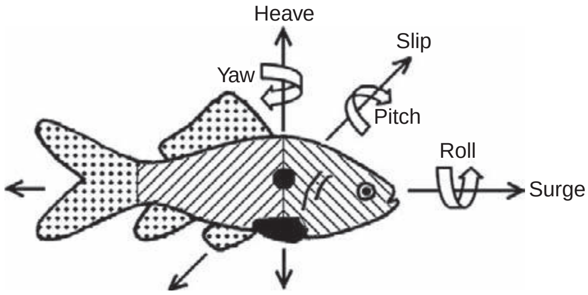

Figure 1 Maneuvers and stability control are mirror images of each other. Both maneuvers and displacements may occur along three translational axes (slip, heave, and surge) and three rotational axes (yaw, roll, and pitch), defined around the center of mass (filled circle). Control surfaces driving maneuvers and controlling stability involve the body (cross-hatched) with the anterior and head being destabilizing, and used for rapid steering turns. The pectoral fins (solid shading) anterior to the center of mass similarly can steer fast turns. The body and the median and paired fins (MPFs) (stippled) posterior to the center of mass can be used for steering and trimming. The body and fins may also beat to drive powered maneuvers and for powered stability control.

with translation, results in turns. Fish usually swim forward, but can also swim backward.

In addition to being changes of state, maneuvers are executed at various rates. Fishes that can execute maneuvers at higher rates are termed more agile. Rates of turning are usually described in terms of degrees per second, as described above for yawing rotations. Angular velocities are determined largely by swimming speed.

There is some debate as to the appropriate measure of size for comparing turning radii of maneuvers among fishes. The most common measure of size is a characteristic length – body length, depth, or width. Comparisons among fishes are usually made by normalizing performance with a fish total length. However, maneuvering performance is also expected to be affected by body shape. It has been suggested that body volume is a more useful measure of fish size, and volume is conveniently numerically equal to mass for neutrally buoyant fishes. Volume is considered limiting because it determines the amount of muscle that can be carried, space for digestive and other systems, and room to produce and store gametes. As such, volume$^{1/3}$ has also been used as a length scale. The ranking of maneuvering performance among species can be affected by the length scale used to normalize data.

Methodology

There are few common methods and no common protocols for measuring maneuverability. Maneuvers are usually analyzed from video or film records of routine swimming, especially during activities such as agonistic and predator–prey interactions that are expected to require high levels of maneuvering performance. Attempts to experimentally force fishes to maneuver in controlled and repeatable manners have proved to be challenging.

Maneuvering performance is quantified in various ways. Turning radius is calculated for turns, and performance is inversely proportional to turning radius. Agility is measured as rotation rates during hovering. During translocation, swimming speed is measured, which, with turning radius, determines angular velocities and centripetal acceleration. However, acceleration rates have not often been reported, except for fast-starts and braking. For these measures of maneuverability, performance is proportional to agility. The volume swept out by the body of a fish during a maneuver has also been considered as a measure of maneuvering performance.

Ideally, locomotor performance is evaluated at known physiological–mechanical limits occurring at gait transitions. Executing a maneuver diverts forces and energy from translocation, so that any maneuver at a gait transient is expected to reduce speed. Furthermore, the smaller the radius of a turn or the more agile the maneuver, the greater would be the reduction in the overall, net speed of swimming. Therefore, maneuvering performance should be expressed as functions of swimming speed for each gait for gait transitions; however, such a response surface is lacking for any maneuver.

Fishes may perform any maneuver up to the boundary set by the speed–maneuver limit. Many maneuvers are measured during routine swimming such as feeding and agonistic interactions presumed to require maximum performance, an assumption that is difficult to verify. Some studies hope to capture maximum performance by reporting results for the 20% highest-performance maneuvers during such activities.

Of all maneuvers, fast-starts or surging yawing turns have received most attention, and superficially would appear to be maximum, repeatable behaviors, whether induced during interactions such as predation situations or through artificial stimuli (**see also Buoyancy, Locomotion, and Movement in Fishes**: Fast Start). In practice, several methods have been used to induce fast-starts, and results for response variables, such as response duration, turning angle, turning radius, acceleration rate and speed, are affected by the method employed.

Effectors

Maneuvers are executed using the body and all the median and paired fins (MPFs) (**Figure 1**), with occasional contributions from respiratory water jets and hydrostatic forces. As with control systems for stability, the body and fins are dynamic effectors working in two ways. First, steering (trimming) effectors create maneuvering forces as a result of water flow over their surfaces during translation of the body to which the control surface is attached. Second, powered effectors generate flows with motions independent of body translation.

In steering, effectors anterior to the center of mass, notably the head and pectoral fins, can drive maneuvers at high rates (**Figure 1**). The forces acting on these surfaces increase rapidly with time, amplifying the maneuver. Control surfaces downstream from the center of mass – the posterior body, paired pelvic fins, dorsal, anal, and caudal fins – are not self-amplifying and hence tend to steer maneuvers, but with lower agility. The caudal fin is the most important of these steering surfaces being both large and most posterior to the center of mass.

For powered maneuvers, effectors are also propulsors, and all of them can power maneuvers with high agility. Powered maneuvers are executed by varying the stroke rate, the plane in which a propulsor beats, or by recruiting additional effectors. For example, a yawing turn can be executed by the caudal fin beating asymmetrically or by recruiting pectoral fin propulsors.

During swimming, steering and powered effectors often work together, especially at higher speeds. For example, extension of a pectoral fin may be used in a yawing turn while swimming with the caudal fin, or the caudal fin may help steer turns during swimming with the MPFs.

Types of Maneuvers

Many fishes rotate to change body posture while hovering using powered MPF effectors. Rotation while hovering always involves powered effectors. It is often associated with searching and vigilance maneuvers, for example, yawing and pitching to look for prey, especially when feeding on prey silhouetted against the water surface. Fish may roll to use refuges. Yawing rotation rates of 140–180° s^{-1} have been reported.

Powered effectors are also essential during slow swimming. The lower range of swimming speeds is powered by the MPF gaits (**see also Buoyancy, Locomotion, and Movement in Fishes**: Paired Fin Swimming). Powered maneuvers are common because steering forces are proportional to the square of swimming speed and hence cannot be large at low speeds. Minimum yawing turning radii approach zero at low speeds with a value of 0.05 L (where L is the total length of the fish), at 107° s^{-1} being reported for a spotted boxfish, *Ostracion meleagris*. For other teleosts, yawing turning radii of 0.3–0.7 L at 100–2000° s^{-1} have been reported at maximum MPF swimming speeds of 0.7–2 L s^{-1}. Stiff-bodied fishes, such as flatfishes (order Pleuronectiformes) and rays (superorder Batoidea) that maneuver using long-based dorsal–anal and pectoral fins, respectively, have lower yawing turning performance, with mean radii ≈1 L and rates of 30–44° s^{-1}. Mean radii of pitching turns have been recorded of 0.08–0.16 L for some reef fishes.

Fishes may swim at low speeds with a pitched body posture called tilting. Such tilting is postulated to reduce net swimming costs. At low speeds, locomotor muscle would work at low strain rates when efficiency is small (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops). Tilting increases drag allowing the muscle to work at high strain rates. The metabolic costs of overcoming the higher drag are offset by the savings in muscle efficiency.

Backward swimming is most commonly seen in bony fishes during MPF swimming with speeds reported from –0.4 to –3.9 L s^{-1}. Yawing turns while swimming backward have been described for angelfish, *Pterophyllum scalare*, with a radius of 0.7 L, very much larger than forward-swimming turns, and at a speed of 0.9 L s^{-1}, lower than typical routine forward-swimming speeds.

Higher swimming speeds are powered by body and caudal fin motions (BCF gaits) and it is likely that maneuvers combine powered forces and steering (**see also Buoyancy, Locomotion, and Movement in Fishes**: Stability and Turbulence). Faster turns are steered by the head and pectoral fins, while slower steered turns involve the posterior body and median fins. Body and fin effectors power smaller-radius maneuvers. Yawing turns are especially prominent during routine swimming reflecting the locations of median fins and body compression in the vertical plane. Yawing turns are usually made through large angles, sometimes even exceeding 360°. Pitching maneuvers involve depth changes and are usually steered with the pectoral fins typically through <20°. Rolls are least common among rotational maneuvers, probably because they reduce the effectiveness of camouflage and of sensory systems. Like pitching maneuvers, rolling maneuvers are usually of small magnitude, <20°. Rolls may be steered by asymmetrical deployment of the fins as fishes inspect refuges or prey and build nests, while more-rigid fishes bank in turns, combining yawing and rolling.

Most observations of turning maneuvers during BCF swimming are for the lower portion of the speed range powered by slow oxidative muscle. Reported radii in yawing turns range from 0.01 to 0.8 L (600–10 000° s^{-1}) for swimming speeds up to 6 L s^{-1}. Centripetal forces required for turning are high at higher speeds. However, BCF effectors develop large forces and torques because a large muscle mass powers large body and fin areas to generate the requisite forces and torques. Due to higher swimming speeds in BCF gaits, agility is higher than that in MPF swimming.

Elongate fishes swim backward during BCF swimming. Values reported for eels around $-0.8\,\mathrm{L\,s^{-1}}$ are comparable to routine forward speeds. Some fish swim backward by bending the caudal fin to beat while pointing forward, propelling a fish backward. Backward BCF swimming is much less efficient than forward BCF swimming.

Maneuvering usually conjures up images of turning, but translational maneuvers are major factors in behavior. The best-known translational maneuver is intermittent swimming, alternating a powered swimming phase with an unpowered phase (one of coasting, a decelerating surge at constant depth; gliding, a decelerating surge and heave by negatively buoyant fish sinking through the water column; and a jump through the air). The intermittent swimming pattern saves energy because the powered phase requires at least 3 times more power than that expended during the unpowered phase.

Surges also occur during braking. In routine swimming, braking is characteristic of saltatory search for food, a repeating sequence of swimming to an observation site, slowing to a stop, and hovering while visually searching for food. Fish can brake during active swimming by modulating propulsor beating rates and/or directions, or by reversing the direction of propulsive motions. Braking may also be unpowered, with drag being increased by extension of the fins. Unpowered braking rates have been reported from 0.1 to 1 × the acceleration of the Earth's gravity or -5 to $-155\,\mathrm{L\,s^{-2}}$.

Perhaps the best-studied maneuver is the fast-start, a large-amplitude tail beat with the body bending first to one side and then the other. Fast-starts are common in predator and prey interactions and in recovering from control-system failures, in rapid or turbulent flows, as well. Fast-starts are acceleration surges at rates from 1 to 15 × the acceleration of the Earth's gravity. They commonly include a yawing turn with average turning radii from 0.01 to 0.5 L (**see also Buoyancy, Locomotion, and Movement in Fishes**: Fast Start).

Rotational- and translational-state changes are often combined as fishes commonly change speed while turning. As noted, fast-starts are a combination of high rates of surge and a yawing turn. Agonistic interactions, courtship, and mating involve combined translational and rotational components in a variety of displays.

Fish Size

Size affects maneuverability. During ontogeny, fishes range in size from larvae, 2–3 mm in length, to adult tuna and sharks that can exceed 3 m in length. The mechanisms driving maneuvers depend on Reynolds number, *Re*, an estimate of the ratio of viscous forces to inertial forces (**see also Buoyancy, Locomotion, and Movement in Fishes**: Experimental Hydrodynamics). Numerically, $Re = \rho L u / \mu$, where ρ is the density of water, L is a characteristic length, u is the swimming speed, and μ is the viscosity. At small *Re*, for small fishes swimming at low speeds, viscous drag forces dominate. At high *Re*, inertial forces dominate, and drag and lift forces used for steering and powered maneuvering can be large. Hence, options for maneuvering are reduced for larvae working at small *Re* compared with larger juveniles and adults.

The fins of larvae work at very small *Re*, and hence are unable to generate significant maneuvering forces. Therefore, maneuvering by larvae depends on a flexible tail that can generate forces to maneuver in any direction. Consequently, the body forms of larvae are most similar among species. Body-fin plans diverge during metamorphosis to juvenile and adult body-fin plans as fishes and their fins and function at larger *Re*. Larvae also cannot use intermittent swimming until they grow large enough to coast, a maneuver that is only possible at large *Re*.

Radii of turns tend to be proportional to fish size. In terrestrial and aerial animals, this is an important factor in predator–prey chases, when the typically smaller prey can escape a larger predator by maneuvering inside the predator's turning circle. The principle is theoretically applicable to fishes. In practice, turning radii are so small that such tactics are rarely an option. The timing of escape maneuvers may be more important than the spatial component of maneuvers.

Agility is also affected by fish size. Absolute swimming speeds increase with size, as will maximum centripetal acceleration. Size-specific swimming speeds, in $\mathrm{L\ s^{-1}}$, decrease with size so that for their size, small fishes are more agile, an observation equally well known by humans trying to retrieve small children. For large fishes, low size-specific maneuverability and agility affect feeding patterns, with predation in the largest of aquatic organisms involving group behaviors and/or diet changes to nonevasive foods.

Braking also becomes more difficult with increasing size. Drag that causes deceleration is proportional area of the body and fins while inertia sustaining a motion is a volume force. As a result, the inertia of a fish increases more rapidly with size than the drag force so that braking rates should vary with $\mathrm{L^{-1}}$. However, braking rates range from 0.1 to 1 × acceleration of the Earth's gravity for the fish over a range of sizes because the mechanisms used to brake also vary with fish size. Small fishes brake using median-fin extension to increase friction drag, while larger fish extend the median fins normal to the flow to generate much larger pressure drag including bending the body, and even bending the tail so that the tip projects forward.

Body Form

The shapes of fishes are extremely diverse, but all must drive a wide range of maneuvers. The earliest fishes, as with fish larvae, lacked control surfaces other than the tail, and hence a flexible posterior body must have provided the ability to orient control forces in any direction. Modern fishes, such as eels, with reduced fins still maneuver in this manner.

Control surfaces evolved early in fish evolution for stability. However, even a small ability to vary angles of attack of these stiff control surfaces would have converted them into steering effectors. This condition is seen in many modern elasmobranchs, which are typically less maneuverable than typical bony fishes. Such modern elasmobranchs with stiff fins retain high caudal-peduncle flexibility so that the tail continues as a major trimming and powered effector for maneuvers.

A major change in maneuverability occurred with the evolution of rayed fins. The highly flexible fin structure of actinopterygian fishes provides versatile control surfaces that can generate a large diversity of forces for trimming and powered maneuvers. Compared to less-derived fishes, the flexibility and distribution of actinopterygian MPFs provide multiple effectors that increase the range of maneuvers, especially at low speeds, while minimizing turning radii and the volume swept out. Truncated bodies are common among ray-finned fishes that minimize rotational resistance.

The importance of body-fin form for maneuverability can be shown across large systematic and morphological differences, such as among actinopterygians versus less-derived fishes, and it reflects the form of body and fins used for propulsion. Among teleosts, the highly flexible body form of eels is superior in maneuvering in burrowing-type situations such as holes and among dense macrophytes. In contrast, pelagic thunnids with stiff bodies and small-area caudal fins have the largest-reported turning radii for BFC maneuvers, and they require two or more tail-beats to make turns that less-stiff fishes achieve in a single beat. Stiff-body fishes also sweep out a larger volume while turning compared with more flexible fishes.

It proves harder to show differences in maneuverability when morphological differences are smaller, even for apparently large systematic and morphological differences seen in major divisions of actinopterygian fishes. Less-derived soft-rayed malacopterygians tend to have fusiform bodies, antero-ventral pectoral fins, and postero-ventral pelvic fins. The more recently evolved spiny-rayed acanthopterygians, in contrast, tend to have deeper bodies, lateral pectoral fins, and antero-ventral pelvic fins.

It has been considered that the more-derived acanthopterygian body-fin plan facilitates maneuverability, but current measures of performance for soft- and spiny-rayed fishes with different body-fin plans are often very similar. Current research shows that the fins of less-derived soft-rayed fins are functionally versatile, and often drive maneuvers similar to those of spiny-rayed fishes.

Maneuvering is clearly vital for key activities such as foraging and reproduction. Perhaps maneuvering similarities for a wide range of body-fin forms shows only that there are many ways to execute critical behaviors. However, natural history observations show differences between soft- and spiny-rayed forms in the directions expected. Numerous observations find deep-bodied spiny-rayed fishes in structurally complex habitats where maneuverability would be at a premium. Ethograms show more diverse maneuvering repertoires for deep-bodied spiny-rayed fishes, especially longer periods of hovering, swimming backward, braking, and maneuvering to follow prey in chases. Soft-rayed fishes swim through prey positions, overshooting if prey escapes. Spiny-rayed fishes are more likely to extend the pectoral fins laterally, brake rapidly, turn, and reorient the attack. Indeed, the evolutionary advantages of ray-finned forms may relate to increased stability and maneuverability at low swimming speeds and in braking.

The weakness of laboratory demonstrations of differences in maneuverability for some large differences in body-fin forms, such as those associated with evolution in ray-finned fishes, eventually returns to the question of methodology: Are protocols and methods adequate to describe maneuvering and agility? Are they sufficient to test differences in performance among different species? Clearly, there is great potential for further study and novel approaches to explore a mechanical basis for maneuvering.

Glossary

Added mass A mass added to the inertia of an accelerating body because some volume of fluid is affected by that body.

Boundary layer A thin region of flow adjacent to any surface in which viscosity acts to create a velocity from that of the surface, where there is no slip between the water and the surface, to the velocity of the free stream.

Circulation Integral of vorticity over a given area.

Doppler effect The perceived change in frequency of a wave due to the motion of the sensor relative to the source of the wave.

Kármán gait The use of a Kármán vortex street to avoid active swimming.

Kármán vortex street A repeating pattern of alternating vortices shed by unsteady separation of flow over a bluff body.

Reynolds number The ratio of inertial to viscous forces in a flow.

Vortex strength The circulation calculated over a vortex tube, an area of constant vorticity.

Turbulence intensity The ratio of the standard deviation of turbulent flow variations relative to the mean velocity.

Vortex A mass of fluid in whirling or circular motion. Vortices always appear where hydrodynamic lift is being generated.

Vorticity A measure of angular velocity in a fluid or the local angular rate of rotation, that is, the tendency of a fluid to spin.

Introduction

Casual observation of aquatic habitats shows the ubiquity of turbulence, characterized by variations in flow velocity in space and time. Winds create surface waves, and currents flow over complex surfaces studded with projections that range from other animals and plants to inanimate rocks and boulders. Even apparently still waters regularly turn over.

Turbulence challenges stability of posture and of holding a desired trajectory during locomotion. Some stability challenges arise from a fish itself due to density differences among tissues and due to propulsion with periodic body and fin motions. However, external-flow perturbations associated with turbulence are larger and more likely to create problems for stability.

The study of fish interactions with turbulence is in its infancy. Most research has reported negative effects of turbulence on swimming speeds and increased metabolic costs. Other studies, however, show that fish can use some components in a turbulent flow as a booster, reducing energy costs and/or migration times. These impacts and opportunities from turbulence affect fish distribution and community structure.

Instabilities

Turbulence is characterized by variability in flow velocity. Any variation is a perturbation tending to create a displacement in postures and/or trajectory, and hence is a source of instability. Displacements are defined in a fish frame of reference in three translational directions and rotations about three axes (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability, **Figure 1**). Translations are slip (a lateral displacement), heave (a vertical displacement), and surge (a fore–aft displacement). Rotations are roll (rotation around the longitudinal axis), yaw, (rotation about the dorso-ventral axis), and pitch (rotation about the lateral axis).

Of the various displacements, fish appear to be especially sensitive to rolling instability. Control for rolling is continuously necessary for many fishes that are hydrostatically unstable in roll when the center of mass is above the center of buoyancy. Rolls are undesirable because they negate any dorso-ventral camouflage and could degrade sensory perception.

The Nature of Turbulent Flows

The natural world is a source of an essentially infinite range of types and magnitudes of stimuli. Organisms respond to a subset of stimuli having the largest impact on fitness. Only some perturbations in turbulent flow have potential to influence fish activities so that the fundamental questions for biologists are (1) what factors associated with turbulent velocity fluctuations affect fishes and (2) in what ways?

Turbulence may appear chaotic, because it is not possible to describe – or predict – velocity magnitude and direction at a given point. Nevertheless, predictable patterns occur within the flow in the form of eddies, or vortices. There are two major approaches to describing turbulence: a statistical approach describing velocity variation and a physical approach based on the properties of eddies (**Figure 1**).

Statistical descriptors of turbulence start with measures of velocity and its variation. Acoustic doppler velocimetry (ADV) is increasingly used in aquatic studies to measure instantaneous velocities in x, y, and z axes, from which mean velocity, $\bar{u}$, and its standard deviation, σ, are typically reported. These correlate with momentum and turbulent kinetic energy (TKE) associated with flow fluctuations, both of which contribute to displacement of fishes embedded in the flow. Stability problems increase, and control can fail, as momentum and TKE become large relative to the momentum and energy due to the motion of a fish.

Each of $\bar{u}$, σ, and TKE has been shown to correlate with reductions in one or more of posture, swimming speed, metabolic rate, habitat choice, and fish abundance. However, fish responses do not appear to be linear. Thus, salmonids tend to chose intermediate values of $\bar{u}$ or σ, while population abundance of salmonids is also higher at intermediate values of TKE.

Methods used to determine turbulence statistics usually measure velocity fluctuations in a small volume, essentially at a point. These measures are most useful in interpreting habitat locations for fishes, such as salmonids, that tend to hold station at a focal point. However, fish are exposed to spatial gradients when flow asymmetries will be experienced along various body dimensions. This would be expected to amplify destabilizing forces and torques. Using multiple measurements with flow probes, it has been found that spatial velocity and TKE gradients affect preferred locations for salmonids and salmonid density. Such spatially explicit data are essential in exploring how fish choose passages through turbulent flow fields.

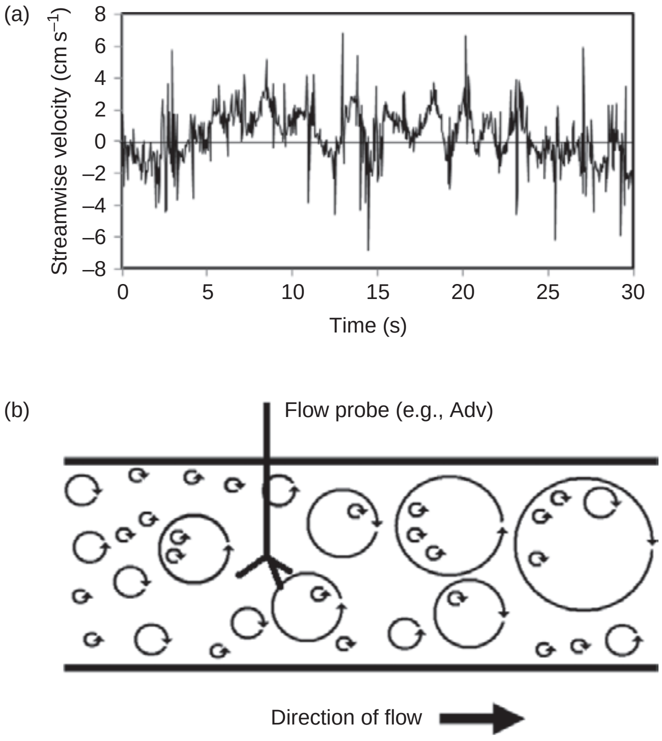

Figure 1 (a) Statistical and (b) physical representations of turbulent flow. (a) A record of streamwise (x-axis) velocity fluctuations measured at a point using a flow probe (ADV) in a trout stream. (b) A schematic of eddies of various sizes, rotations, and locations comprising the flow in a stream. A flow probe in the stream would record flow variations such as those in the upper panel.

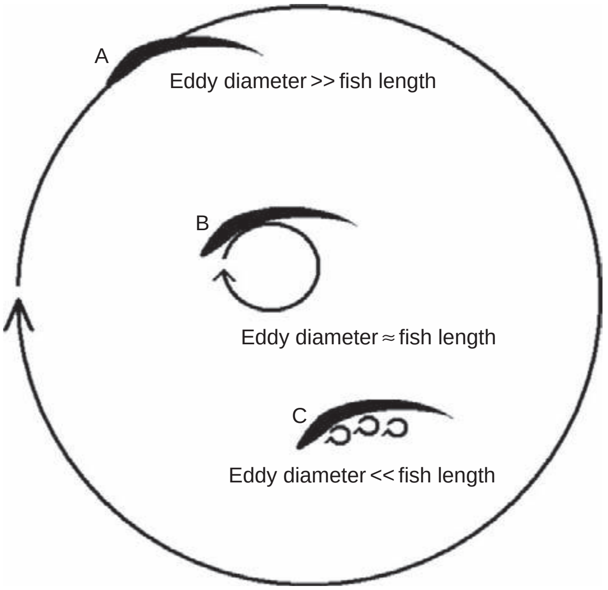
The physical approach to turbulence considers structures in turbulent flow. Many images of structures in turbulent flow are found on the Internet, for example, eFluids website (see section Relevant Websites) that includes a gallery of videos and images of turbulence. Methods to determine turbulent-flow structures, such as ultrasound or particle imaging velocimetry (PIV), start with spatially explicit data. For example, PIV determines flow from the positions of particles in the fluid at successive small time intervals. PIV is currently the method of choice in the laboratory, and has been deployed in ocean and atmospheric applications. Small reliable instruments for river and shoreline applications are in development.

The physical approach recognizes that turbulence originates in gradients that cause streamlines to bend. The resulting curvature, or curl, in velocity vectors is defined as vorticity, and the structure in turbulent flows arises as curls roll up to create eddies or vortices. The limits of a vortex – and hence the diameter – can be found where vorticity declines to approach that of the surrounding water. From vorticity, an aerial measure of turbulence is obtained, and circulation is computed as the integral of vorticity over an area of the flow. When circulation is calculated over a vortex tube, that is an area of constant vorticity, the integral represents the strength of that vortex tube.

Circulation is a good measure of the potential impact of an eddy on fishes as it relates to the momentum and energy carried by that eddy. Real flows include numerous eddies of many different sizes and vorticities, and hence an area of flow could have a zero mean circulation. To avoid this problem, it has been suggested that turbulence should be measured as the absolute value of circulation. This correlates with fish densities at stream-reach scales, but has not been explored at finer scales. In practice, understanding how eddies affect fishes requires consideration of the sign of the rotation of eddies. For example, the ability to swim in energy-saving Kármán gait, slaloming without swimming in the alternating eddies of the Kármán vortex street, depends on both the size and direction of rotation of eddies. Examples of fish using the Kármán gait can be seen at the websites mentioned in the section Relevant Websites.



A
Eddy diameter >> fish length
B
Eddy diameter ≈ fish length
C
Eddy diameter << fish length

Figure 2 Eddies range in diameter, λ, from (a) $\lambda << L$, where L is fish total length, (b) $\lambda \approx L$, and (c) $\lambda << L$. When $\lambda << L$, a fish will treat the flow the same as a rectilinear flow. When $\lambda << L$, the small eddies are ignored. Stability problems occur when $\lambda \approx L$.

The Importance of Scale

There are several advantages to the physical approach to turbulence; for example, results are spatially explicit, results can generate all the statistical measures for flow and the spatial distribution of these measures. However, the effect of turbulence on fishes (and other organisms) depends on the size of eddies relative to the size of the organism. Therefore, the most important advantage of describing the structures in turbulent flow is that length scales of eddy structures can be estimated for comparison with fish size.

Initial consideration of eddy/fish scale focused on length scales (**Figure 2**), in which the measure of relative size is the diameter of an eddy, λ, relative to the total length of a fish, L. Early estimates suggested that flow-regime choices and negative effects of turbulence on swimming performance began to occur when $\lambda/L \approx 0.66$, with λ based on mean eddy diameter. In experimental studies, negative effects for creek chub, *Semolitus atromaculatus*, occur when $0.5 < \lambda/L < 1$ and similar values are found for rainbow trout, *Oncorhynchus mykiss*, using the Kármán gait.

Length scales provide a framework from which to evaluate fish responses to a given physical perturbation, but parameters based on Newton's laws, considering momentum or circulation related to forces and torques, would be more useful. For a fish fully embedded in an eddy, ratios of fish to eddy momentum and energy approach unity when stability failure occurs.

Response Latency

In addition to the spatial variations in velocity in turbulent flows, velocities also vary with time, for example, as wind or boat-generated waves travel over a shoreline. There is an eddy-specific rotation period, t_{eddy}, depending strongly on eddy size, vorticity, and the flow Reynolds number. Thus, typical records of flow variations (**Figure 1**(**a**)) are a mix of velocities peaking at various times.

Fishes cannot respond instantly to a displacement caused by an eddy, but rather there is a response latency, T, between a displacement growing to a level requiring a response and the corrective motor response. Fishes can respond to strong threatening stimuli in as little as 10 ms via the Mauthner cells. Response latencies for simple flow-induced displacements of the body are of the order of 60 ms for rolls, and 100–200 ms for other disturbances. The complex velocity stimuli of turbulent flows are likely to be associated with the latter longer-response latencies.

Response latency probably contributes to postural or trajectory failure when $T \approx 0.5 t_{\text{eddy}}$. Then the intended correction is in phase with a disturbance, so that the correction amplifies the disturbance. This promotes stability failure, a phenomenon known in the aeronautical industry as 'pilot-induced error'; data on t_{eddy} for eddies that just cause stability failure are lacking.

Fish–Eddy Interactions

Consideration of length scales has been instrumental in reaching current ideas on fish–flow interactions in turbulence. In general, it is recognized that when $\lambda << L$, eddies are sufficiently small to have only negligible effects and are ignored by a fish. Indeed, this is an assumption in the design of many flumes that induce microturbulence to obtain a rectilinear flow profile. Furthermore, those experiments that expected but did not show negative effects of turbulence on fishes have attributed this to λ/L being too small to create stability problems.

At the other extreme, with $\lambda << L$, eddy diameters can span oceans, as seen in various oceanic gyres. Fish will perceive the water velocity of large eddies as any other current. The eddy flow is likely to be ignored other than as a barrier to be breasted or more likely as a stream to be ridden in migration.

It is eddies with λ of the order of L, which have rotational rates, dimensions, momentum, and energy of sufficient magnitude relative to size, momentum, and energy of a fish, that cause major displacements and stability failure. Knowing the relative size for such eddies is important for understanding behavior, habitat choice, for exploring migration strategies to reduce energy costs, or to minimize passage times, etc. Such understanding has immediate utility for many fishway designs.

However, all the current considerations of eddy–fish interactions resolve eddy and fish characteristics at the scale of the whole eddy and fish cross sections. In practice, the impact of an eddy is expected to depend on local effects, especially the edge of an eddy acting on the anterior of a fish. Although simultaneous observations of turbulent flow and fish swimming in that flow are currently lacking, fish will experience maximum angular velocities as they enter an eddy. The shape of the anterior fish body, increasing in depth and width from zero at the nose to maxima at about 0.33 L from the nose reduces the rate at which forces and torques grow as a fish enters an eddy compared to more bluff shapes.

The degree to which a fish might penetrate an eddy depends on the speed of the fish. At typical cruising speeds of around 1 L s^{-1}, >20% of the fish body would enter an eddy within typical response times. Thus, the shape of the fish body is such that displacements should be small within likely response times, an interaction favoring a fish being able to execute stabilizing responses, reducing the chance of stability failure. Unusual body forms, such as the head of hammerhead sharks, *Sphyrna* sp., would clearly be at a disadvantage in high levels of turbulence, but their pelagic habits probably lack potentially disruptive turbulence.

Sprinting fishes could penetrate further into eddies. Migratory fishes seeking to minimize passage time and traverse obstacles, such as waterfalls, rapids, fish ladders, and turbines, would be expected to penetrate eddies with large circulation within typical response-latency times. Two factors reduce this problem. First, the momentum and energy of a fast-swimming fish is high so that threshold circulation for control failure will be associated with larger – and less common – eddies. Second, swimming fish do not experience the absolute size of an eddy but rather an apparent size, which, like the Doppler effect, is affected by speed. Thus at a high velocity, perceived eddy dimensions are reduced compared with absolute values. Then, the absolute size of eddies that are likely to challenge control systems are increased at higher swimming speeds.

The axis of rotation of eddies affects fishes. Vertical eddies have less impact than horizontal eddies for fish with compressed bodies. Although forces and torques will be increased for a vertical eddy in direct proportion to body compression, damping and corrective forces and torques are increased much more. Similar interactions occur for depressed forms experiencing horizontal eddies.

Control Systems

Damping Instability

Fishes stabilize posture and trajectories in a variety of ways. Turbulent perturbations can occur rapidly (**Figure 1**) so that the first factor promoting stability is damping. Damping the potential growth of a disturbance depends on resistance forces, momentum, and energy of a fish. Resistance forces, drag and inertia, for the fish plus an added mass of water that is dragged along with any body trying to move in that water, are larger for larger body spans at right angles to the direction of a disturbance slowing the rate of growth of a displacement. For example, body compression and deploying median fins promote damping of yaw and slip disturbances. Deployment of paired fins (**see also Buoyancy, Locomotion, and Movement in**

Fishes: Paired Fin Swimming) similarly damps heave, pitch, and roll.

Increased swimming speed (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming and Fast Start) also leads to greater damping. Instabilities arise from the differences between the mean and instantaneous velocity, the velocity component that is the signature of turbulence, quantified by σ. However, the momentum and energy of a fish, moving against the flow or holding position in the flow, slow down the growth of displacements. The smaller the ratio of σ to $\bar{u}$, the easier it is to control stability; an approximate analogy that illustrates the point is the well-known experience that it is easier to control stability while riding a bicycle at high speed than when moving slowly. The ratio of $\sigma/\bar{u}$ is defined as the turbulence intensity, TI, and fishes have been shown to avoid habitats with high TI. In addition, observations on reefs and in freshwater shoreline communities show that more powerful swimmers moving at higher speeds occur in more-turbulent locations.

Correcting Displacements

Damping only slows the growth of displacements. The body and all the median and paired fins provide additional hydrodynamic control mechanisms, in which the flow over control surfaces generates correction forces (**see also Buoyancy, Locomotion, and Movement in Fishes**: Paired Fin Swimming). Body and appendage control surfaces can be functionally classified in two ways. First, trimming forces are created when the flow over an effector control surface results from translocation of the body. A fish can, of course, modify angles of attack to modulate these forces. Second, many control surfaces also act as propulsors, and hence can actively generate forces that can be harnessed for stability control. These can be described as powered effectors creating correction forces by their own motions. In practice, many effectors combine trimming and powered control, and powered forces are generally most important for stability.

The stabilizing functions of control surfaces depend on their location relative to the center of mass (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability, Figure 1). The head, embellishments such as the extensions of hammerhead sharks, and pectoral fins all anterior to the center of mass are generally destabilizing. A displacement increasing the angle of these surfaces to the flow amplifies the destabilizing forces acting on the surface, thereby tending to increase the initial displacement.

Failure of stability control appears to start with such positive feedback (**Figure 3**). As a fish approaches the control limits of its stabilizing systems, the fish tends to begin to slip and heave, and, to some extent, surge. Rotational displacements may increase to a small extent, but are largely actively minimized. Failure invariably starts with a yaw or pitch of the head, and as the head is anterior to the center of mass, the displacement continues to grow. Within 100 ms, the head, normally in line with the flow, can be bent so that it is normal to the flow!

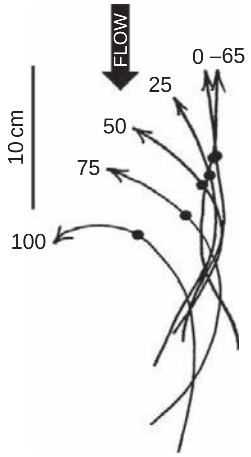


Figure 3 Kinematics of a stability failure in Atlantic salmon, *Salmo salar*, swimming in a flume at a flow speed of 10 L s^{-1}; numbers indicate time in milliseconds. The nose is indicated by the arrow head and the center of mass by the filled circle. Two outlines are shown at –65 and 0 ms as the fish swam steadily. The instability starts at the head after time 0 ms after which the nose begins to yaw as the fish could no longer sustain a head-into-flow posture. The head subtended an increasing angle to the flow, with increasing drag driving positive feedback causing the displacement to grow. The fish is no longer able to control posture as the center of mass moves laterally and downstream. The fish begins to respond after 100 ms with a turn downstream.

Fish may show two general types of responses as failure approaches. First, a fish may attempt to use a high-thrust fast-start to correct posture to keep the anterior of the body heading into the flow. However, the trajectory is displaced laterally from its initial path. Additional tail-beats are required to return the trajectory to its original path.

Second, when the initial displacement grows too fast to correct, the fish further amplifies the displacement into a turn downstream before attempting to turn back into the flow. In experimental flumes, short flume lengths give insufficient space and time for fishes to recover from such a failure, and this reduces the maximum speeds that can be attained compared to results in longer flumes. In streams, turning downstream not only provides space and time for recovery, but often there are flow refuges in which a fish can recover.

In contrast to control surfaces anterior to the center of mass, effectors posterior to the center of mass (the posterior body, median fins, and, usually, the pelvic fins) tend to be self-correcting. In this case, the displacement of a control surface is associated with a force that counters the displacement, reducing the growth or correcting the displacement.

Self-correcting control surfaces are especially important when t_{eddy}/T takes values that might promote pilot-induced error.

Powered control systems may also be self-correcting. This has been demonstrated for flying birds and the same principles apply to swimming fishes. Then the angle of attack of a powered fin effector is increased by a displacement with a force increase correcting the displacement.

The tail is an especially important trimming and powered effector, because its area is further downstream from the center of mass than other control surfaces. Hence, the tail can generate large corrective forces and torques. The earliest chordates lacked fins, but had a flexible tail, which presumably was able to bend and rotate to create corrective forces in any direction. Such flexibility is retained as part of the control system of aquatic vertebrates. In bony fishes, tail flexibility becomes of diminished importance, superseded by median and paired fins, with concomitant stiffening of the caudal skeleton.

Using Eddies

Both fishes and humans seek to use eddies for various purposes. Small eddies produced by the placoid scales of elasmobranchs may help reduce drag. The eddies increase the energy in the thin layer of flow adjacent to the fish – the boundary layer – which makes that boundary more resistant to separating from the body, a result that creates larger eddies and is a source of energy waste. The rigid carapace of boxfishes creates eddies that trail backward. These can vary in strength when the body posture is perturbed, and in this situation provide a self-correcting stabilizing mechanism. Schooling fish may use eddies created by the tails of school members ahead to give themselves a lift, reducing their costs of swimming.

Managing fishways also requires considering eddies (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance). In principle, the eddies in turbulent flow could be manipulated to promote various goals, although this is an area on which there are few studies to elaborate on potential mechanisms. Fish ladders that provide passageways for fishes around dams are commonly comprised of successive chambers through which fish pass. The openings between chambers, and sometimes structures within them, create eddies that may both serve as stimuli to promote passage and create low-flow areas as well, where fishes can rest. Alternatively, very high shear flows over dams and raceways will create substantial turbulence that may provide fish barriers, for example, at lamprey dams seeking to prevent these fishes from entering streams to breed. Raceways, recirculating tanks, and cages in rivers or tidal areas are used in aquaculture. The flow through such fish-culture systems will create eddies, and these are important for ensuring that the water is well oxygenated, the carbon dioxide and other wastes are removed, and the food is appropriately distributed. The eddies could also be sources of disturbance increasing metabolic rates. In principle, fish-culture designs could consider the nature of eddies they create to explore systems that might improve growth.

Glossary

C-start A fast start in which the body of the fish is bent into a C-shape at the end of stage 1. It is used mainly in escape responses, but it also has been observed in predator strike in certain species (e.g., in archerfish).

Double-bend response A C-start including both stages 1 and 2.

Escape latency The time between stimulus onset and the fish's reaction.

Escape response A sudden acceleration maneuver (i.e., a fast start) as a response to a threatening stimulus.

Fast start A sudden acceleration from resting or swimming. It can be an escape response or a predator strike, or a maneuver observed during social interactions.

Mauthner cells Two giant neurons located in the hindbrain of most fish species. These cells usually control escape responses. However, non-Mauthner-cell escapes also have been reported, and the Mauthner cells may be involved in other behaviors such as post-feeding turns.

Predator strike A sudden acceleration (i.e., a fast start), generally in line with the body axis, aimed at catching prey.

Single-bend response A C-start lacking stage 2.

S-start A fast start in which the body of the fish is bent into an S-shape at the end of stage 1. It mainly is used in a predatory strike, but a type of S-start also has been observed in escape response (e.g., in pike).

Stage 1 The first body bend occurring during a fast start, analogous to a half tail-beat in continuous swimming. Kinematically, it starts at the onset of the response, and it ends when the angular motion of the head reverses direction.

Stage 2 The second body bend occurring during a fast start, analogous to a half tail-beat in continuous swimming. Kinematically, its beginning corresponds to the end of stage 1 and it ends with the next reversal of the turning of the head.

Startle response Any reaction caused by a threatening stimulus. It may imply an escape response or other responses such as freezing and withdrawal.

Introduction

Fast starts are sudden accelerations performed by fish either from rest or while swimming. They are a fundamental component of a fish's locomotory repertoire, because they are used by most species for avoiding predation and by some species for capturing prey (**see also Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics). Fast-start maneuvers have been associated also with social interactions in a number of species. Fast starts are the result of the contraction of fast glycolitic (anaerobic) fibers and can be considered as a form of burst swimming that lasts only for a fraction of a second. Mechanically, fast starts are unsteady swimming behaviors that can be classified as body–caudal fin (BCF) transient motions.

Fast starts are divided into three stages: stage 1, the first body bend; stage 2, the second body bend; and stage 3, a variable stage, involving continuous swimming, coasting, or braking. Most experimental work has focused on the first two stages. Early work considered stage 1 and stage 2 as the preparatory and propulsive stages, respectively. However, recent work has demonstrated that stage 1 alone can provide thrust, which is consistent with the finding that fast-start escape responses lacking a stage 2 still result in forward motion.

Fast starts can be classified further based upon the type of curvature achieved by the fish at the end of the first muscular contraction (stage 1). The two main types of fast starts are the C-start and the S-start, in which the body curvature at the end of stage 1 assumes a C- or an S-shape, respectively. C- and S-starts often are associated with escape

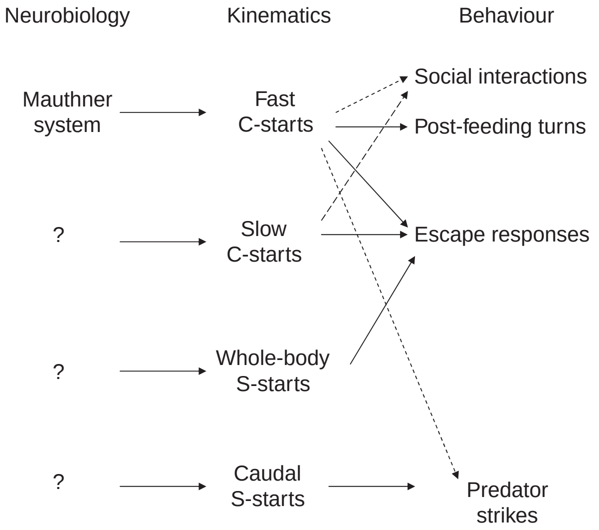

Figure 1 Diagram showing various types of fast starts and their relative neural control, kinematics and the behavioral context within which they are observed. Dotted arrows indicate uncertain links (i.e., the activation of the Mauthner system in fast C-starts has not been demonstrated in social interactions and predator strikes; the presence of distinct fast and slow C-start in social interactions has not been demonstrated). Whole-body and caudal S-starts are shown in **Figure 3**; fast and slow C-starts are shown in **Figure 6**. responses and strikes, respectively. However, recent work has demonstrated that C-starts can also be used as predator strikes, and that two kinematic types of S-starts exist in some species (e.g., pike *Esox lucius*) that can be used for escaping and for prey capture, respectively. In addition, while C-start escape responses usually are controlled by a pair of giant neurons (the Mauthner cells), experiments have shown that Mauthner cells can be used also in other contexts, such as in post-capture maneuvers. A diagram elucidating the kinematic classification of fast starts, the underlying neural control, and the behavioral contexts in which they are used is shown in **Figure 1**.

Neural Control

Most work on neural control has focused on escape responses. Escape responses usually are controlled by a pair of giant reticulospinal neurons located in the hindbrain of most fish species, the Mauthner cells (**see also Hearing and Lateral Line**: Auditory System Morphology and **Brain and Nervous System**: Physiology of the Mauthner Cell: Function), and in several other associated reticulospinal neurons. All of these neurons together make up the Mauthner system controlling the features of the initial phase of escape responses. In a typical, mechanically triggered C-start escape response, the generalized sequence of events is: fish perceive the threatening stimulus; the sensory neurons excite the Mauthner cell ipsilateral to the stimulus; the ipsilateral Mauthner cell inhibits the contralateral Mauthner cell and excites the contralateral axial musculature as well as other motor components (e.g., pectoral and dorsal fins and opercula); and the fish body bends into a C-shape, giving rise to the stage 1 of the response. Stage 2 often follows stage 1, although its execution is not directly activated by the Mauthner cells. The Mauthner cells receive stimulation from a number of ipsilateral sensory inputs, typically visual and/or mechano-acoustic, and escape responses can be triggered by a variety of stimuli such as visual (shadows or looming images), sudden noise, vibration, and chemical and tactile stimuli. An approaching predator is likely to provoke stimulation of more than one of these sensory modalities.

In light of the high variability in timing, performance, and kinematics (see below), escape responses cannot be considered highly stereotypic. Correspondingly, recent work has demonstrated the existence of many variants of the typical escape response described above. Escape responses may or may not include a stage 2 (double-bend and single-bend responses, respectively; **Figure 2**); in certain species, S-start escape responses can be observed in which contractions on both sides of the body occur during stage 1; and escape responses in which Mauthner cells are not activated have been observed in both intact fish and in fish with ablated Mauthner. Therefore, the Mauthner cells are not necessary for escape responses to occur, although Mauthner cell-mediated responses tend to show higher performance (e.g., shorter reaction times and higher turning rates) than non-Mauthner-cell responses.

Furthermore, while fast-start escape responses commonly are observed in fish when threatened, other startle responses that do not necessarily imply locomotion, such as withdrawal (head retraction) and freezing responses, can occur. Head retraction usually is observed as a response to head stimulation in some elongated species (e.g., *Anguilla rostrata* and *Petromyzon marinus*) and it does not involve a propulsive phase. These species avoid predators by retracting their head back into a burrow rather than by swimming away from the threat. Like escape responses, withdrawal responses are thought to be mediated by the Mauthner cells. The Mauthner cells of the lamprey, unlike those of teleosts, lack reciprocal inhibition – both cells fire at the same time.

Mauthner-mediated fast starts can be observed during feeding. When goldfish (*Carassius auratus*) capture a prey

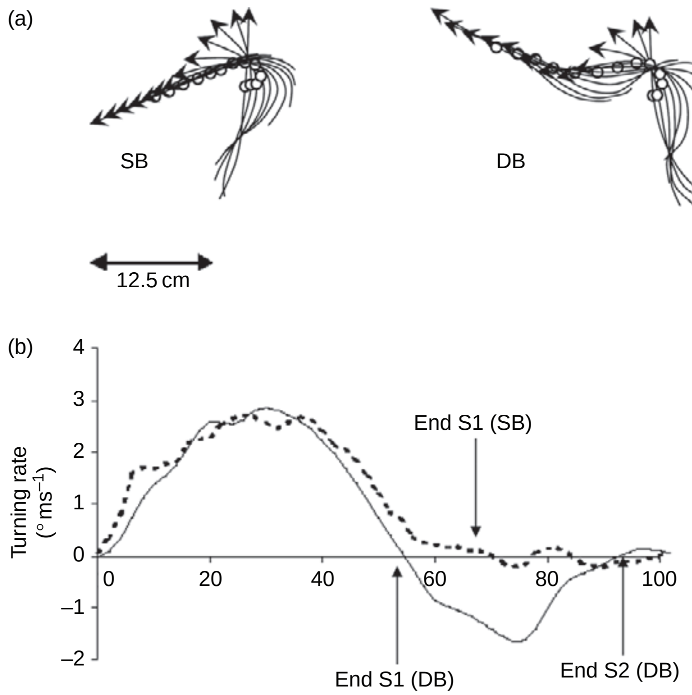

Figure 2 (a) Tracing of the mid-line of grey mullet (*Liza aurata*) in successive positions during a single-bend (SB) and a double-bend (DB) response. The arrows and the circles indicate the positions of the head and the CM, respectively. (b) Turning rate of the head for the responses shown in (a). While the DB response (continuous line) shows a reversal of turning rate in correspondence with stage 2 (S2), the SB response (dotted line) shows turning rate values around zero after the end of stage 1 (S1). Reproduced from Lefrançois C, Shingles A, and Domenici P (2005) The effect of hypoxia on locomotor performance and behaviour during escape in the golden grey mullet (*Liza aurata*). *Journal of Fish Biology* 67: 1–19, with permission from Wiley-Blackwell.

fallen on the water surface, prey capture often is followed by a quick Mauthner-mediated C-start. Hence, a startling stimulus is not a necessary event for triggering Mauthner cells. Little is known about the neural control of predatory strikes, although high-speed video observations suggest that S-start strikes may be controlled by different mechanisms than S-start escape responses because of the kinematic differences between these two fast-start types (**Figure 3**).

Muscle Activity

The muscle activity involved in C- and S-starts differs considerably. The C-bend commonly observed in C-type escape response is the result of the unilateral contraction of the anaerobic axial fibers. These fibers are designed for fast, high-power muscle contractions and typically constitute most of the muscle mass of fish. Electromyography shows that a unilateral contraction at the onset of an escape response is common among teleosts (due to the reciprocal inhibition of contralateral Mauthner cells), although primitive forms such as the bowfin (*Amia calva*) and bichirs (*Polypterus senegalus*) show bilateral muscle activity during stage 1. Muscle activation in stage 1 is simultaneous along the whole body length. However, the duration of muscle activity in stage 1 increases at posterior sites. Stage 1 usually is followed by stage 2 in double-bend responses, which corresponds to a contralateral wave of muscle activity propagating posteriorly.

Studies of muscle activity (based on electromyography) in predator and escape S-starts have revealed the muscular basis for differences in kinematics. In certain elongated species such as pike, posteriorly triggered escapes consist of whole-body S-starts, in which, during stage 1, the contralateral body bend of the S-shape occurs approximately halfway along the fish, with rostral and caudal muscle activity on opposite sides and almost simultaneous. A different type of S-start can be observed during predator strikes, in which the contralateral bend of the S-shape is restricted to the tail region (**Figure 3**), and the rostral muscle activity during stage 1 is delayed relative to the caudal muscle activity. Predatory S-starts may imply sudden S-bending in stage 1 followed by stage 2, or a relatively long-lasting S-posture during which the predator is relatively still, followed by successive muscle contractions.

The anaerobic fibers have different contractile properties depending on their location along the fish. Generally, rostral fibers show faster contractile properties than posterior ones. In addition, the anaerobic fibers, the main muscle fibers that fuel fast starts, are generally more massive anteriorly than posteriorly. As a result of these differences in contractile properties and muscle distributions, the forces developed

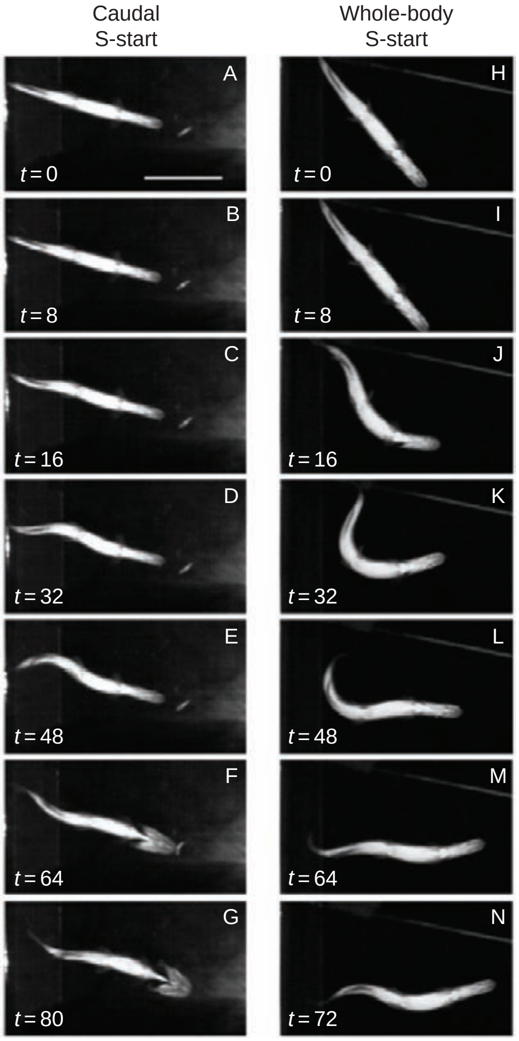

Figure 3 Predatory strike (caudal S-start; left panels) and escape response (whole-body S-start; right panels) S-starts in pike (*Esox lucius*) filmed from below using high-speed video at 500 Hz. The S-start of a predatory strike involves a contralateral bend restricted to the caudal region, while in escape responses the S-bend occurs along the whole length of the fish. *t* indicates time in millisecond. From Schriefer JE and Hale ME (2004). Strikes and startles of northern pike (*Esox lucius*): A comparison of muscle activity and kinematics between S-start behaviors. *Journal of Experimental Biology* 207: 535–544.

anteriorly are larger than those developed posteriorly. This large force development causes a delay in the peaks of bending in caudal sites relative to rostral sites during fast starts, resulting in a wave of body bending along the length of the fish, in line with kinematic observations.

Because most of the white (i.e., anaerobic) muscle mass in fish tends to be in the central region, this is where most of the mechanical power is produced during a fast start. However, most hydrodynamic forces are generated in the posterior region of the fish because muscle power is transmitted to the posterior region as a result of the stiffness of the muscle and the skeleton.

Hydrodynamics

Early work on fast start describes stage 1 as the preparatory phase and stage 2 as the propulsive phase. However, more recent kinematic work has shown that (1) the center of mass is accelerated even during stage 1 and (2) fast starts associated with considerable forward propulsion can occur even in the absence of a stage 2 in single-bend escape responses (**Figure 2**). This suggests that some thrust is produced during stage 1. Earlier work calculated the acceleration and lift forces during S- and C-start maneuvers. Acceleration forces were the dominant component during stage 1, while lift forces dominated during stage 2. Fast starts show high amplitude motions when compared with routine swimming, with large accelerations and decelerations, and forces produced not only in the direction of motion but also perpendicularly. As a result of these features, fast starts show relatively low efficiency of locomotion. However, fast starts are likely not designed for locomotor efficiency, but rather for high power and high acceleration, which maximize success in life-threatening situations.

Recently, digital particle image velocimetry (DPIV; **see also** (**Buoyancy, Locomotion, and Movement in Fishes**: Experimental Hydrodynamics) was applied to C-type escape responses in order to estimate the flow pattern around the fish and the underlying hydrodynamics. DPIV is a video technique that allows visualizing and quantifying the flow around objects. Briefly, it consists of adding neutrally buoyant particles to the fluid. A given plane of interest is then illuminated by a laser sheet. Video recording allows quantifying the distance covered per unit time by the particles and therefore the motion of the fluid. Experimental work using DPIV suggests that both stages 1 and 2 produce thrust. Specifically, a C-start escape response produces three orthogonal jets (**Figure 4**). Jet 1 opposes the final swimming trajectory of the fish, in line with the low efficiency of fast starts and it may be an unavoidable property of such a high-amplitude maneuver. Jet 2 is the main propulsive jet, being in a direction opposite to the final swimming trajectory of the fish. This jet starts forming during stage 1, because bending the fish into a C-shape generates a region of suction within the C. This demonstrates that stage 1 is a propulsive phase of C-type fast starts, albeit most of the thrust is generated during stage 2. Jet 2 further develops during stage 2 as a result of the return flip of the tail. Flow generated by the dorsal and anal fins provides a relatively large proportion of the total momentum by adding to jet 2. Jet 3 develops as a result of stage 2 and is directed perpendicularly to the escape trajectory of the fish. This jet may contribute to steering, by opposing the angular momentum generated during stage 1. Further work using DPIV techniques is

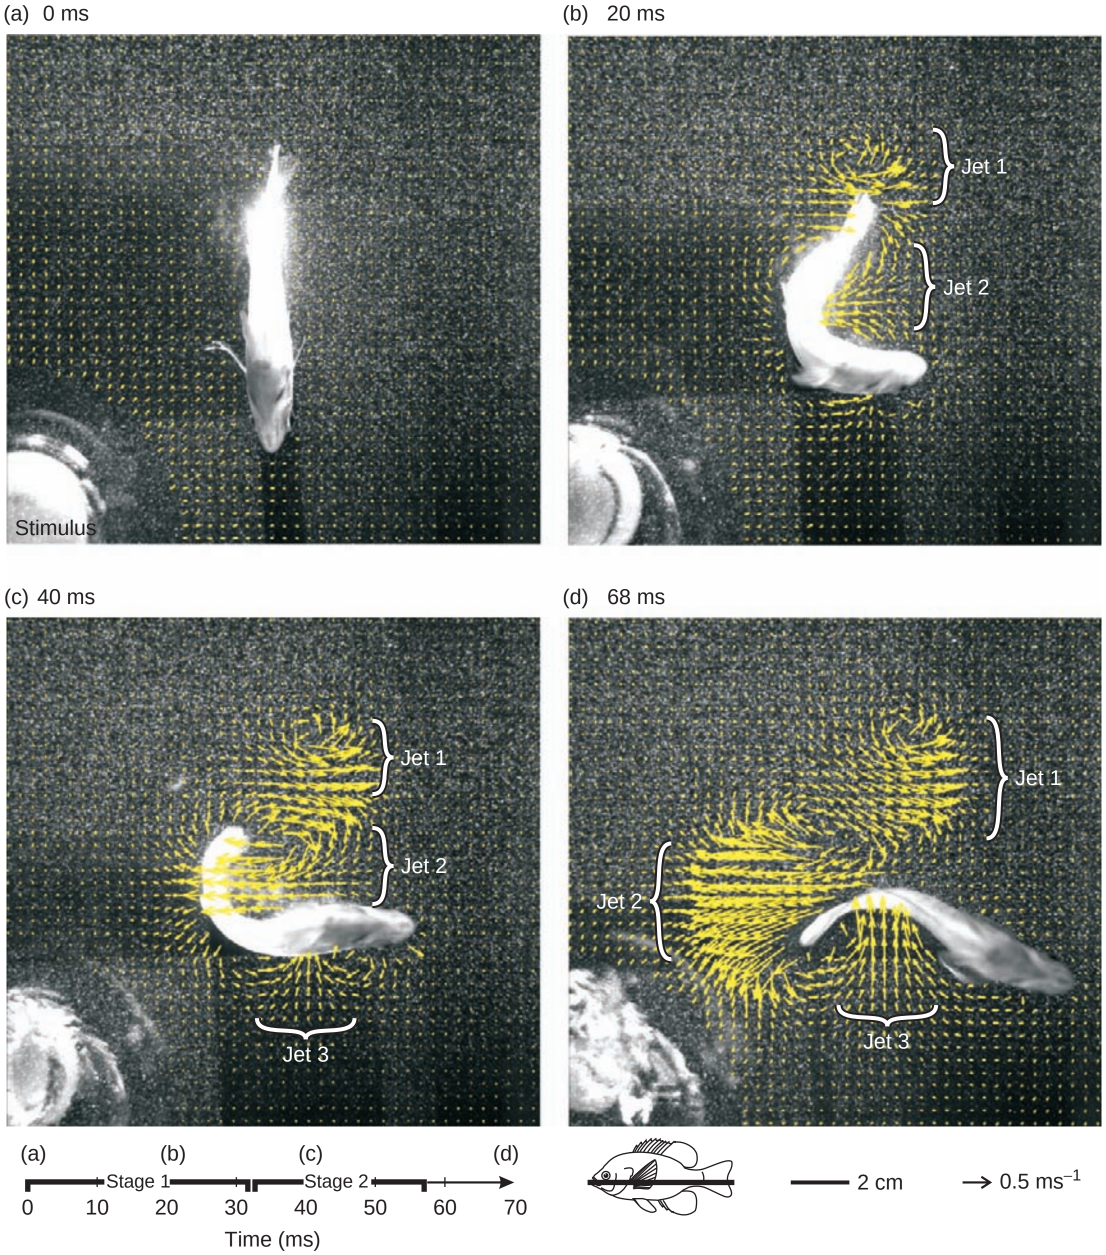

Figure 4 The jets created during an escape response in bluegill sunfish, *Lepomis macrochir*, based on digital particle image velocimetry. View from below. Stimulation is from the bottom left of each panel. Time is shown on the top left of each panel. Panels (a)–(d) show the position of the fish at different times, from the onset of the response (a, 0 ms) to 68 ms later (d). The timing of each panel relative to each stage of the escape response is shown in the bottom drawing. The bluegill drawn at the bottom shows the position of the laser light sheet on the vertical plane (black line). The arrow at the bottom right shows flow velocities of 0.5 m s^{-1}, for comparison with the flow vectors shown in the four panels. See text for details. From Tytell ED and Lauder GV (2008) Hydrodynamics of the escape responses in bluegill sunfish, *Lepomis macrochirus. Journal of Experimental Biology* 211: 3359–3369.

necessary to elucidate the flow fields and underlying hydrodynamics of other types of fast starts, including predatory strikes.

Performance and Kinematics

Fast-start performance can have a major effect on the outcome of predator–prey encounters, because fast starts are used by most species of prey and by many predators. When considering escape responses, there are a number of components that affect survival that can be related to both reactivity and swimming performance. The main components are described and defined below, together with the main factors affecting them. From a methodological point of view, high-speed video ($\geq$250 frames s^{-1}) is the most common tool used for

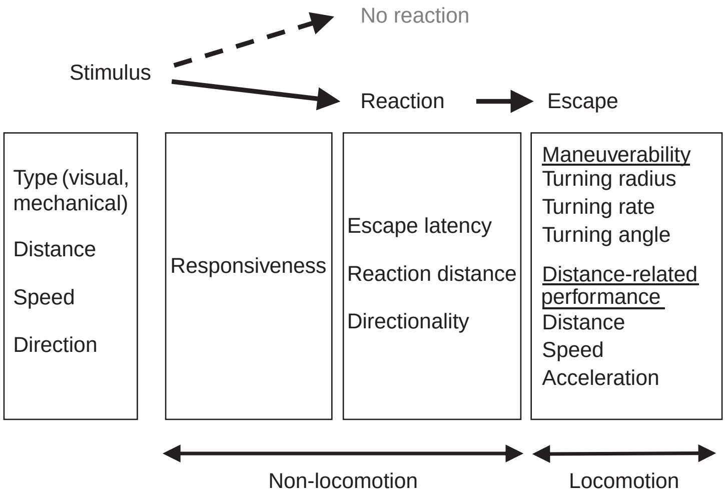

Figure 5 The components of an escape response, including stimulation, non-locomotion, and locomotion variables. Reproduced with permission from Domenici P, Lefrançois C, and Shingles A (2007) The effect of hypoxia on the antipredator behaviour of fish. *Philosophical Transactions of the Royal Society B* 362: 2105–2121.

assessing fast-start performance (**Video Clip 1**). The main components of fast-start performance are shown in **Figure 5**. For each component, a range of indicative performance levels is identified in **Table 1**. Once a predator attacks, the first step is to determine whether the prey executes an escape response or not. The proportion of responses over the total number of attacks for any given sample can be scored as responsiveness and was found to be a major determinant of prey vulnerability. Responsiveness is affected by the strength (or distance) of the stimulation, with supra-threshold stimuli yielding up to 100% of responses.

If a fish executes an escape response that is triggered by an approaching stimulus (e.g., a predator), its reaction distance can be measured as the distance between the prey and the snout of the predator at the onset of the response. Reaction distances tend to increase with the frontal size and speed of the approaching predator. This is because the rate of change of the angle of the predator's frontal profile as seen by the prey (the apparent

Table 1 Indicative performance levels for escape response variables of adult fishes

Variable type	*Variable*	*Size effect*	*Performance (indicative range)*
Escape behavior	Responsiveness	[a]	Up to 100%
	Latency	[a]	5–100 ms
	Prey reaction distance (apparent looming threshold)	↗[b]	0.1–1 rad s^{-1}
	Directionality	Not tested	50–100%
	Escape trajectories	[a]	90–180°
Kinematics (maneuverability)	Turning radius	↘[c]	0.05–0.2 L
	Turning angles	[a]	0-180°
	Stage 1 turning rate (average)	↘	500–5000° s^{-1}
Kinematics (distance–time variables)	Fast start duration	↗	30–200 ms
	Distance covered during fast start	↗	1–20 cm
	Distance covered within a fixed time[d]	[a]	1–20 cm
	Speed within fast start	↗	3–30 L s^{-1}
	Speed within a fixed time[d]	[a]	3–30 L s^{-1}
	Burst speed[e]	↗	5–30 L s^{-1}
	Acceleration	[a]	20–150 m s^{-2}

[a] Indicates that no size effect was found.
[b] Apparent looming threshold decreased with size in some species (i.e., reaction distance increases).
[c] Indicates a size-related increase in turning radius (turning radii measured in cm are larger in large fish, although when measured in Lengths (L), they are relatively constant)
[d] Fixed time taken as the average duration of stage 1 plus stage 2.
[e] For swimming performance beyond fast start stages.
Arrows (↗ and ↘) represent a size-related increase and a decrease in performance, respectively.
Indicative values are for a range of sizes spanning approximately 5–50 cm.

looming threshold) at the onset of the escape response is relatively constant for any given prey. In addition, reaction distance is affected by factors that affect prey risk and the cost of fleeing, such as the presence of refuges and the engagement in feeding activities, respectively. Sudden stimulation, as often used in laboratory settings, allows the measurement of escape latency, defined as the time between stimulus onset and the fish's reaction. Minimum latencies of the order of 5–10 ms are characteristic of Mauthner-cell-mediated responses, although longer latencies (as long as 50–100 ms) have been reported in responses possibly not mediated by the Mauthner cells. Latencies tend to decrease with stimulus strength and proximity. In C-type escape responses, fish tend to contract their body into a C-shape opposite to the threat as a result of the activation of the Mauthner cell ipsilateral to the stimulation. The proportion of this type of responses (also called away responses as opposed to the less common towards response, in which the C-bend is directed toward the threat) over the total number of responses for a given treatment can be scored as directionality. Directionality is largely affected by the orientation of the fish relative to the approaching stimulus, with values around 80–90% when the stimulation is perpendicular, decreasing to almost 50% for stimuli that are nearly head on or tail on. In addition, directionality is affected by the presence of nearby obstacles. Finally, the overall swimming direction (escape trajectory) shown by fish at the end of the escape response tends to be in the sector 90–180° away from the threat, with high variability related to multiple peaks in frequency.

A number of kinematic variables related to swimming performance affect escape success and consequently survival. These are mainly variables related to (1) maneuverability and (2) distance–time performance. In most cases, performance has been measured by considering the center of mass of the fish when stretched straight (CM_s). While this point is not the physical center of mass when the fish is moving (unless it is gliding in a straight position), this convention has been used because CM_s approximates the point upon which forces act and it is the point where many predators aim.

Maneuverability (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability) is often a determinant of predator–prey interactions. Generally speaking, small fish are more maneuverable than their larger predators, but are slower when swimming along a straight course (**Table 1**). Indeed, swerving is often used by fish under attack, allowing prey to benefit from their superior maneuverability. This behavior has the additional advantage of increasing the unpredictability of their movement. Maneuverability can be measured using a number of variables whose relative importance may depend on the type of interaction. Maneuverability has mainly been measured in escape responses, because predatory strikes tend to be in line with the stalking orientation of the predator and involve little turning during the strike.

The main maneuverability variables measured during escape fast starts are turning radius, turning angles, and turning rates. The turning radius is usually measured as the roughly circular path of CM_s during stage 1 and it provides an indication of how sharply a fish can turn. Turning radii in escape responses are independent of speed and proportional to fish length, such that turning radii measured in Length (L) tend to be relatively constant, around 0.05–0.2 L depending on the species. Fish with high maneuverability, living in structurally complex environments, tend to have small turning radii, while fish from pelagic environments tend to show relatively large turning radii. These differences are related mainly to differences in body flexibility. While fish from structurally complex habitats usually are quite flexible and can show high-amplitude maneuvers, fish from pelagic environments, such as tuna, usually are relatively rigid, which minimizes recoil and therefore drag. The ability of fish to accomplish a turn within one-half tail beat (i.e., stage 1 of an escape responses) can be assessed by simply measuring the angle between the head at the onset of the response and at the end of stage 1 (i.e., turning angle). Because fish tend to escape in a direction away from the stimulus, the average turning angle, when using various stimulus directions, tends to be around 90°. However, maneuverability should be assessed by measuring the full range of turning angles available to a fish using stimulation spanning 180° from both sides, rather than the mean turning angle. Relatively flexible fish such as angelfish (*Pterophyllum eimekei*) and goldfish show turning angles ranging from about 10 to 180°, while rigid fish such as tuna can achieve a 180° turn only if using 2–2.5 tail beats.

The agility of fish can be measured as the rate at which they can change their orientation (commonly measured as the turning rate or angular velocity of the line joining the tip of the head and CM_s). Turning rate can assess the ability for swerving and it is a fundamental variable for survival since it affects the outcome of predator–prey interactions. Small fish show a higher turning rate than large fish, because the minimum muscle contraction time increases with fish size. For example, a 90° turn is accomplished in about 20 ms in a 10-cm fish and in about 100 ms in a 30-cm fish. In addition, turning rate should be related to the amount of muscle power used in the contraction and inversely related to body rigidity and drag. Escape responses show fast and slow turning rates (possibly related to different neural control; **Figure 6**), although both are faster than the turning rates observed during routine swimming.

Propulsive performance in fast starts commonly is measured as distance traveled, speed, and acceleration of the CM_s. Fast starts are characterized by extremely high accelerations, of the order of 5–20 g. Locomotor performance shows relatively high variability and tends to be

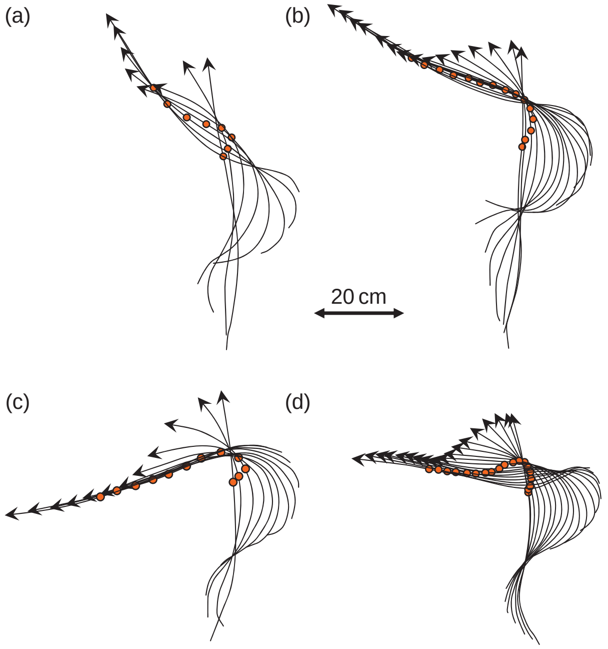

Figure 6 Escape responses in dogfish (*Squalus acanthias*) with slow (a, c) and fast (b, d) turning rates (corresponding to fast and slow responses in **Figure 1**). The arrows and the circles indicate the positions of the head and the CM, respectively. Time between positions is 40 ms. Fish in (b) and (d) take longer to achieve a similar stage 1 angle as (a) and (d), respectively. higher in escape responses than in predator strikes, possibly because faster attacks cause larger reaction distances in the prey. In both escape and strike fast starts, a peak in acceleration is observed during stage 1 (followed by a peak in stage 2; **Figure 7**). Hence, the time course of the propulsive power is associated with the tail beats. Although, on theoretical grounds, acceleration is expected to decrease with size (because thrust, proportional to L^2, is used to move the inertia of the body and added mass, proportional to L^3), experimental data show no clear scaling trend. Because acceleration is obtained by a double differentiation of distance over time, it is usually noisy. Although a number of smoothing techniques have been developed, it is advisable to consider, in addition to acceleration, other less noisy measurements for the assessment of fast-start performance. In particular, speed and distance traveled are good predictors of the outcome of predator–prey encounters. The speed at the end of stage 1 is usually around $10\,\mathrm{L\,s^{-1}}$ (or even higher in small fish), and it increases in stage 2. In order to provide ecologically relevant measures, speed and distance traveled are commonly calculated within a fixed time. Experimental work using predator–prey encounters suggests that an ecologically relevant fixed time to use is the cumulative duration of stages 1 and 2. Nevertheless, the relevant time within which performance should be assessed may depend on the species of predators and prey involved, as well as on the habitat type in which they live. For example, structurally complex habitats providing shelters are likely to result in short-lived predator–prey encounters. Although burst speed increases with fish size, when measured within a fixed time, speed is independent of size, in line with data on the scaling of acceleration.

Body Design

Both shape and size can affect fast-start performance. A summary of the scaling issues mentioned in the above sections is listed in **Table 1**. Large fish are at an advantage when swimming in a straight line because of their higher burst swimming speed. However, predator–prey encounters often involve swerving and most maneuverability variables show higher performance in small fish.

Fish shape can affect a number of fast-start components. Theoretical considerations predict that fast-start performance should be higher in fish with a large posterior body section, a large tail for thrust production, a flexible body for high-amplitude motions, and a high proportion of white/red muscle mass. These characteristics trade off with those maximizing cruising, such as a drag – minimizing body shape with a fineness ratio (length/depth) of about 4.5, with the maximum depth positioned at about a third of the body length, a lunate tail for drag minimization, a rigid body for recoil (hence drag) minimization, and a high proportion of red/white muscle. Experimental work using intraspecific comparisons is in line with these predictions. However, body shape is likely to affect factors other than swimming performance that will in turn also affect the predator–prey encounters. For example, the fineness ratio of prey may affect their vulnerability to predation by gape-limited predators. Similarly, a narrow frontal section in predators allows them to minimize the reaction distance of the prey. In addition, body shape may affect other factors such as reproductive success. Body shape is therefore likely the result of a number of evolutionary forces that are not necessarily related only to swimming performance or to predator–prey relationships.

Environmental Factors

Fast-start performance is affected by a number of environmental factors. Temperature is one of the main factors affecting fast starts, because it affects nerve conduction speed and muscle power output (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops). The effect of temperature on reactivity has been particularly studied in escape responses. Responsiveness increases with acclimation temperature, although it increases at low temperatures when acute exposure is used. As expected from the generalized effect of temperature on nerve conduction speed, escape latencies decrease with temperature. However, acute exposure to high temperatures can have a negative effect on reactivity of fish, measured as reaction distance. Similar to responsiveness, the effect of temperature on directionality is modulated by acclimation. Fish show low directionality when acutely exposed to low temperatures. On the other hand, low directionality was observed also in fish acclimated to high temperatures. These contrasting results are due to changes in the properties of the Mauthner cells in acute treatments, and to changes in the processing time of the neural circuitry in fish acclimated to high temperatures, respectively. For both escape responses and predator strikes, propulsive performance (distance, speed, and acceleration) tends to increase at high temperatures as a result of increased muscle performance. Acclimation can provide some degree of compensation. Maneuverability (turning rates and angles) also can be negatively affected at very low temperatures.

Fast starts are fueled anaerobically; therefore, it may be surprising to find that oxygen levels can affect fast-start performance. Recent work has found that exposure to hypoxia does have a negative effect on a number of escape components. Escape responsiveness decreases in hypoxia, possibly as a result of sensory malfunctioning or lower motivation or other physiological factors. While hypoxia did not have an effect on escape latency, directionality decreases in hypoxia, possibly as a result of impairment in the left–right discrimination of stimulus direction. In some species (e.g., Mugilidae), fish show a higher proportion of low-performance (i.e., single bend) responses than high-performance ones (double-bend responses), with negative consequences for propulsive performance. These observations may be explained by physiological exhaustion and negative effects on neural control. Therefore, while relatively acute hypoxia exposure may not directly affect the muscle performance of fish, it may have negative effects on their brain and sensory functions, with direct consequences on the execution of the escape response at all levels. Although specific studies on the effect of hypoxia on predatory strikes have not been carried out, it is likely that the main effect of hypoxia on predators might be a decrease in hunger level.

Other environmental factors such as salinity and turbidity affect reaction distance in escape responses. Osmotic stress in freshwater salmonid smolt exposed to seawater results in a decrease in reaction distance. As expected, turbidity decreases reaction distance, although it also decreases locomotor performance, possibly as a result of a lower amount of sensory information present in the visual stimulus.

A number of pollutants affect fast starts. Ammonia is toxic and it impairs nervous and muscle function in fish. Ammonia exposure increases escape latency and decreased propulsive performance in both escape responses and predator strikes. Other pollutants, such as metallic compounds originating from industrial discharges, can affect fast starts. Cadmium exposure decreases responsiveness, increases latency, and decreases speed in European seabass (*Dicentrarchus labrax*) as a result of impairment of the mechano-sensory system, and mercury-exposed zebrafish (*Danio rerio*) show a decrease in responsiveness and an increase in escape latencies, as a result of an alteration in the neuromuscular performance.

Future Directions

A number of unresolved issues related to the mechanistic basis of fast start remain to be elucidated. Among these, the neural control and the hydrodynamics of predatory strikes need to be investigated. In addition, more work is necessary on the hydrodynamics of different types of escape responses, as well as on the neurobiological basis of this diversity. More efforts taking into account trade-offs in functional morphology should be made to understand the evolutionary basis of the variety of body shapes found in fish. This should take into account the effect of body design on fast start and routine swimming as well as on other factors that are not necessarily related to locomotion. Fast starts have been studied from a number of perspectives, including biomechanics, physiology, functional morphology, neurobiology, behavior, ecology, and evolution. An approach that integrates these disciplines will be necessary in order to assess the fitness value of fast starts. For example, the relationship between fast-start performance and the outcome of predator–prey encounters should be studied both in the laboratory and in the field by combining biomechanics, physiology, and behavioral ecology approaches. Finally, environmental change can affect the fast-start performance of predators and prey to different extents, thereby potentially influencing their relative abundance and distribution. An integrated experimental and modeling approach that takes into account context-dependent variability in fast-start performance is necessary in order to generate predictive ability of environmental change at the ecological level. (**Video Clip 1**).

Glossary

Buccal cavity The mouth (oral) cavity at the anterior end of the fish in front of the gills.

Digital particle image velocimetry (DPIV) A modern computational technique used to visualize the movement of fluids. Neutrally buoyant reflective particles are placed in the water, illuminated using a laser light sheet and are used to measure water movement. The movements of the particles during feeding are captured using high-speed video.

Ecomorphology The relationship between morphology and ecology.

Exaptation A character, previously shaped by natural selection for a particular function, that later is co-opted for a new use.

Ram The forward movement of the fish.

How Do Fishes Capture Prey?

Suction (mouth expansion), ram (forward swimming), and manipulation are three mechanisms of prey capture in fishes. Despite the considerable diversity among the approximately 28 000 species of fishes, the most common mode of prey capture involves suction feeding. Although the general principles underlying suction feeding are relatively straightforward, several aspects of the feeding system can be modulated in order to alter feeding performance. For example, the rate and magnitude of mouth expansion, the distance between the fish's mouth and prey item, and body movements will influence suction-feeding performance. Jaw protrusion is an additional feature that can enhance suction-feeding performance. Based on recent evidence, intraoral processing (chewing) also appears to be a relatively common feature among fishes. For example, bowfin (*Amia calva*), salmonids (e.g., *Salmo salar*), and pike (e.g., *Esox niger*) all chew prey with their oral jaws. Modern experimental techniques, including sonomicrometry, digital particle image velocimetry (DPIV), *in vivo* pressure recordings, and computational fluid dynamics, all have propelled our understanding of the biomechanics of feeding in fishes. Some websites include videos that show examples of these features of fish feeding (**see** the Relevant Websites section).

The prevalence of suction feeding is the major focus of this article. The mechanisms underlying suction feeding in fishes are fairly complex. For example, the initial expansive phase is a result of hyoid depression, cranial rotation, jaw protrusion, and jaw opening. The musculature involved in feeding is discussed in other articles (**see also The Muscles**: Cartilaginous Fishes Cranial Muscles and Bony Fish Cranial Muscles).

Ram

Several species of fishes capture prey without generating suction or manipulating the prey. Ram feeding occurs when a fish swims over a prey item with its mouth open. Examples of fishes that employ ram include tunas and whale sharks.

Suction

As indicated above, suction feeding is the most common mode of prey capture. It involves the rapid expansion of the buccal cavity, which ultimately draws water into the mouth due to a pressure gradient formed (**Figure 1**). The majority of bony fishes (Osteichthyes) employs suction feeding in order to capture prey (see **Video Clip 1** for an example of a fish employing suction feeding).

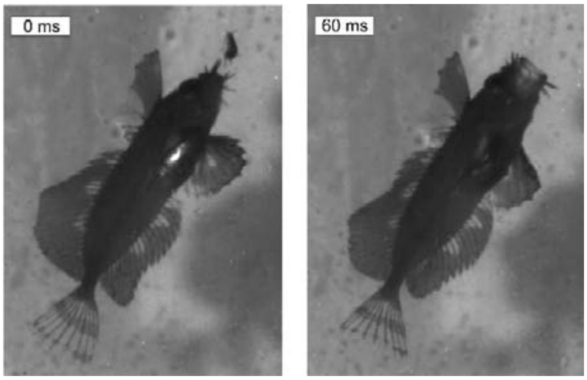

Figure 1 Suction feeding in the silverspotted sculpin, *Blepsias cirrhosus*. These images highlight the extent to which the jaw is protruded during suction feeding and the fact that ram (swimming) is not necessary for capturing prey with suction feeding.

Manipulation

In addition to suction and ram, fishes can obtain prey by physically contacting it and bringing it into the mouth, that is, biting. For example, biting is relatively common among shark and teleost fishes. Every species of heterodontid sharks is ecologically and functionally specialized for durophagy, which involves the consumption of hard prey such as mollusks or crabs. In many cases, the oral jaws of fishes are used to bite a prey item that is located on the substratum. Furthermore, some fishes will bite other animals (e.g., specialized for eating scales) and some will bite off small pieces of plants. As explained below, jawless fishes also use manipulation in order to obtain food.

Feeding in Jawless Fishes

Hagfishes and lampreys feed in a complex and very different way compared with other fishes (**see also Hagfishes and Lamprey**: Hagfishes, Lampreys: Energetics and Development, and Lampreys: Environmental Physiology). The feeding system includes posteriorly directed keratinous teeth that are attached to dental plates, a paired series of cartilages. The dental plates are moved in and out of the mouth during feeding via retractor and protractor muscles. The movement of the dental plate acts in a similar way to a fixed pulley. This system appears to have both advantages and disadvantages relative to fishes with jaws. The pulley system allows maximal force transmission, but does not permit speed amplification. Speed amplification is likely a key aspect of jaws that has facilitated the success of jawed fishes.

The Evolution of Suction Feeding

The invasion of new habitats by early fishes was likely facilitated by the evolution of jaws. The diversity of gnathostomes (jawed fishes) exploded in the Silurian and gnathostomes is currently represented by the chondricthyans and bony fishes. Later advances, such as jaw protrusion (discussed later) and pharyngeal jaws, then enhanced the basic feeding plan. However, it is important to discuss first the origin of jaws and ultimately suction feeding.

Jaws evolved in fishes over 460 million years ago. Recently, two hypotheses have been put forth explaining the origin of jaws. Several commonalities persist in both hypotheses. For example, both agree that jaws represent the first branchial arch, also termed the mandibular arch (**Figure 2**). The evidence supporting this includes the fact that most of the elements of the jaws (skeletal elements, muscles, etc.) resemble those of other branchial arches. Also, both agree that the lower jaw resides in the ancestral position of the mandibular arch, whereas the upper jaw

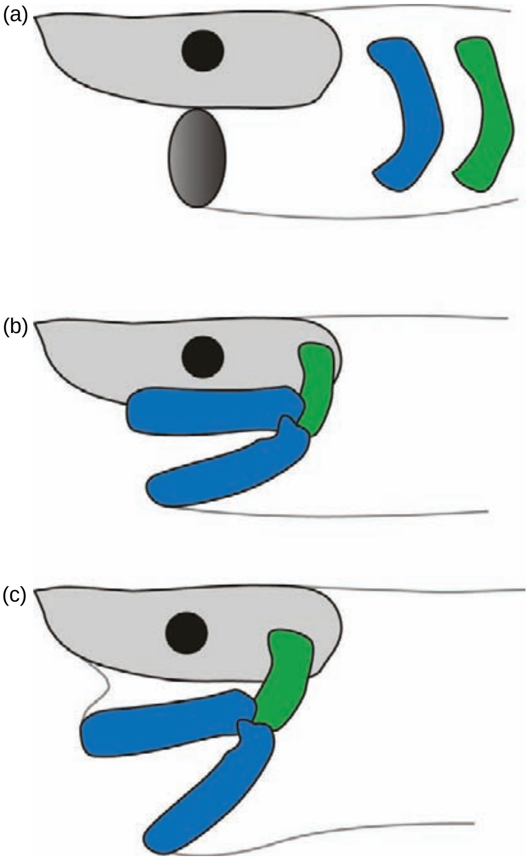

Figure 2 A hypothetical schematic the evolution of jaws for suction feeding. (a) Here the mandibular (blue) and hyoid (green) arches before being involved in the jaws. (b) Here the mandibular arch has become the jaws, which are suitable for respiration. In this amphistylic jaw suspension, the mandibular arch is directly connected tot the cranium. (c) Here the mandibular arch is not directly connected with the cranium, which is more suitable for feeding.

stems from the forward extension (in front of the mouth opening) of the maxillary part of the mandibular arch (**see also The Skeleton**: Bony Fish Skeleton).

The first hypothesis for the origins of jaws is the neoclassical hypothesis, which asserts that the jaw first evolved for stronger ventilation and then to grasp prey. As ventilation increases, prey would be sucked in and potentially consumed. Thus, what originally began with a ventilatory function eventually became utilized for suction feeding, indicating that the current use in feeding is an exaptation. Eventually, the ability to grasp prey was improved when dentition became associated with the mandibular arches. In the neoclassical hypothesis, few or no oral structures were lost during the jawless-to-jawed transition.

The second hypothesis for the evolution of the jaws is the heterotopic hypothesis, which is based mainly on modern developmental studies. This hypothesis asserts that the upper jaw did not evolve through a series of intermediate stages. Instead, certain genes are expressed farther back in the head of gnathostomes compared with lamprey embryos, which leads to different skeletal structures being generated by different parts of the neural crest between the two clades.

What Is Suction-Feeding Performance?

In general, generating high fluid speeds (due to negative pressure in the mouth cavity) during suction feeding is a good indication of suction-feeding performance. However, several other factors have been implicated in suction-feeding performance, including the ingested volume of water (IVW), the volumetric flow rate, strike accuracy, and fluid acceleration. The importance of these metrics depends on the ecology of the fish. For example, largemouth bass (*Micropterus salmoides*) depend strongly on a large IVW and high ram speeds in order to capture prey. For this species, maximum fluid speed is likely not as important for capturing prey. Thus, species-dependent metrics of suction-feeding performance are necessary to understand the feeding diversity of fishes.

Hydrodynamics of Suction Feeding

Modern techniques have greatly enhanced our understanding of feeding mechanics in fishes. One such area that has contributed substantially is hydrodynamics. Advances have emerged in both experimental and modeling techniques.

Visualization of Fluid Movement

The flow of water generated during suction feeding can be quantified using DPIV, which is a modern computational technique used to visualize the flow of fluids. This technique has recently been utilized to study the flow generated by suction in centrarchid fishes and sharks. The speed of the water being sucked into the fish's mouth is highest at the mouth aperture and decays rapidly moving away from the fish's mouth (**Figure 3**). Thus, suction feeding is most effective when the mouth of the predator is in very close proximity to the prey item.

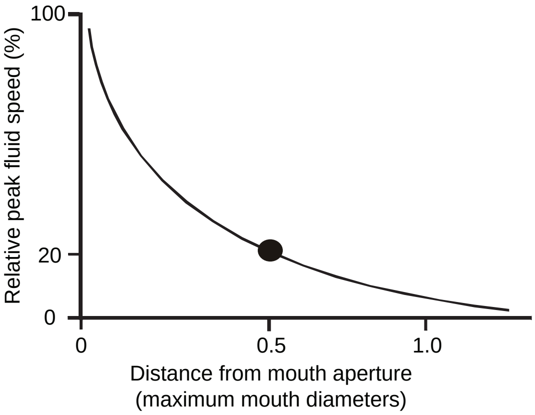

Figure 3 The general relationship between fluid speed and relative distance from the mouth opening (aperture). Fluid speed drops off exponentially going away from the mouth aperture, highlighting the importance of being close to the prey item for succesful suction feeding. The black circle indicates the location that fluid speed is typically measured using digital particle image velocimetry (DPIV).

Direct measurements of fluid flow permit the calculation of the ingested volume, which is strongly correlated with mouth size. Because the flow of water is unidirectional in fishes (i.e., flows in the mouth and out the opercular cavity), the amount of water ingested can exceed the size of the buccal cavity. In addition to the size, one can also calculate the shape of the IVW, which is strongly influenced by swimming speed.

Swimming during suction feeding can alter the hydrodynamics of suction feeding. Direct measurements from bluegill sunfish and largemouth bass indicate that, as swimming speed increases, the ingested volume becomes increasingly narrow and elongate (**Figure 4**). For further details, see section The Integration of Locomotion and Feeding.

Modeling

When experimental measurements are difficult (or impossible) to obtain, modeling the flow of water becomes increasingly informative. In addition, modeling allows one to predict the effects of manipulating a single variable while holding everything else constant. Modeling can ultimately provide insight into animal diversity and predator–prey interactions. Several attempts have been made to model the hydrodynamics of suction feeding in fishes. In the early 1980s, the expanding mouth cavity was

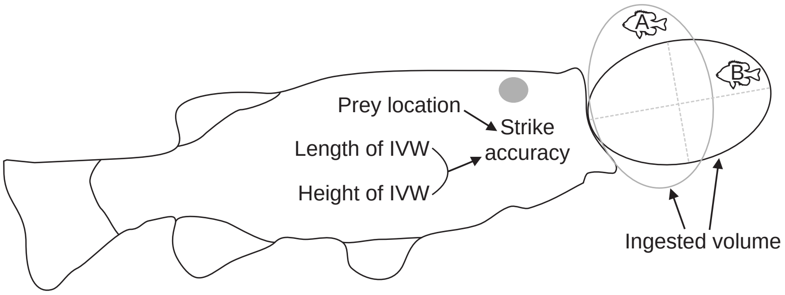

Figure 4 The influence of swimming (ram) speed on the shape of the ingested volume of water (IVW) and strick accuracy. In situation A, the forward swimming speed of the predator is negligible and prey item A is caught. However, prey B cannot be caught because the IVW is not long enough. In situation B, there is substantial ram speed and prey B is caught. However, prey A cannot be caught because the IVW is too narrow. Ultimately, the length of the IVW, and the location of the prey, will play a large role in capture success.

modeled as a single truncated cone with a gape (anterior end) and a posterior height. A number of input parameters define how the buccal cavity expands. This model yielded pressure and fluid speed for given dimensions and expansion profile of the feeding event. More than 20 years later, the model was modified to include three truncated cones connected in series.

Recently, the early model was tested by measuring both pressure and fluid speed simultaneously during suction feeding in largemouth bass and bluegill sunfish (*Lepomis macrochirus*). Pressure transducers were implanted through the dorsal aspect of the skull and they ultimately protruded into the buccal cavity. DPIV was used to quantify fluid speed. The dimensions of the buccal cavity, and the profile of expansion, were also used to predict fluid speed using the early model. Ultimately, the predicted values of fluid speed exceed those measured under *in vivo* conditions. Reasons that the model could not fully explain the actual fluid speeds may include complex patterns of expansion within the mouth cavity and/or unsteady flow normal to the long axis of the fish. However, more work is needed to understand the dynamics of water flow inside the mouth of a fish.

Another technique for modeling fluid flow during suction feeding is computational fluid dynamics - a branch of fluid dynamics that utilizes the incompressible Navier–Stokes equations, which govern the flow of water during suction feeding. An interesting conclusion from a recent study is that prey size is a very important factor when considering the timing and magnitude of peak forces exerted on prey. Based on modeling, it is apparent that peak force can be reached most quickly for prey items that are approximately 33% of mouth diameter. This has important implications for prey selection by fishes.

Ecomorphology of Feeding

The relationships between morphology and ecology, and ultimately performance, have been well studied in fishes. In particular, several studies have focused on the relationship between diet and structural aspects of the mouth. Recent work has provided a functional foundation for such studies, making the link between morphology and ecology more evident. For example, mouth size is strongly correlated with prey size such that species with larger mouths are able to ingest larger prey items.

Jaw lever mechanics are commonly studied in relation to ecology. One can measure the closing and opening in- and out-levers of the jaw, and then relate that to the diet or feeding style of the predator. In coral reef fishes of the Caribbean, species that use their oral jaws to grip, manipulate, bite, shred, or crush prey have very high jaw closing lever ratios. In contrast, those species that exhibit ram- or suction-based strike tactics exhibit much lower jaw closing ratios. Higher closing ratios indicate the ability to more efficiently transmit the force generated by the muscles to the tooth surface. Jaw opening ratios do not show an obvious pattern like the jaw closing ratios.

The ecomorphology of feeding in cottid fishes (sculpins) has also been examined in detail. The focus has primarily been on the species of the Northeastern Pacific. In these studies, a larger mouth was linked to feeding on more elusive prey (i.e., fishes, shrimp, mysids, and octopods). In addition to the general ecomorphological approach, functional studies have also been used to test whether the morphology exhibited by some species enhances their performance in an ecological context. Larger-mouthed species of sculpins exhibit significantly higher capture success on evasive shrimp than did smaller-mouthed species. This functional link is critical for providing a mechanism underlying the correlation between morphology and ecology.

Jaw Protrusion

As mentioned above, the flow of water generated by suction is limited to a narrow range outside of the fish's mouth. Thus, being able to get extremely close to a prey item is necessary for effective suction feeding. Jaw protrusion is one way in which the mouth can be extended closer to the prey without having to move the entire body (**Figure 1**). Taken another way, the predator could initiate a strike at a farther distance from the prey.

The ability of fishes to protrude their upper jaw has been cited as a key innovation that facilitated the trophic diversity among fishes. The premaxilla is rotated or pushed into an extended position, and multiple paths to jaw protrusion have evolved. The upper jaw movement can involve anterior, anterodorsal, or anteroventral aspects, and the lower jaw or mandible can pivot around a ball and socket articulation.

Recent work has revealed that jaw protrusion enhances forces exerted on a prey item. Although this had been suggested for quite some time, empirical data exploring the functional ramifications of jaw protrusion are limited. Utilizing a framework based on data from bluegill sunfish, a recent study utilized empirical data and simulations to calculate the contribution of jaw protrusion to the forces exerted on prey. The observed speed of jaw protrusion was positively correlated with the peak measured force on the prey. Ultimately, the independent source of acceleration provided by jaw protrusion can increase the total force on the prey by up to 35%.

The Integration of Locomotion and Feeding

For several reasons, locomotion is critical for most fishes to successfully capture prey. Locomotor performance (e.g., maximum swimming speed and maximum acceleration) will be important for overtaking an evasive or elusive prey item. In addition, controlling the locomotor system (e.g., stability and positioning) will play a significant role in the timing and accuracy of a strike, which will ultimately determine capture success.

Ram Speed

Although ram is often a component of a feeding event, the relative contribution can vary considerably. One ramification of increased ram speed is a decreased capture success. Among other things, swimming fast during prey capture decreases the time that the predator has to adjust its position relative to the prey. This can result in poor aiming and/or incorrect timing of mouth opening. One critical aspect of suction feeding that is altered with ram speed is the shape of the IVW (**Figure 4**). As a fish swims faster during feeding, the resulting IVW will be increasingly elongate and narrow. This is important with respect to positioning of the prey in front of the predator's mouth. If the prey item is located farther away from the predator, an elongated IVW will facilitate prey capture.

Pectoral Fins

As outlined earlier in this article, strike accuracy is necessary for successful prey capture in fishes, especially those species that rely heavily on suction. In acanthomorph fishes, the pectoral fins are well suited for braking without inducing any unsteady maneuvers because of their location relative to the fish's center of mass (**see also Buoyancy, Locomotion, and Movement in Fishes**: Paired Fin Swimming). For these fishes, the reaction force generated by the pectoral fins during braking goes through the center of mass, thus maintaining the fish's position. Many fishes brake during prey capture, but why they do this is still in question. One explanation is that braking reduces the approach speed, which will allow the predator to adjust its position relative to the prey. Thus, braking may increase capture success. Another possible benefit to braking during prey capture is that it puts the predator in a position to quickly maneuver and follow the prey if it escapes. Finally, braking might prevent a collision with the substrate (if the prey is located close to structure), which will ultimately prevent injury.

Future Directions

Where is the field of feeding mechanics in fishes headed? With an increased understanding of the hydrodynamics and mechanics of suction feeding, we are now poised to explore the incredible diversity that is evident in the many thousands of extant species of fishes. In addition, few studies have attempted to understand the evolution of feeding mechanics, in part due to the incomplete understanding of the mechanics and also a lack of well-resolved phylogenies. This will be a fruitful area of research in the future. Finally, although we know much about the feeding and locomotor systems, our understanding of how multiple complex systems are integrated is poor. How do fishes move and rapidly expand their mouths with coordinated timing? What underlying neural control mechanisms permit the simultaneous actions of the systems?

Glossary

Bioinspiration The analytical and synthetic process by which biologists and engineers extract functional principles from biological systems and instantiate those principles in engineered systems.

Biomimetics The analytical and synthetic process by which biologists and engineers duplicate biological structure, function, or both.

Instantiate To represent an abstract concept with a concrete example.

Robot A whole fish or part of a fish that is modeled digitally, using a computer-based simulation, or physically, using a mechanical device. The modeled whole or part moves and thus interacts mechanically with the environment.

Fish and Robotic Fish

Biologists classify fish as propulsive machines of two types: (1) body-caudal fin swimmers (BCF), who use body undulations and oscillations of the caudal fin (**see also Buoyancy, Locomotion, and Movement in Fishes:** Undulatory Swimming) and (2) median-paired fin swimmers (MPF), who use any combination of pectoral, pelvic, dorsal, and anal fins to produce thrust (**see also Buoyancy, Locomotion, and Movement in Fishes:** Paired Fin Swimming). Many species combine BCF and MPF mechanisms, using BCF swimming for cruising and escape and MPF swimming for station-holding and maneuvering in tight quarters (**see also Buoyancy, Locomotion, and Movement in Fishes:** Maneuverability and Stability and Turbulence).

Biological targets for BCF robotic fish have included lamprey (unspecifed species of the order Petromyzontiformes), eel (unspecifed species of the order Anguilliformes), sea bream (unspecified species of the family Sparidae), koi carp (*Cyprinus carpio*), coelacanth (*Latimeria chalumnae*), pike (unspecified species of the family Esocidae), trunkfish (unspecified species of the family Ostraciidae), and tuna (unspecified species of the family Scombridae). Biological targets for MPF robotic fish have included bluegill sunfish (*Lepomis macrochirus*), bird wrasse (*Gomphosus varius*), stingray (unspecified species of the family Dasyatidae), manta ray (*Manta birostris*), and knifefish (unspecified species of the order Gymnotiformes).

The first robotic fish is a subject of controversy. RoboTuna is often given credit as being the first. Working in the laboratory of Michael S. Triantafyllou at the Massachusetts Institute of Technology (United States), David Barrett began creating Charlie I, the first RoboTuna, in 1993. Charlie I undulated like a BCF fish (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming) in the water as it was towed from above on a gantry. Charlie I and then II provided the foundation that allowed Jamie Anderson of Draper Laboratories (United States) to build a self-propelled BCF descendent of the original RoboTunas, the Vorticity Control Unmanned Undersea Vehicle (VCUUV). In 1998, the VCUUV swam for the first time under its own power in a pool.

Some people consider the first robotic fish to be TwiddleFish. Invented by Charles Pell and Stephen Wainwright, the self-propelled BCF TwiddleFish was designed at Duke University (United States). Working with graduate students, the duo hit upon the simple idea that a fish-shaped piece of rubber would generate undulatory waves in water if the fish was actuated by an oscillating torque within the head. By 1995, Pell published a scientific paper using the TwiddleFish platform to study how changes in a fish's body stiffness control swimming performance. Descended from the TwiddleFish is the Nektor, a class of flapping flexible foils used as thrusters on underwater vehicles, instead of rotary propellers, when high-performance maneuverability is desired.

Working robotic fish are found in the entertainment industry as well as in academia. For example, autonomous, self-propelled BCF robotic fish swim with adaptive behavior in the London Aquarium. These entertainment robots were created by researchers at the Human Centered Robotics Group at Essex University (United Kingdom), under the leadership of Housheng Hu. The first robotic fish built for aquarium markets was the sea bream, a collaboration of Yuuzi Terada, Fukui University of Technology (Japan), and Ikuo Yamamoto, Mitsubishi Heavy Industries (Japan). By 2003, they and their collaborators had BCF robotic sea bream and coelacanth swimming in specially designed tanks that allowed the behavior of the robotic fish to be externally controlled.

In China, Wang Tainmiao, of Beijing University of Aeronautics and Astronautics, and Tan Min, of the Chinese Academy of Sciences, built a BCF robotic fish, SPC-03, for underwater archeology; it has operated successfully in exploration missions. Kristi Morgansen, University of Washington (United States), built a coordinated school of three self-propelled, autonomous, and communicating BCF/MPF robotic fish. In a multinational project, FILOSE, sponsored by the European Union (Seventh Framework Programme), Maarja Kruusma, Talinn University of Technology (Estonia), is coordinating biologists and engineers from the Italian Institute of Technology (Italy), Riga Technical University (Latvia), the University of Verona (Italy), and the University of Bath (England). They are designing a biomimetic lateral line and a BCF robotic fish to go with it; using the lateral line, the robotic fish will sense currents, detect objects, swim efficiently, and navigate.

Biomimetics as an Approach to Fish Robotics

Why make robotic fish? Researchers build robotic fish for three main purposes: (1) to test biological hypotheses about propulsion, perception, behavior, and evolution of fishes; (2) to engineer biologically inspired propulsion, perception, and behavior into underwater vehicles; and (3) to serve as objects of entertainment. Built for whichever purpose, robotic fish are, by definition, biomimetic.

The term 'biomimetics' refers to the process by which biologists and engineers duplicate biological structure, function, or both. To differentiate duplication *per se* from emulation, some researchers use the term 'bioinspiration', the process by which biologists and engineers extract functional principles from biological systems and instantiate those principles in engineered systems. The level (size, process, material, or element) of structural or functional duplication or inspiration is determined by the investigator's goals and knowledge of the biological source.

Among biologists, controversy exists about whether structure and function can be analyzed and duplicated independently or if structure and function occur only in one-to-one causal mappings. Functionalists argue that many different mappings exist: single structures may be capable of having multiple functions and multiple structures may be capable of having identical functions. This functionalist framework forms the premise for most work in biomimetics, since the biological target can, strictly speaking, only satisfy one-to-one mapping by duplication via reproduction. Duplication via engineering uses materials that are often nonbiological and are rarely identical to those of the biological source. Inspiration, by definition, assumes that many different kinds of structure can implement the same function.

Classification of Fish Robots

Within the fields of robotics, artificial intelligence, engineering, and biology, no single definition of 'robot' exists. For biologists interested in fish, 'robot' can mean a whole or part of a fish that is instantiated digitally, using a computer-based simulation, or physically, using a mechanical device. Robotic fish can be distinguished by the following dimensions:

1. proportion of fish (states: whole or part);
2. instantiation (states: mechanical, digital, or combination);
3. propulsive mode (states: self-propelled, towed, or tethered);
4. propulsive mechanism (states: body-caudal fin, median fin (s), paired fins, or combination);
5. control type (states: autonomous, remote-controlled, or open-loop);
6. control architecture (states: behavior-based, cognitive, or combination);
7. energy source (states: internal or external);
8. processor type (states: analog or digital);
9. processor location (states: internal or external);
10. actuator types (states: hydraulic, pneumatic, electric, polymeric, shape-memory alloy, piezoelectric, or combination);
11. actuator location (states: internal or external);
12. sensor types (states: single, paired, array, and/or various);
13. sensor locations (states: internal, body surface, and/or off-vehicle);
14. chassis type (states: rigid with hinges, flexible without hinges, or combination);
15. habitat (states: benthic, pelagic, surface, amphibious, or combination);
16. behavior types (states: navigation, escaping, exploring, schooling, other, or combination);

17. purpose (states: hypothesis-testing, commercial application, entertainment); and
18. biological target (states: structure, function, taxon, or combination).

The remainder of this article focuses on mechanical instantiations of robots.

Design of Fish Robots

The design process varies depending on the purpose of the robot (see item 17, above) as determined by the investigator or engineer. Options are constrained by practical considerations.

For hypothesis testing, the investigator must first generate or select a hypothesis that can be tested using robots. Hypotheses about the mechanics and control of swimming abound (**see also Buoyancy, Locomotion, and Movement in Fishes:** Maneuverability), Stability and Turbulence, Undulatory Swimming, and Paired Fin Swimming) and many of these hypotheses are testable with robots. Examples of robotically testable hypotheses include: (1) propulsion is mediated by vortex shedding at the trailing edges of fins; (2) gliding performance can be controlled by lifting surfaces on the body or fins; (3) lift-based flapping in fins produces more propulsive work than drag-based rowing; and (4) turning in yaw is enhanced by reducing the mass moment of inertia of the body.

For commercial application, the engineer must first identify one of the following: (1) a function of a fish or function within a fish that is novel to engineering and can be reduced to a mechanical or mathematical principle; (2) a behavior of a fish or system of fish that is novel to engineering and can be reduced to an algorithm; and (3) a structure of a fish that is novel to engineering and can be duplicated in other materials.

In practice, biologists and engineers often collaborate. Biologists bring expertise about fish, ecology, performance, and evolution. Engineers bring expertise about constructing the mechanical, electrical, and software systems. Also, cognitive scientists, computer scientists, and artists can be found on many design teams.

Following the hierarchical analytical approach of David Marr, the design team must answer the following questions within their purpose-specific framework:

1. What function(s) or behavior(s) will the robot perform? The answer to this question is informed by the hypothesis to be tested or the function or behavior to be targeted for application.

2. How, in terms of mechanical and algorithmic processes, will the robot accomplish the desired function(s) or behavior(s)? This level of design decomposes the overall design into information flow, interactions of physical subsystems, and the conceptual choices needed on each design dimension (see list of 18 dimensions in previous section). If the desired function(s) or behavior(s) require an autonomous, self-propelled robot, it is crucial at this stage of design to recognize that behavior depends on the robot's interaction with a specific environment. Because behavior cannot be fully predicted on the drawing table, it is likely that the team will iterate between this level and the next (number 3, below) during prototyping.

3. How will the robot be physically implemented? This is the level of engineering design, and the question can only be answered once the higher-level questions are addressed and specifications are created. Referring to the 18 dimensions of classification (see previous section), decisions must be made about specific hardware and software. The team must procure or create motors, sensors, power source, computer, and mechanical mechanisms that meet the specifications identified at the previous level.

Beyond these general guidelines, the specifics of the design process are different for every new robotic fish. To demonstrate different design processes and systems, two case studies are given in the next sections.

Case Study 1: Testing Biological Hypotheses Using Evolving Robots

One use of robotic fish is to reconstruct the ecological and evolutionary situation in which extinct species might have evolved structural and functional characters. Researchers at Vassar and Lafayette Colleges (United States) were interested in the evolution of vertebrae and caudal fins, macroevolutionary events that began in the earliest vertebrates, the jawless fishes of the Cambrian and Ordovician Periods that lived as long as 530 million years ago. The first vertebrates had no vertebrae and had caudal fins that tapered to a point. From these ancestral states, vertebrae and flared caudal fins evolved over the next 100 million years. The biological question was: what are the plausible selection pressures that might have increased the number of vertebrae (reducing the size of the intervertebral joints) and the span of the caudal fin?

Because predation is a powerful selection force in the evolution of living fish, such as the guppies of Trinidad, the researchers hypothesized that predation was likely to have been important in the fossil fish, too. Recognizing that prey, and not just the predator, must also eat, the team generated the following hypothesis:

selection for enhanced foraging and predator avoidance in a population of prey robots will evolve an increase in the number of vertebrae (=smaller intervertebral joints) and an increase in the span of the caudal fin (=larger flare). The connection between selection and the change of structures was detailed in two functional hypotheses: (1) increasing the number of vertebrae stiffens the axial skeleton, increasing elastic energy storage and (2) increasing the span of the caudal fin increases the thrust power.

For the design of a robotic system, the team decided that they needed an autonomous, self-propelled prey robot that could eat and avoid being eaten. This answered Marr's design question one (see previous section). To accomplish this task (Marr's question number two), the team decided to build a fish robot that would seek light as the equivalent of foraging; for predation avoidance, the robot would detect an approaching predator robot and then escape. Drawing from what is known about the neuro-motor patterns of swimming fish that perform an escape maneuver while cruising, the team wanted the prey robot to have its escape behavior override its foraging behavior. They also decided that they would build a predator fish robot that would not evolve; its only function would be to chase the prey robot and attempt to ram it. To swim, the prey robot needed to have a propulsive, undulating tail that could vary in number of vertebrae and span of the caudal fin. Finally, the characters needed to be genetically coded; genes needed to go through biological processes such as mutation, independent assortment, and gametogenesis. Random mating would also be conducted, with breeding parents determined by evolutionary fitness.

To address Marr's third design question, about physical implementation, the team decided to build the vertebral column and caudal fin as a biomimetic tail (**Figure 1**). The tail was built to be attached to a motorized shaft that input a sinusoidal bending couple that propagated down the tail as an undulatory wave, resulting in the caudal fin moving laterally and generating propulsion. The tail and caudal fin generated thrust and turning moments for steady cruising used during foraging; the tail and caudal fin also created the rotational forces used during an escape maneuver. The tail was driven by a servo motor attached to a round plastic bowl that acted as a hull for the surface-swimming robots (**Figure 2**). In the prey robot, two paired photoresistors acted as light-detecting eyes, and laterally placed infra-red proximity detectors acted as a predator-detecting lateral line. These sensors were monitored by an on-board microcontroller programmed to have the robot seek light in the absence of the predator and avoid the predator when it was detected. Power for the robots was also on-board in the form of batteries. The genetics were implemented on a separate computer using a genetic algorithm approach, with number of vertebrae, tail span, and predator detection threshold each coded as quantitative traits on separate chromosomes. Random mutation occurred during gametogenesis. A population size of 18 prey robots was used, with six different genotypes each cloned in triplicate to provide replication. A single predator robot was built. All experiments were conducted in an artificial ecosystem, a 3.1-m diameter aquaculture tank painted matte black to minimize reflections from the single over-hanging light source.

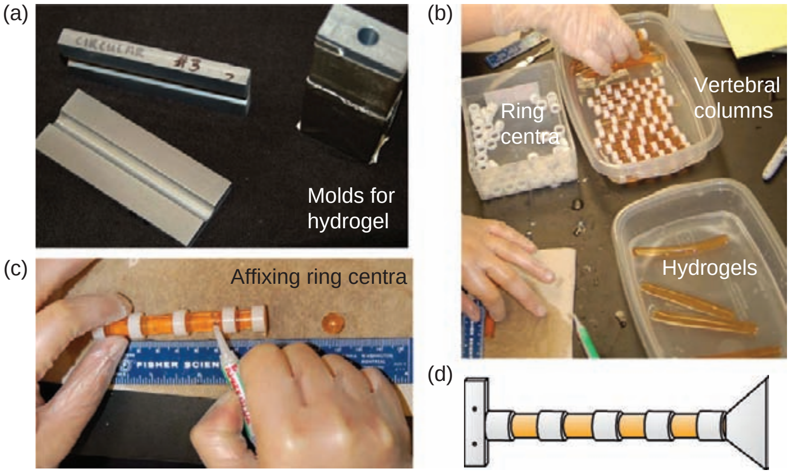

Figure 1 Building a biomimetic tail for a self-propelled fish robot: (a) Right, circular hydrogels are created from gelatin in molds. The hydrogels are cross-linked to achieve the desired Young's modulus. (b) Hydrogels are cut to size and then turned into vertebral columns by adding ring centra. (c) The ring centra are affixed using cyanoacrylate glue. (d) The final tail has a caudal fin (to right) and a grip (to left) by which to attach the tail to the robot's servo motor. Depending on a combination of random (mutation, drift, and reproduction) and deterministic (selection) processes, the number of vertebrae and caudal fin span for any individual varies from 2 to 13 and 0 to 50 mm, respectively. Photos by John Long; tail illustration by Hannah Rosenblum.

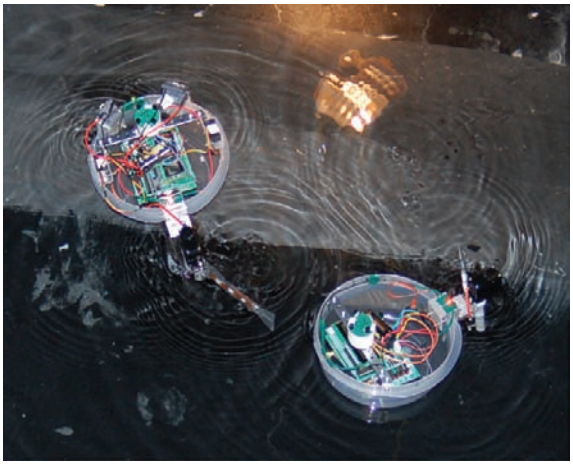

Figure 2 Biomimetic, self-propelled, and autonomous fish robots in action. A prey robot (upper left) and a predator robot (lower right), were built to test the hypothesis that the number of vertebrae and size of the caudal fin span increased in a population of prey as an evolutionary response to selection for improved foraging and predator avoidance. Note the biomimetic tail (see **Figure 1**) propelling the prey robot. In this selection experiment, the prey robot finds and orbits the light source (reflection in upper right) while being tracked by the predator (lower right). These biomimetic robots have control, energy, and actuators located on-board. Sensors include photocells, infrared proximity detectors, and TR-tracking Sensors. Photo by John Long.

For each generation, each of the 18 individual prey robots was tested in a 3-min trial with the predator. Overhead video and an on-board accelerometer were used to log information about the prey's speed, average distance to the light source, average distance from the predator, number of escape maneuvers initiated, and maximum acceleration during the escapes. These metrics were combined in a compound fitness function that rewarded individual genotypes, relative to other genotypes in that generation. The genotypes with the top three fitness values were permitted to breed. For the next generation, new offspring genotypes provided instructions for the new 18 prey robots.

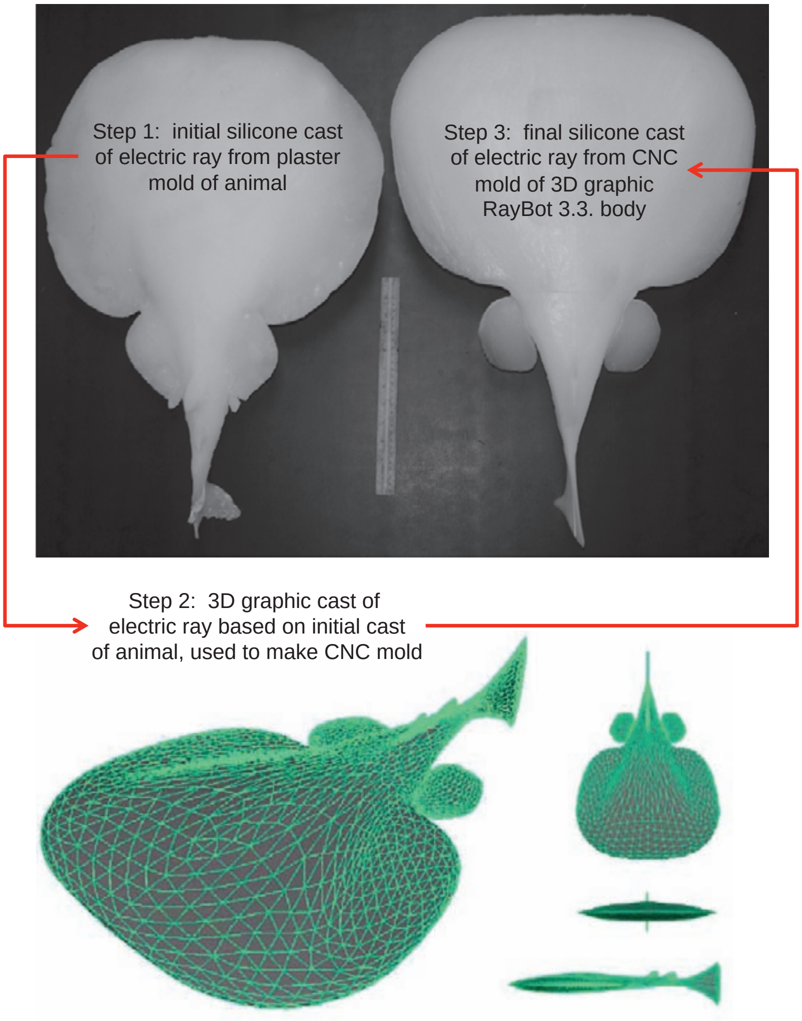
Under these experimental conditions, the team found support for the hypothesis. Selection for enhanced foraging and predator avoidance resulted in an evolutionary response by the population: the mean number of vertebrae and the mean caudal fin span increased. This result suggests that the following scenario is plausible: selection for enhanced foraging and predatory avoidance in ancient vertebrates drove the evolution of vertebrae and caudal fins. Note that the researchers do not claim that this is what happened, only that they were unable to eliminate this particular selection scenario as possible.

Case Study 2: Engineering Fish-like Vehicles for Near-Shore and Benthic Operations

One use of robotic fish is to build a mobile instrument platform that combines low-power swimming, high maneuverability, and stable benthic station holding. Benthic interactions are particularly important in near-shore coastal environments that contain and combine high-energy tides, currents, surf, obstacles, and fixed and mobile marine structures. This zone, which includes busy harbors, rivers, and beaches, is the focus of terrestrial–marine interactions, and humans need mobile instruments that allow detection, tracking, and mapping of phenomena such as thermal gradients, salt isoclines, and seepage or spills. To build a mobile instrument platform for this environment, researchers and engineers at Vassar College and IntelliTech Microsystems (United States) collaborated to build a biomimetic fish robot designed to be a commercial-grade autonomous, underwater, and self-propelled vehicle.

To satisfy as many of the requirements for working in the nearshore zone as possible, the team sought a biological target. Skates (order Rajiformes) and rays (order Myliobatiformes) were a tentatively identified because they live in the zone, are stable on sandy bottoms by virtue of burrowing, and are maneuverable. Both groups were disqualified after considering implementation problems: members of those orders undulate or oscillate their body disk for propulsion, and this motion is either (1) difficult to emulate or (2) disruptive of payloads that might be housed in the body disk. Both of these implementation difficulties were obviated by the choice of electric rays (order Torpediniformes), because electric rays possess many of the desired engineering features: (1) propulsion by an undulatory tail that is independent of the nonpropulsive body disk; (2) the body disk houses a nonpropulsive payload, the electric organs; and (3) mid-water swimming is combined with high maneuverability in yaw and low-power station holding via benthic burrowing.

Duplication of an electric ray was not the goal for the team. In response to Marr's first design question (see section above) – what function(s) or behavior(s) will the robot perform? – the team decided to focus on the functions of propulsion, maneuverability, and simple gradient navigation for the first prototype, named RayBot. In terms of Marr's second design question – how will the robot accomplish the desired function or behavior? – the team decided to build an autonomous and self-propelled robot, to drive it with a biomimetic actuator connected to an undulatory tail, to house the actuator within the body of the robot, to place power and control on-board, to build the body of the robot as a single flexible unit shaped like an electric ray, to design the body disk to bend its trailing edges for



Step 1: initial silicone cast of electric ray from plaster mold of animal
Step 3: final silicone cast of electric ray from CNC mold of 3D graphic RayBot 3.3. body
Step 2: 3D graphic cast of electric ray based on initial cast of animal, used to make CNC mold

Figure 3 Creating a biomimetic commercial fish robot, RayBot. Step 1: a rubber cast made of a real electric ray (*Torpedo nobiliensis*) was the physical model for our 3D graphic. Step 2: From the electric ray cast, a 3D computer graphics cast was created. The 3D coordinates were then used by a CNC milling machine to cut a mold. Step 3: using the CNC mold (see **Figure 4**), the final body of RayBot was cast using a flexible silicone (Dragon Skin, Smooth-On Inc., Easton, PA). Since the initial cast contained asymmetries and transitions difficult to machine, the 3D graphic representation was a simplification. RayBot is collaboration between Vassar College and IntelliTech Microsystems. Figure created by John Long and Joshua de Leeuw.

control of maneuverability and body lift, to make the body negatively buoyant so that station holding on the bottom could occur passively, and to equip RayBot initially with simple paired sensors for navigation up or down light gradients.

Physical implementation of RayBot – the topic of Marr's third design question – centered around the design of the ray-like flexible body (**Figure 3**). The team acquired a large (50-cm-wide body disk) electric ray, *Torpedo nobiliensis*, from the Marine Biological Laboratory, Woods Hole, Massachusetts. A mold of this ray was made using plaster of Paris. From the mold, the team created a flexible silicone-based cast (Dragon Skin™, Smooth-On Inc., Easton, PA). The problem with the cast was its asymmetry; bulges and concavities on the body's surface were created by the displacement of viscera during mold making. To overcome these asymmetries, the team used the Dragon Skin™ cast as the model to create a three-dimensional (3D) rendering of the ray's surface (**Figure 3**) using Autodesk® Maya® (San Rafael, CA) 3D modeling software. This 3D rendering was a simplification of the real electric ray, with paired and median fins reshaped to allow the machining of a mold. The coordinates for the 3D rendering were transferred to a three-axis computer-numerically-controlled milling machine, which then cut the nine-piece mold. The nine-piece mold was assembled, including the internal housing and actuator system, and filled with Dragon Skin™. The resulting 50 cm × 75 cm, 5.5 kg cast was a single piece with the embedded payload, actuator, and microcontroller (**Figure 4**).

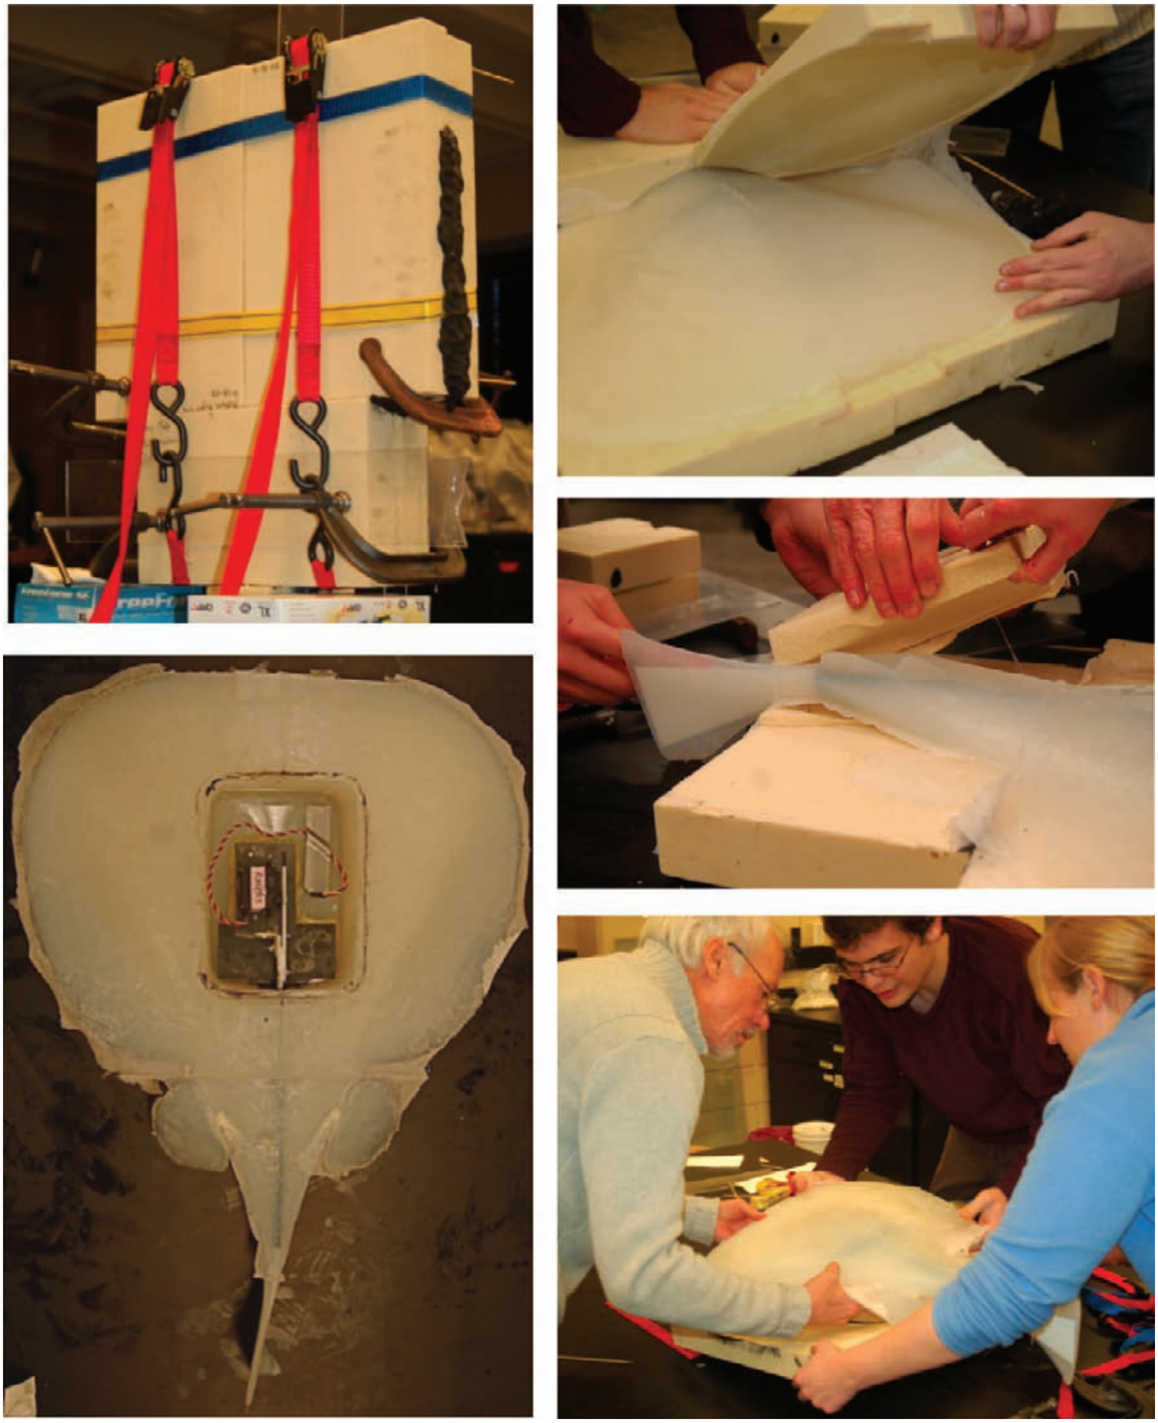


Figure 4 Casting the flexible body of RayBot. Clockwise from upper left: the mold machined to create the negative form of the 3D graphic model (see **Figure 3**) was assembled and filled with Dragon Skin (Smooth-On Inc., Easton, PA). Once set, the mold, in nine pieces, was removed and the body was freed. Lower left: ventral view of the cast body, untrimmed, showing the central payload for the servo motor and microcontroller. Also visible is the fin-shear actuation system that extends from the payload to the caudal fin, a system that permits a single, centrally located motor to drive bending distributed along the tail's axis. Photos by John Long.

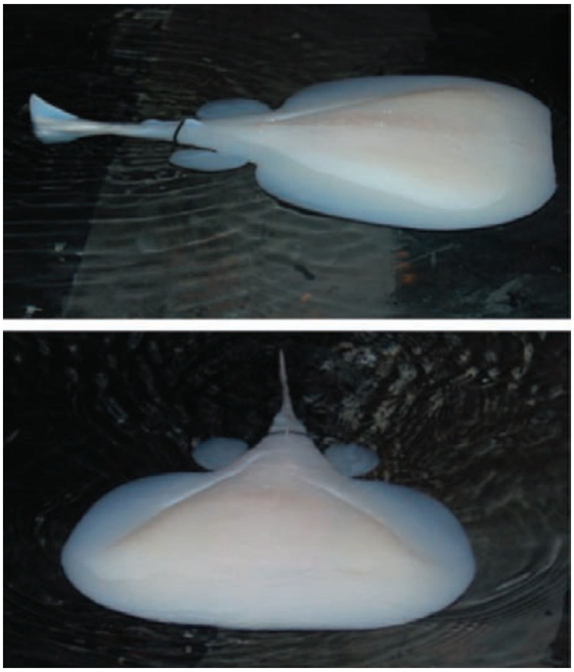

Figure 5 RayBot swimming. RayBot is self-propelled, autonomous, with control, energy, and actuators located onboard. Designed to be a submerged swimmer with benthic station-holding capabilities, RayBot is shown here swimming at the surface at the start of a mission. Sensors include photocells for navigation by light-gradient tracking. Photos by Joshua de Leeuw.

The actuator was a fin-based shear mechanism, inspired by the biomimetic work done in the laboratory of George Lauder at Harvard University. The RayBot team used a single servo motor to shear a movable shaft held parallel to a fixed shaft; with the parallel shafts attached distally and the shear of one causes the two to bend. With this implementation, a single, centrally located motor can do mechanical work on the flexible tail, creating undulations that propel and steer RayBot (**Figure 5**).

To measure RayBot's steady swimming performance, the team attempted to alter two kinematic variables that fish use to modulate steady swimming speed: tail-beat frequency (Hz) and tail-tip lateral amplitude (cm). Tail-beat frequency was altered by changing the drive signal to the servo motor. Top steady swimming speeds were obtained at an intermediate tail-beat frequency of 1 Hz (**Figure 6**(**a**)). The team attempted to alter tail-tip amplitude by driving the rotary servo pinion, attached to a rack that drove the fin-shear actuator, through high and low drive cycles of 22.5° and 45°; only at the performance peak of 1 Hz did the two drives yield different speeds (**Figure 6**(**a**)). Moreover, only when swimming with the low actuator drive did RayBot's speed increase linearly with increasing tail-tip amplitude (**Figure 6**(**b**)). The complexities in locomotor control are explained, in part, by the relation between tail-beat frequency and tail-tip amplitude (**Figure 6**(**c**)): as tail-beat frequency increased, tail-tip amplitude decreased, most likely as a result of increased hydrodynamic loading (added mass) with increasing accelerations. Programming RayBot to accelerate and then glide provided a method for estimating the robot's drag coefficient (**Figure 6**(**d**)). While able to swim, glide, and perform turning maneuvers with low power consumption, RayBot currently lacks the range of swimming behaviors and performance seen in real electric rays.

Robotic Fish: The Next Generation

The race has begun. Multidisciplinary teams of academic researchers and industrial engineers from around the world, fueled by funding from governments and industries, are competing to create the next generation of robotic fish. While the purposes of these fish vary from testing biological hypotheses, to engineering new exploratory vehicles, to creating fresh entertainment experiences, two themes are likely to emerge.

The first theme is that robotic fish will move into the wild. This migration from the controlled environment of the laboratory to the complex and variable world of rivers, lakes, and oceans is perhaps the biggest promise made by today's robot builders. Robotic fish will become the working tools of ecologists, fisheries managers, oceanographers, marine archeologists, ocean engineers, and navies. Highly maneuverable, stealthy, and energy efficient, these mission-capable robotic fish will carry a new generation of underwater sensors and be propelled by novel bioinspired and biomimetic actuators, tails, and fins.

The second theme is that robotic fish will become autonomous. Using the principles of artificial intelligence and embodied cognitive science that have been deployed effectively in robotic automobiles and the Mars Exploration Rovers, autonomous robotic fish, operating in the wild, will be programmed to make decisions on their own. In real time, robotic fish will use their on-board intelligence to decide how to navigate unfamiliar terrain and how to adjust to unexpected events. This autonomy will extend their mission time, increase their reliability, and, most importantly, increase the complexity of their activities.

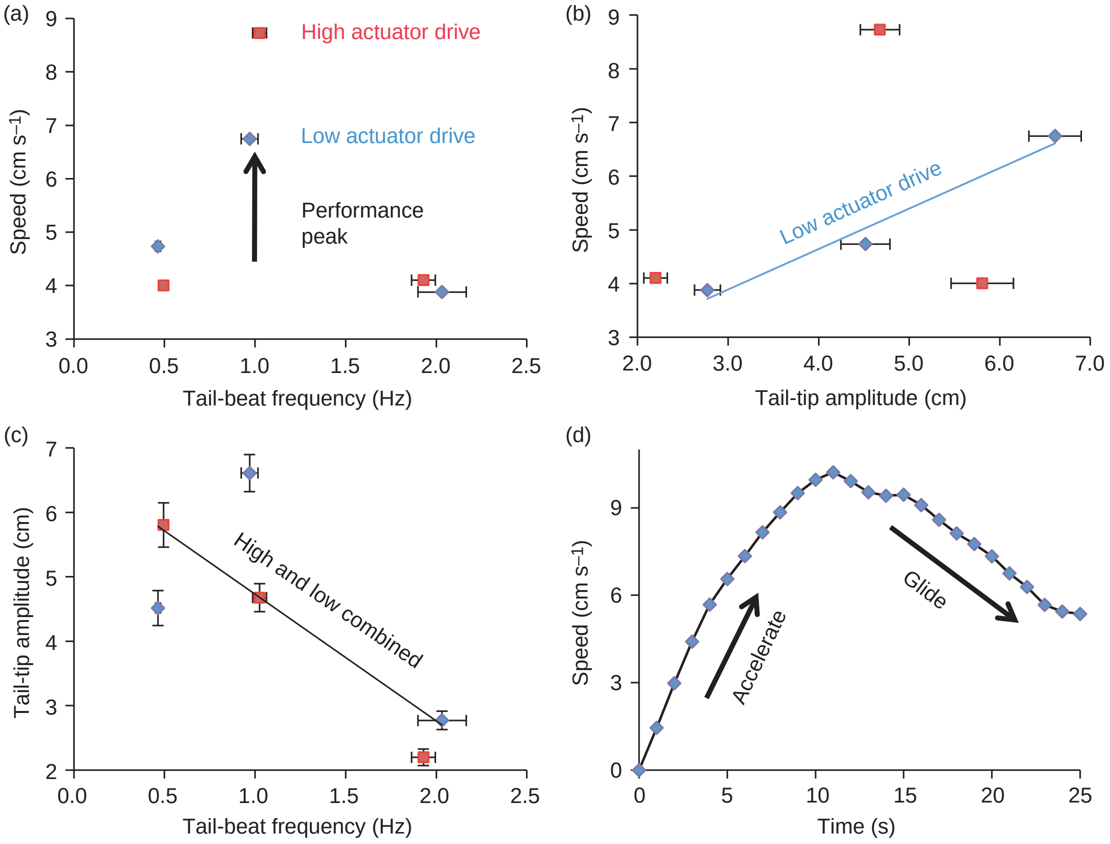

Figure 6 RayBot's performance as a self-propelled undulatory swimmer. (a) During steady swimming, RayBot swims fastest at the intermediate tail-beat frequency of 1.0 Hz. At peak performance, high actuator drive (±45° rotation of servo driving fin-shear mechanism) increases swimming speed relative to low actuator drive (±22.5°). (b) Tail-tip amplitude is proportional to swimming speed (slope of 0.75) in the low actuator drive. (c) In both high and low drives, tailtip amplitude decreases with increasing tail-beat frequency (combined slope of −1.97). (d) RayBot can be programmed to swim unsteadily, accelerating from rest and then gliding. Over the acceleration period, average acceleration is 0.93 cm s–2; average acceleration during the glide phase is –0.35 cm s^{-2}. Drag on the decelerating body was 0.02 N, which yielded a drag coefficient (based on projected area) of 0.032, in the range expected for streamlined bodies. Error bars (±1 standard error) represent within-trial variation; a total of six trials are shown for steady swimming. Figure created by John Long.

Glossary

Embryogenesis Stages of development between fertilization and hatching.

Gonochorism Sexual pattern in which individuals mature as one sex and remain that sex.

Gynogenesis Formation of offspring possessing only maternal genetic information; a type of parthenogenesis where embryogenesis is triggered by the presence of sperm, although the sperm does not contribute any genetic material.

Hermaphroditism Sexual pattern characterized by individuals that function both as males and females either simultaneously or sequentially.

Iteroparous Capable of reproducing more than once (usually many times) in a lifetime.

Ovoviviparity Production of eggs that develop and hatch within the mother before being released as live young to the external environment.

Oviparity Production of eggs that develop and hatch after being released into the external environment.

Parthenogenesis The ability of an egg to develop without contribution from sperm.

Semelparous Capable of reproducing only once in a lifetime, usually just before dying.

Vitellogenins Precursors of the major egg yolk proteins comprised of up to five different domains, each of which corresponds to one of the stored yolk proteins (see also yolk proteins). Vitellogenins are large (> 350 kDa), homodimeric hospholipoglycoproteins. Common abbreviations for vitellogenin are Vg, VG, and Vtg.

Viviparity Production of live young that develop before being released into the external environment.

Given that there are well over 25 000 species of fish, it is perhaps not surprising that reproductive strategies in fishes are extremely diverse. In some species, mating pairs form between fish that matured as either male or female, a strategy that we perhaps perceive as a normal breeding strategy where a male and female form a lifelong breeding pair. In complete contrast, other species can change from being male to female in a matter of seconds. External fertilization through the release of unguarded eggs and sperm is a common reproductive strategy in fish, yet many species give birth to live young or care for their offspring until or beyond the time they reach sexual maturity. The diversity is simply amazing.

Consideration of the diversity of fish reproductive strategies can be traced back over centuries, from Aristotle's observations of fish hermaphroditism to Darwin's interest in the ability of male seahorses to raise offspring in brood pouches. Many articles within this encyclopedia review one or more aspects of fish reproduction and the aim of this article is to provide a very brief overview of fish reproduction with links to other articles in the encyclopedia that cover this fascinating topic in more detail.

Many fish species mature into either a male or female (gonochorism) and, at the point of reproduction, males and females simultaneously release gametes (sperm and eggs, respectively) into the water (known as broadcast spawning), with fertilization occurring externally. For this process to be successful, sexually mature males and females of the same species must arrive in the same place at the same time and be able to coordinate the release of gametes. Some fishes release chemical cues into the water to attract mates (**see also Hormones in Communication:** Hormonal Pheromones) while others use signals such as sound (**see also Sensory Systems, Perception, and Learning:** How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling) and electricity (**see also** Shocking Comments: Electrocommunication in Teleost Fish) to attract and secure potential mates. Visual courtship displays have also been documented in a myriad of fish species (**see also Social and Reproductive Behaviors:** Sexual Behavior in Fish).

The production and release of gametes are controlled by hormones (**see also Hormonal Control of Reproduction and Growth:** Endocrine Regulation of Fish Reproduction), and during egg formation, females of most fish species will invest energy into future offspring by providing the egg with nutrient stores. The main yolk protein present in fish eggs is vitellogenin (**see also The Reproductive Organs and Processes:** Vitellogenesis in Fishes), and for eggs released into drifting currents to fend for themselves from the point of fertilization, this nutrient supply is a vital lifeline, allowing the embryo to develop and grow while obtaining a size large enough to be able to catch its own food. This nutritional investment by the mother enhances the likelihood that her genes will be passed on through generations; if her offspring successfully feed and avoid predation for a long enough period of time, they will then mature into sexually reproductive adults, (**see also The Reproductive Organs and Processes:** Anatomy and Histology of Fish Testis, and **Fish Migrations:** Tracking Oceanic Fish) and have the potential to reproduce themselves. The process of sex differentiation (**see also Hormonal Control of Reproduction and Growth:** Endocrine Control of Sex Differentiation in Fish) and the functioning of the reproductive system are strongly influenced by the environment and may be negatively impacted by both natural and anthropogenic influences (**see also Behavioral Responses to the Environment:** Anthropogenic Influences on Fish Behavior).

In some fish species that show external fertilization and broadcast spawning, groups of fish congregate together with the potential for sperm from one male to fertilize the eggs of many females and the eggs from one female to be fertilized by many males. In other species, one male and one female form a breeding pair where males will vigorously defend the female from other males. It is not uncommon, under these circumstances, for males of the same species to adopt alternative reproductive tactics. Here, intrasexual variation in reproductive behavior and phenotype occurs, with bourgeois males that actively compete among themselves for access to females unlike parasitic males that sneak in to fertilize a female's eggs, thereby exploiting the courtship and resources of the bourgeois male.

Not all fish are gonochoristic, that is, male or female. The ability to change sex (hermaphroditism) is common among some families of fish, including wrasses, parrot fishes, damselfishes, and gobies (**see also Social and Reproductive Behaviors:** Socially Controlled Sex Change in Fishes). Additionally, a few fish species are able to reproduce asexually without the egg having any contribution from sperm – this is known as parthenogenesis. In the Amazon molly, *Poecilia formosa*, females reproduce asexually; their eggs containing only female DNA. Interestingly, although there is no genetic contribution from male sperm during asexual reproduction of the Amazon molly, the presence of sperm from the males of closely related species is still required to trigger the development of the embryo (embryogenesis).

Not all oviparous fishes (those that release eggs) release their eggs unprotected into the external environment, leaving them to the mercy of prevailing water currents. Laying eggs on selected areas of substrate, or building nests to lay eggs in, provides offspring with additional protection (**see also Social and Reproductive Behaviors:** Sexual Behavior in Fish). Nest provision and design varies greatly from burying of eggs in gravel nests, as seen in salmon and trout, to the elaborate nests built by male sticklebacks, *Gasterosteus aculeatus*. Nests can also be used to remove offspring from detrimental water-quality conditions such as in the air-breathing catfish *Hoplosternum littorale* (**see also Behavioral Responses to the Environment:** Behavioral Responses to Hypoxia).

The location of offspring in one place, such as in a nest or more simply just attached to the substrate, allows parents to defend their young against predation during the early, more vulnerable, developmental period. Parental-care strategies in fishes are extremely diverse (**see also Social and Reproductive Behaviors:** Parental Care in Fishes) and may be carried out by the female, the male, or both parents. Types of care range from either guarding of eggs within a nest or fanning of eggs by parents to increase water flow, to complex cooperation behaviors among groups of fish where socially subordinate helpers work together to raise the young of more dominant breeding individuals.

Another way that parents can invest in offspring survival is through the additional provision of nutrients after hatch or through internal fertilization (**see also Social and Reproductive Behaviors:** Nutritional Provision During Parental Care). Particularly in sharks and rays, although eggs are produced, these are retained within the mother until after they have hatched. Following an internal developmental period where nutrients are provided by the mother, offspring are then released into the external environment as live young, a reproductive strategy known as ovoviviparity. True viviparity also occurs in fishes, with mothers developing placental relationships with offspring as seen in mammals.

The majority of fishes reproduce more than once in their life time (iteropary); although investment strategies in the future generation vary drastically from the release of hundreds of gametes for external fertilization on a regular basis with no parental care, to long gestation periods and low offspring numbers associated with viviparity. For a few fish species, the journey to reproductive success is extremely grueling (**see also Fish Migrations:** The Biology of Fish Migration). Several species of salmon migrate many hundreds of miles to spawning grounds undergoing complete osmoregulatory changes as they move through marine to freshwater environments and develop reproductively while no longer feeding (**see also Fish Migrations:** Pacific Salmon Migration: Completing the Cycle). These migrations can be so physiologically demanding that the journey to spawning grounds is made only once, leaving them only one opportunity to reproduce (semelparity) and pass their genes onto the next generation.

The collection of articles on aspects of fish reproduction within this encyclopedia provides an insight into the fascinating lives of fishes and the amazing variety of reproductive strategies that they employ. Yet, with fish displaying the widest diversity of reproductive strategies across all of the vertebrates, there is still so much that we have left to learn about fish reproduction.

Glossary

Crossing over An exchange of genetic material between homologous chromosomes.

Heterochromatin A tightly packed form of chromatin (DNA-protein complex) that is less accessible for the transcription of mRNA.

Self-renewal A process by which stem cells replicate themselves, maintaining, therefore, their pool in the tissue.

Spermatogenesis A cellular development during which spermatogonial stem cells give rise, via proliferation and differentiation steps, to a large number of sperm cells or spermatozoa. The germ-cell types formed successively during spermatogenesis are spermatogonia, spermatocytes, spermatids, and spermatozoa.

Spermatogonial stem cells The only stem cells in the body able to transmit genetic information to offspring. They are the foundation of spermatogenesis, being responsible for sustaining male fertility during the reproductive lifespan.

Stem cell Cell capable to both self-renew (in order to maintain their pool) and differentiate into a particular cell type. The balance between self-renewal and differentiation is crucial for tissue homeostasis.

Introduction

Sexual reproduction is the typical mode of reproduction in fish (**see also Hormonal Control of Reproduction and Growth**: Endocrine Control of Sex Differentiation in Fish); it requires eggs and sperm. Testes produce a large number of small gametes that evolved as motile genome vectors (spermatozoa), and ovaries produce a comparatively small number of large gametes (eggs) that are rich in reserves (**see also The Reproductive Organs and Processes**: Vitellogenesis in Fishes). This article describes the anatomy of teleost testis and sperm-duct systems, and then turns to the histological and morphological characteristics of male germ cells and to how these characteristics change during spermatogenesis. The crucial roles of a somatic cell type, the Sertoli cell, for germ-cell survival and development are also highlighted. Elsewhere (**see also The Reproductive Organs and Processes**: Regulation of Spermatogenesis), the testis is considered as an endocrine organ producing sex-steroid hormones and growth factors, and the roles of hormones and growth factors in the regulation of spermatogenesis are described. In both these articles, it is to be realized that fish are the most diverse and numerous group of vertebrates, and yet detailed knowledge on spermatogenesis and its regulation is limited to the few species used in basic and/or applied research. Hence, general statements often lean on information from only a handful of species from a few orders.

General Structure of the Teleost Testis

Following the general vertebrate scheme, the fish testis is composed of two compartments, the interstitial (or intertubular) tissue and the germinative (or spermatogenic) tissue (**Figure 1**). The interstitial compartment contains the steroid-producing Leydig cells, blood/lymphatic vessels, macrophages and mast cells, and neural and connective tissue elements, including the peritubular myoid cells (**Figure 1**); the connective tissue elements are continuous with the tunica albuginea, the testis organ wall. A part of the wall of the seminiferous tubules is a basement membrane that is formed by two cell types, the Sertoli cells in the seminiferous tubules, and the peritubular myoid cells in the interstitial compartment (**Figure 1**). The somatic Sertoli cells and germ cells are the only two cell types within the germinative compartment and they together form the germinal epithelium. In this epithelium, germ-cell survival and development depends on the constant and intimate contact with Sertoli cells (**Figure 1**). Depending on the age of the males, or the season, germ cells are found in different stages of spermatogenesis.

Central within, lateral to, and/or caudal of the testis, an efferent duct collects the spermatozoa formed by the spermatogenic tissue. The efferent duct also serves as a sperm storage site, participates in the control of the composition of the seminal fluid, and, thereby, determines the environment, in which capacitation (i.e., attaining the ability to fertilize eggs) of the spermatozoa occurs. Finally, the duct system transports sperm toward the genital pore for fertilization. In certain species, specialized tissue can differentiate along the efferent duct, which is then referred to as seminal vesicles.

Anatomy of the Testis, Efferent Duct, and Seminal Vesicles

Fish testes are usually elongated paired organs attached to the dorsal body wall by a fibrous sheath of connective tissue called mesorchium (**Figures 1** and **2**). In the

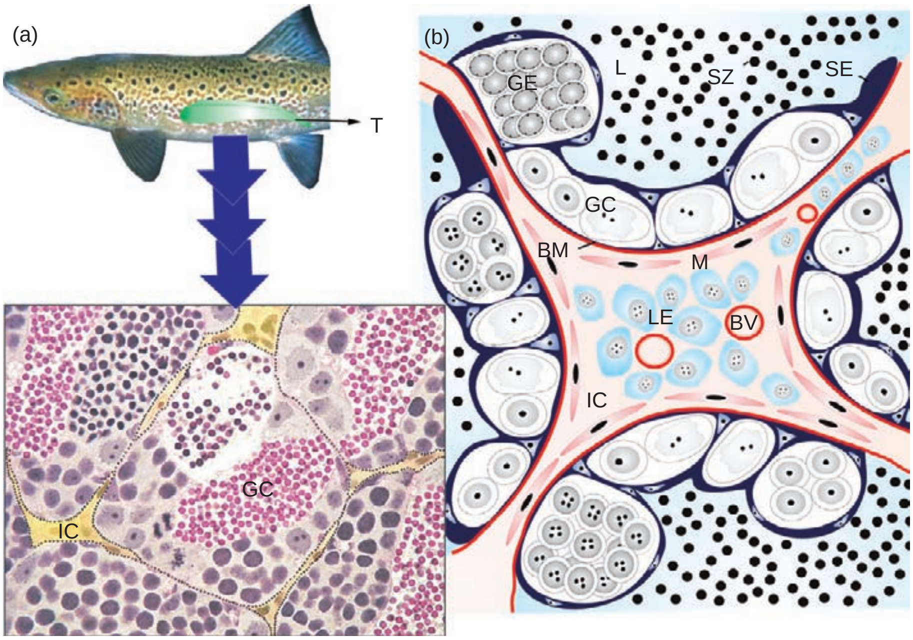

Figure 1 Schematic representation of the testicular structure in fish. (a) The fish testis (T) is divided into two compartments, the interstitial compartment (IC, yellow) and the germinative compartment (GC), separated from each other by a basement membrane (stippled line). (b) Schematic drawing of the two compartments. The interstitial compartment (IC) is composed of steroid-producing Leydig cells (LE, light-blue cytoplasm), blood/lymphatic vessels (BV), and connective tissue elements, including the peritubular myoid cells (M). The germinative compartment (GC) holds the germinal epithelium, formed by somatic Sertoli cells (SE, dark-blue cytoplasm) enveloping germ cells (GE) in different stages of development. Tubular lumen (L) and spermatozoa (SZ) are also shown. IC and GC are separated by a basement membrane (BM), which together with the layer of peritubular myoid cells, constitutes the wall of the spermatogenic tubules.

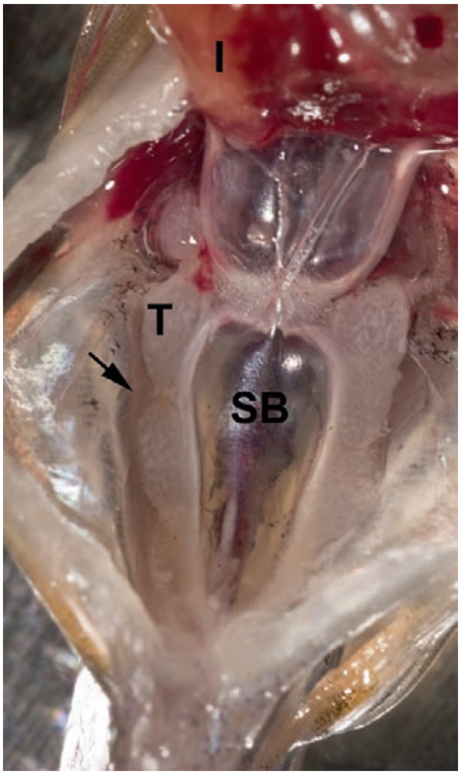

Figure 2 Zebrafish (*Danio rerio*) testis anatomy. Testes (T) are paired elongated organs (left and right) located ventral of the swimbladder (SB) and dorsal of the intestine (I), which was partially removed to expose the testes. The testes are attached to the dorsal body wall by the mesorchium (arrow).

coelomic cavity, the testes are located ventral of the swimbladder and dorsal of the intestine (**Figure 2**). The efferent duct arises from the meso/dorsal surface of each elongated testis, and continues into the spermatic duct that forms a short, unpaired segment before opening into the urogenital papilla (**Figures 3** and **4**). Together, the efferent and spermatic ducts form the testicular duct system, which transports sperm as well as is involved in storage, nutrition, and reabsorption of spermatozoa, secretion of seminal fluid, and induction of sperm motility by changing the ionic composition of the seminal fluid (**see also The Reproductive Organs and Processes**: Regulation of Spermatogenesis). Different variations of testes and testicular duct anatomy can be observed in different fish species. For example, in some species, for example, *poeciliids*, the two testes are fused to a single organ. In others, for example, in the order *Siluriformes*, it ranges from the basic type of elongated paired organs to testes composed of several fringes or lobes (**Figure 5**). The cranially located lobes contain germinal epithelium and the lumina are filled with sperm (**Figure 5**(**c**)) and the caudal lobes contain purely somatic, secretory epithelium producing seminal fluid. In some species of this order (e.g., the African catfish *Clarias gariepinus*), seminal vesicles differentiate under the influence of rising androgen levels during puberty from the caudal part of the immature testis where spermatogenic tissue merges into the spermatic duct system. Their columnar, single-layered epithelium is derived from Sertoli cells while the thin lamina propria, on which they reside, contains cells that show morphological characteristics of Leydig cells, which may be a source for pheromones.

Germ-Cell Clones, Sertoli Cells, and Cystic Spermatogenesis

Germ-cell development starts from spermatogonial stem cells (SSCs), the most undifferentiated type of spermatogonium, which usually occurs as single cells. When an SSC enters the differentiation pathway toward the spermatozoa, it shows a peculiar behavior upon dividing in all animals. At the end of mitosis, when the two new cells have formed, a cell division is incomplete in these differentiating cells since the daughter cells remain interconnected by a cytoplasmic bridge, instead of forming two separated cells. These bridges are also formed during all subsequent germ-cell divisions. In this way, the germ cells derived from a given SSC form a clone of interconnected cells. All members of the same clone are in the same stage of development, synchronized in their activities via the cytoplasmic bridges. These bridges are broken when spermatogenesis is completed and germ cells leave the germinal epithelium as spermatozoa. However, when dividing, an SCC can also form two independent cells. These daughter cells are two new SCCs and this mode of division is called stem-cell self-renewal.

Since germ-cell survival depends on its contact with Sertoli cells, the number of Sertoli cells determines the spermatogenic capacity of a testis. In birds and mammals, Sertoli cell numbers increase until puberty, when tight junctions are formed between neighboring Sertoli cells as a prerequisite to initiate spermatogenesis. However, once formed, these junctions are incompatible with further Sertoli-cell proliferation. Hence, the adult testis of higher vertebrates contains a fixed number of immortal Sertoli cells that support successive waves of spermatogenesis. During these waves, a given Sertoli cell supports at the same time different developmental stages of germ cells (i.e., cells belonging to different clones; **Figure 6**(**a**)).

In fish (like amphibians), on the other hand, we find the cystic type of spermatogenesis. There are two main differences when compared with higher vertebrates. First, cytoplasmic extensions of Sertoli cells contact each other to form a cyst that envelopes a single, synchronously developing germ-cell clone derived from a single spermatogonium (**Figures 1**(**b**) and **6**(**b**)); in this way, a Sertoli cell is usually in contact with only one germ-cell clone. Second, the cyst-forming Sertoli cells proliferate in both prepubertal and adult fish. Indeed, Sertoli-cell

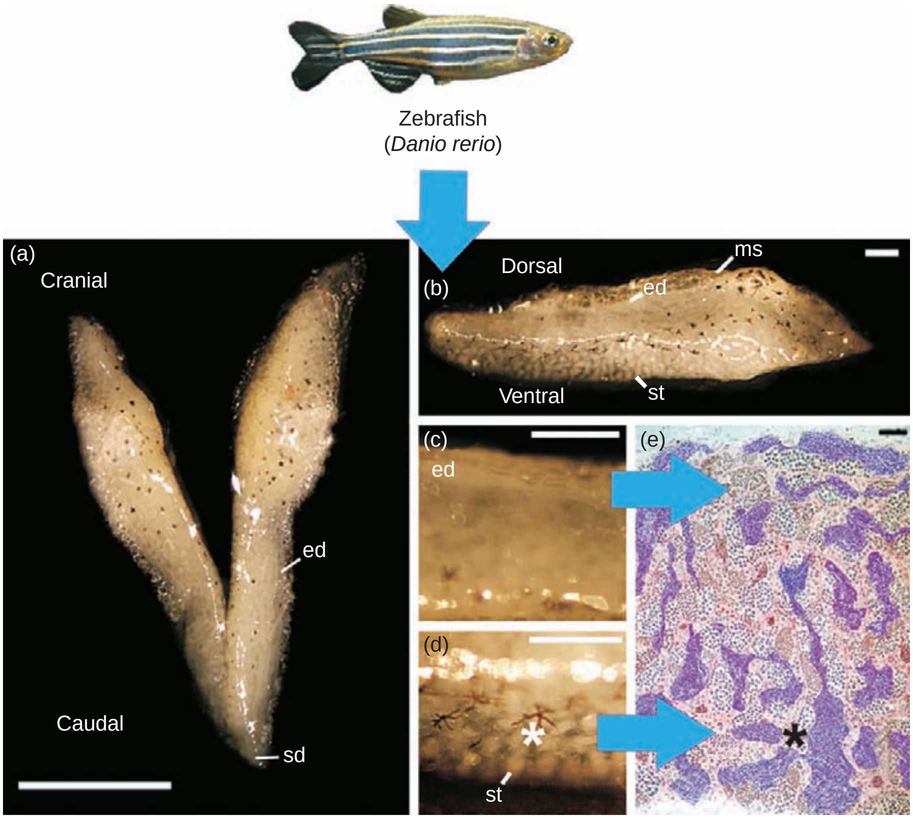

Figure 3 Zebrafish (*Danio rerio*) testis anatomy. (a) Testes are elongated paired organs (left and right) attached dorsally to the body wall by a connective tissue called mesorchium (ms). The efferent duct (ed) arises from the dorsal surface of each testis, and continues as a common, unpaired spermatic duct (sd). Spermatogenic tubules (st) are shown in (b). High magnification of efferent duct (c) and spermatogenic tubules (d), respectively. Tubular anastomoses are shown by an asterisk. (e) Histological section illustrating the areas demonstrated in (c) and (d). Tubular lumen is filled with sperm cells (dark blue). Sperm produced in the spermatogenic tubules is collected in the dorsal efferent duct. Scale = 1 mm (for (a) and (b); 0.5 mm for (c) and (d); and 50 μm for (e).

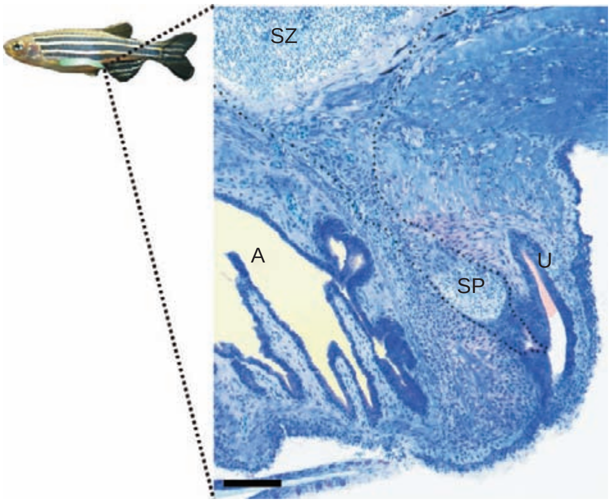

Figure 4 Zebrafish (*Danio rerio*) urogenital papilla. The urogenital papilla is an area between the anus (located cranially; A, yellow) and the ventral fin which gathers the openings of the spermatic duct (SP) and urethra (U, red). The spermatic duct (SP) is indicated by a stippled line and is filled with spermatozoa (SZ). Scale bar = 0.1 mm.

proliferation can be observed during the development of each germ-cell clone to exactly the number of Sertoli cells that is required to optimally support the increasing germ-cell number per cyst. The number of divisions a germ-cell clone undergoes is determined genetically (see below and **Figure** 7), so that the increases in both germ and Sertoli-cell numbers per cyst follow a predictable scheme. Moreover, we find a specific number of Sertoli cells per cyst for a given stage of development. The increases in germ-cell volume and number levels off toward the end of meiosis. Interestingly, this coincides with the formation of tight junctions between neighboring Sertoli cells in fish. Hence, as in higher vertebrates, the differentiation of tight junctions among Sertoli cells terminates their proliferation period.

When spermatogenesis is completed, the close contact between germ and Sertoli cells is broken and the cysts open such that the lumen of spermatogenic cysts becomes continuous with the lumen of the spermatogenic tubules. This process is called spermiation. The term spermiation is used in two ways in fish: in a strict sense to describe the

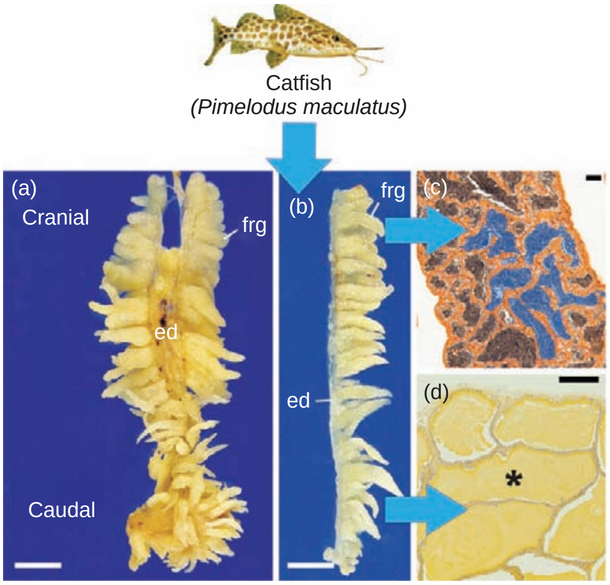

Figure 5 Catfish (*Pimelodus maculatus*) testis anatomy. (a, b) The testes are composed of fringes (frg) or lobes, which are connected centrally to the efferent duct (ed). (c, d) Histological sections of cranial (C) and caudal (D) lobes. (c) Spermatogenic tissue where the lumina are filled with sperm (blue colored). (d) Secretory tissue where the lumina are filled with acellular fluid (asterisk). Scale = 0.5 cm for (a) and (b); 100 μm for (c) and (d). Modified from Nóbrega RH and Quagio-Grassiotto I (2006) Morphological Changes of the Germinal Epithelium, Sertoli Cell Proliferation and 3βHSD Activity during the Reproductive Cycle of *Pimelodus maculates*. Master Thesis, UNICAMP.

termination of close Sertoli–germ cell contact and in a broader sense to indicate that strippable sperm (milt) is present in the spermatic duct system. Here, the term spermiation is used in the strict sense.

After spermiation, Sertoli cells can join the single-layered, flat epithelium that lines the inside of the spermatogenic tubules at places where no developing cysts are present. Thus, the basic functional unit of the spermatogenic epithelium in fish is a cyst formed by Sertoli cells that envelopes and supports one synchronously developing germ-cell clone. Different clones being at different stages of development generate the well-known histological picture of fish testes, where the seminiferous tubules contain groups of germ cells in different stages of spermatogenesis (**Figure 6**(**b**), inset).

Next to supporting germ-cell survival and development, Sertoli cells secrete the fluid present in and generating the tubular lumen. They are also the only phagocytotically active cell type in the seminiferous tubules. Material to be phagocytized is, for example, apoptotic germ cells, residual bodies (cellular material discarded by spermatids during spermiogenesis), or sperm that remained in the testis after the end of a spawning season. A certain loss of developing germ cells via apoptosis is normal during spermatogenesis. Cystic spermatogenesis in fish is more efficient in this regard than the noncystic spermatogenesis in rodents, for example, considering that only 30% of developing germ cells are lost to apoptosis in fish, while 60–70% is normal in laboratory rodents.

Distribution of Spermatogenic Cysts

Two types of spatial arrangements are found in the teleost testes with regard to the spatial distribution of cysts with early spermatogonia. In the restricted type, the cysts with early, undifferentiated spermatogonia, among which are probably the SSCs, are located close the tunica albuginea in the periphery of the testis. During differentiation, the developing cysts migrate toward the efferent ducts where spermiation occurs, that is, the cysts open to release spermatozoa. This type of arrangement is found in the higher teleosts, such as in the orders Atheriniformes, Beloniformes, and Cyprinodontiformes. In the second type, the unrestricted spermatogonial distribution is found, and early, undifferentiated spermatogonia are spread throughout the testis. The cysts do not migrate during their development. The unrestricted pattern is considered as the more primitive one and is found in orders such as the Characiformes, Cypriniformes, or Salmoniformes. Intermediate forms also exist, for example, in the orders Gadiformes, Perciformes, or Pleuronectiformes, where undifferentiated spermatogonia show a preferred, but not exclusive, location close to the tunica albuginea. In the restricted and intermediate types, the observed localization of undifferentiated spermatogonia results in a zonation of, or gradient of, development in the testis: early stages of germ-cell development are found distant from, and advanced stages close to, the efferent duct system.

Some tropical species do not display a seasonal variation of the spermatogenic activity. However, in many species with habitats at higher latitudes, reproduction is a seasonal or cyclic event related to environmental cues. Typically, cysts with rapidly proliferating spermatogonia are observed only at the beginning of testicular recrudescence, while after completion of spermatogenesis, tubules are filled with large numbers of spermatozoa and only some scattered, quiescent type A spermatogonia remain. In other cyclic species, germ cells remaining in the regressed testis may be spermatogonia and spermatocytes (e.g., tench, *Tinca tinca*), or even all germ cell types, such as in goldfish (*Carassius auratus*), where the seasonal regression is of a quantitative rather than of a qualitative nature.

Spermatogenesis – An Overview

During spermatogenesis, normal-looking diploid germ cells, the spermatogonia, transform during a suite of proliferation and differentiation steps, into flagellated

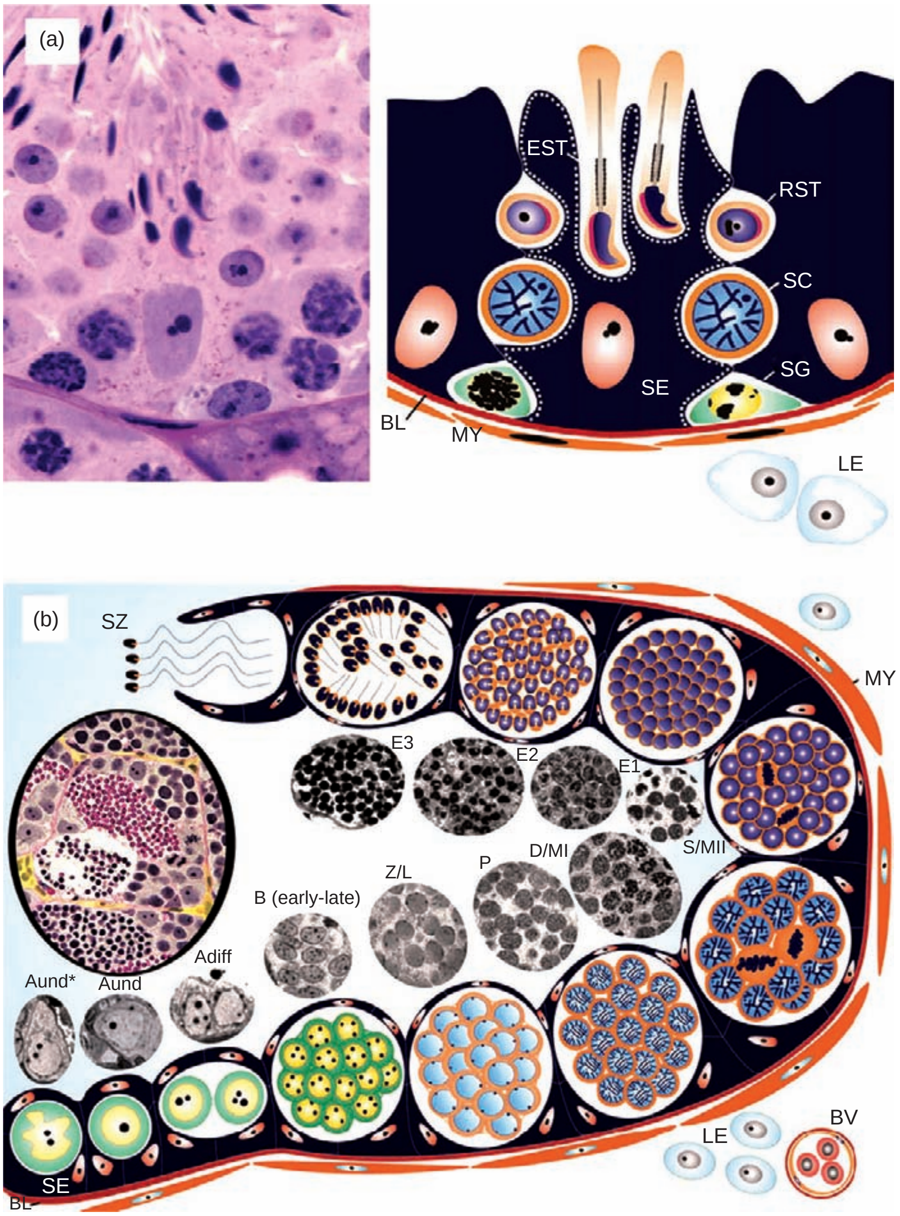

Figure 6 Comparison of mammalian ((a) mouse) and fish ((b) zebrafish) testis. Segments of spermatogenic tubules are shown to illustrate the differences in Sertoli/germ cell relation between cystic (b) and noncystic (a) spermatogenesis. The germinal epithelium contains Sertoli (SE) and germ cells, delineated by a basal lamina (BL) and peritubular myoid cells (MY). The interstitial Leydig cells (LE) and blood vessels (BV) are shown. (a) SG, spermatogonia; SC, spermatocyte; RST, round spermatid; EST, elongated spermatid. (b) $A_{und}*$ (*possible stem cell?), type A undifferentiated* spermatogonia; A_{und}, type A undifferentiated spermatogonia; A_{diff}, type A differentiated spermatogonia; B (early-late), spermatogonia type B; L/Z, leptotenic/zygotenic primary spermatocytes; P, pachytenic primary spermatocytes; D/MI, diplotenic spermatocytes/metaphase I; S/MII, secondary spermatocytes/metaphase II; E1, early; E2, intermediate; and E3, final spermatids; SZ, spermatozoa. From Schulz RW, de França LR, Lareyre JJ, *et al.* (2010) Spermatogenesis in fish. *General and Comparative Endocrinology* 165(3): 390–411 (doi:10.1016/j.ygcen.2009.02.013).

spermatozoa. These motile cells carry a recombined, haploid genome to fertilize an egg. Spermatogenesis can be divided into three phases.

The initial one is the mitotic or spermatogonial phase. Here, the main increase in germ-cell number occurs during successive rounds of mitotic duplication of the spermatogonia. The number of spermatogonial generations (and hence the number of mitotic divisions they undergo before differentiating into spermatocytes) varies among species (**Figure 7**). For example, 14 generations of spermatogonia were found in the guppy (*Poecilia reticulata*), 10–12 in mosquito fish (*Gambusia affinis*), nine in zebrafish (*Danio rerio*), six in mudminnow (*Umbra limi*) and rainbow trout (*Oncorhynchus mykiss*).

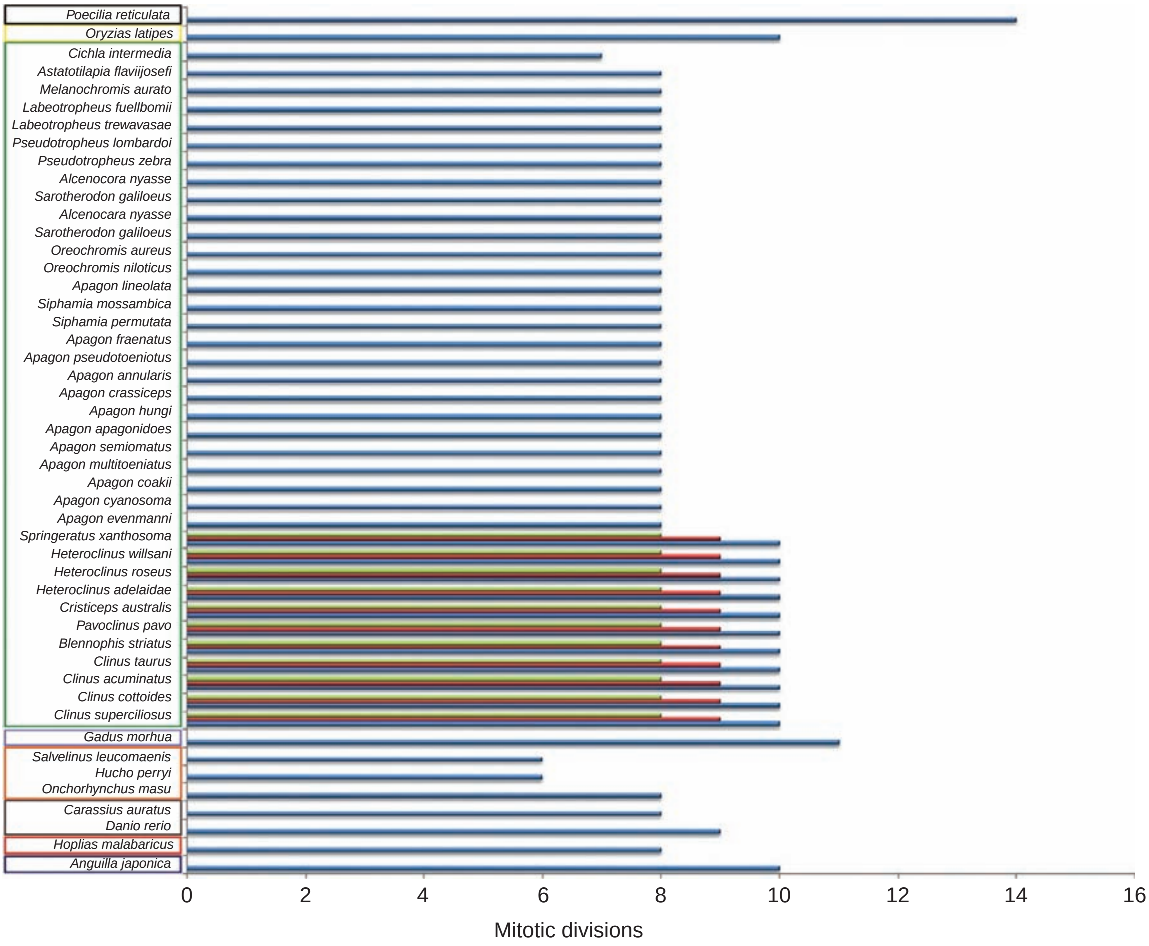

Figure 7 Number of mitotic divisions prior to meiosis. Note that the number of divisions seems to vary with the taxonomic position of the species. Colored squares delimitate orders which are phylogenetically arranged from the most derived (above) to the most primitive (below). The orders depicted follow the aforementioned sequence: Cyprinodontiformes, Beloniformes, Perciformes, Gadiformes, Salmoniformes, Cypriniformes, Characiformes, and Anguilliformes.

When entering the second phase, meiosis, the spermatogonia differentiate into spermatocytes that go through the two meiotic divisions. These are characterized by reshuffling of the paternal and maternal genetic information via crossing over during the first meiotic division and the reduction to a haploid genome during the second meiotic division.

Third, during the spermiogenic phase the haploid spermatids emerging from meiosis differentiate – without further proliferation – into flagellated spermatozoa. The morphological changes in germ cells taking place during spermiogenesis are quite similar among different species (e.g., reduction in cytoplasmic volume and organelles, maximum DNA condensation, and differentiation of a flagellum). However, the final shape of the spermatozoa can differ between species and sometimes provide taxanomic clues.

The duration of meiosis and spermiogenesis has been determined in a few fish species and varies between 1 and 3 weeks in four tropical species, but can take 1–3 months in species living in temperate or cold waters. No information is available yet in fish on the duration of the spermatogonial phase.

Morphological Characteristics of Germ Cells during Spermatogenesis

As all other germ cells, the SSCs in fish are in close contact with cytoplasmic extensions of Sertoli cells. Clear morphological or molecular markers have not been identified yet for SSCs in any vertebrate, but the general view is that SSCs are single cells and part of a population referred to as undifferentiated spermatogonia type A (A_{und}). There is a functional assay for SSCs though, which is based on their capacity to re-start, after transplantation, spermatogenesis in the testis of a recipient animal (in which endogenous spermatogenesis had been stopped experimentally). Transplantation assays exist for certain mammalian species and are being developed for fish now. Although a morphological characteristic of SSCs is that they are single germ cells, that is, not connected via cytoplasmic bridges to other germ cells, not all single type A_{und} spermatogonia seem to be stem cells. In fish, we find two types of single, undifferentiated spermatogonia, type A_{und*} and the type A_{und} spermatogonia (**Figures 8** and **9**). The type A_{und*} shows the most undifferentiated characteristics, such as a large nucleus with little heterochromatin, a high volume of the cytoplasm, a convoluted nuclear envelope and – particularly interesting – darkly staining material on the cytoplasmic side of the invaginations of the convoluted nuclear envelope (**Figure 8(a)**). Such patches are known as 'nuage' in the primordial germ cells, the earliest (embryonic) generation of germ cells (**Figure 8(b)**). The other type of single spermatogonia shows a smooth nuclear envelope and less nuage and these cells are referred to as type A_{und} spermatogonia (**Figures 8** and **9**). To date, it is not known if a mitotic division separates these two types of A spermatogonia.

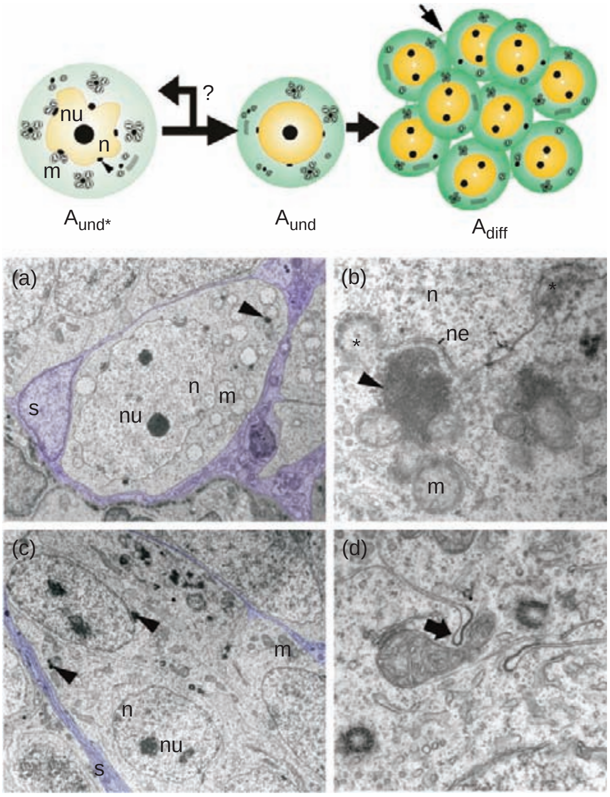

Figure 8 Morphological features of the most undifferentiated ($A_{und}*$ and A_{und}) and differentiated type A spermatogonia (A_{diff}). Schematic drawing (top) of the spermatogonial generations from $A_{und}*$ to A_{diff}. The question mark between $A_{und}*$ and Aund indicates that it is not known yet if they are separated by a mitosis. (a, b) Note that $A_{und}*$ is a single cell surrounded by cytoplasmic extensions (colored area) of Sertoli cells (S). $A_{und}*$ has a large and convoluted nucleus (n) with little heterochromatin and one or two nucleoli (nu). Close to the nuclear convolutions (asterisks) of the nuclear envelope (ne), or associated with mitochondria (m), their cytoplasm contains a large amount of electron-dense material, called nuage (arrowhead). (c, d) Differentiating type A spermatogonia are found in cysts with two, four, and eight cells that are enveloped by thin (colored) cytoplasmic extensions of Sertoli cells. These differentiating germ cells are connected by cytoplasmic bridges (arrow), shown at high magnification in D. A_{diff} have a round or oval nuclei, one or two nucleoli, denser chromatin, and little or no nuage.

A differentiating division produces a pair of spermatogonia A connected by a cytoplasmic bridge. Since this is the first step toward differentiation to spermatozoa, these cells therefore are called differentiating type A spermatogonia (A_{diff}) in fish (**Figures 8** and **9**). Type A_{diff} cells then undergo a species-specific number of mitotic divisions, during which the number of spermatogonia duplicates with each mitotic cell cycle. The last generation of spermatogonia that differentiates – without division – into primary spermatocytes, is always called type B spermatogonia. When several spermatogonial generations are present in a species, further subdivisons become evident, and we present the zebrafish (*Danio rerio*) as an example.

Type A_{diff} spermatogonia in zebrafish are found in cysts with two, four, and eight cells connected by cytoplasmic bridges (**Figures 8(c)**, **8(d)**, and **9**). Their nuclei are round to oval, contain no or very little nuage-like material, and show one or more nucleoli. They are smaller than the type A_{und} spermatogonia but share with them the low amount of heterochromatin in the nucleus, and a relatively large cytoplasmic volume (**Figures 8(c)** and **9**).

Further morphological changes are observed during development of the more rapidly dividing type B spermatogonia. In zebrafish, type B spermatogonia are found in cysts containing 16–512 cells. The successive generations of type B spermatogonia show a progressively decreasing cell and nuclear volume, with a small rim of cytoplasm surrounding an oval to round nucleus that gradually shows more heterochromatin (**Figure 9**).

After the final mitosis, type B spermatogonia differentiate into primary spermatocytes. Upon approaching the first meiotic division, the cells enter the very long prophase of meiosis I, which is subdivided into stages that are named according to the appearance of the meiotic chromosomes in the light microscope: preleptotene, leptotene (slender ribbon), zygotene (threads bound together), pachytene (thick threads), and diplotene (double threads). During this long prophase, crossing over can occur between the paternal and maternal chromosomes (usually one or two per pair of chromosomes), thereby reshuffling the genetic information; the crossing-over sites become visible as chiasmata (cross pieces) during diplotene. This is followed by the first meiotic division, during which the homologous (paternal and maternal) chromosomes segregate into the nuclei of the secondary spermatocytes. The latter quickly enter the second meiotic division, without a duplication of

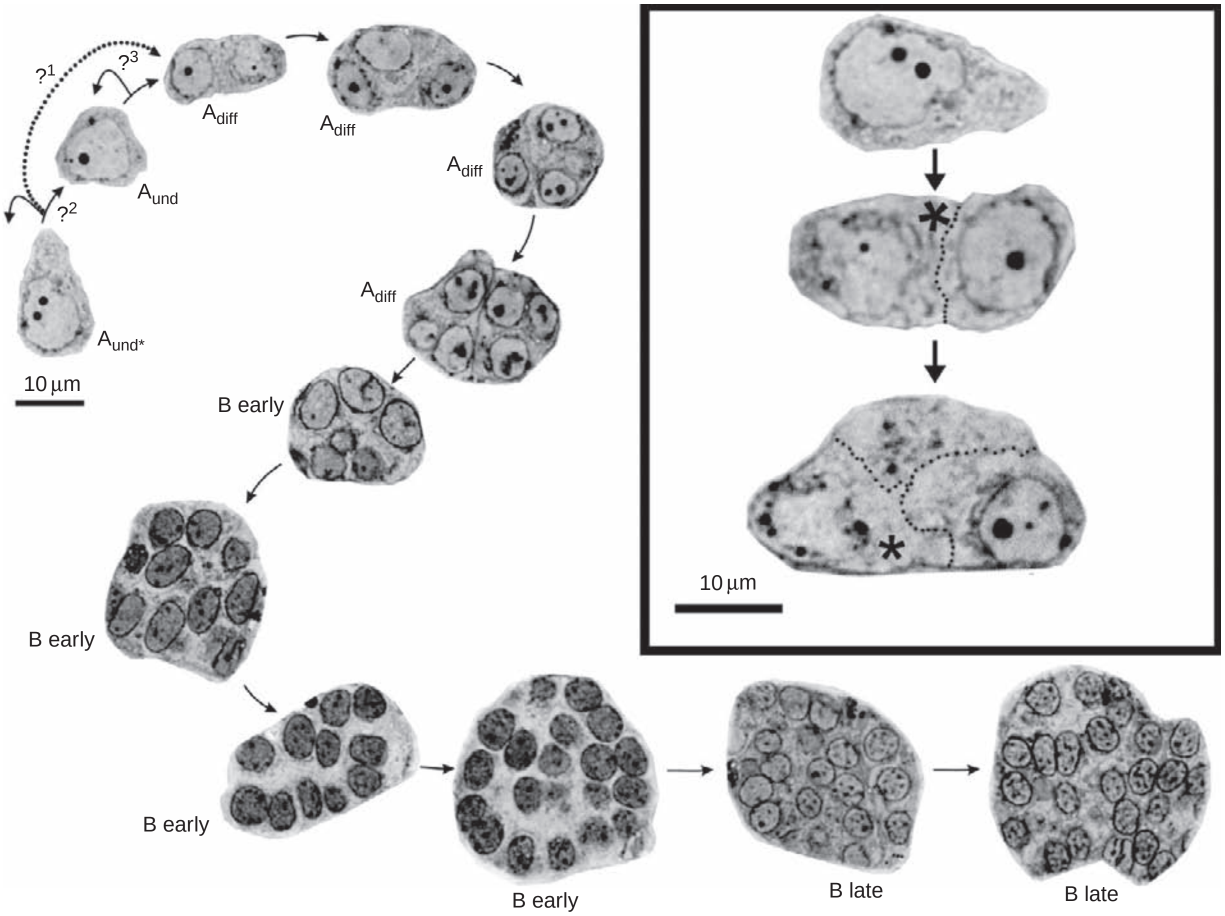

Figure 9 Spermatogonial generations in zebrafish. The terminology to address the spermatogonial generations is based on nuclear (heterochromatin amount) and nucleolar characteristics, and the number of germ cells inside the cyst. Using high-resolution light microscopy applied to araldite-embedded sections, five types of spermatogonia are described: type A undifferentiated* (A_{und*}), type A undifferentiated (A_{und}), type A differentiated (A_{diff}), type B early (B_{early}), and type B late (B_{late}). The curved arrows indicate self-renewal while the simple arrows indicate mitosis. The first question mark ($?^1$) indicates a doubt as regards a possible asymmetric division of A_{und*} (in the inset, note the stippled line toward a pair of spermatogonia). The second question mark ($?^2$) refers to the uncertainty if type A_{und*} is separated from A_{und} by mitosis or if they represent different stages of the same cell cycle. The third question mark ($?^3$) indicates a doubt as regards the stemness of A_{und}. Inset: The asterisks show undifferentiated spermatogonia belonging to cysts with other types of spermatogonia. This observation might indicate that asymmetrical divisions can occur but requires further studies in teleosts. From Schulz RW, de França LR, Lareyre JJ, *et al.* (2010) Spermatogenesis in fish. *General and Comparative Endocrinology* 165(3): 390–411 (doi:10.1016/j.ygcen.2009.02.013).

the DNA, and the chromosomes go through an equational division, that is, the sister chromatids are segregated. This results in four haploid cells derived from each of the last type B spermatogonium, harboring one copy of each chromosome.

Using light microscopy, identification of meiotic cells is based mainly on the appearance of the germ-cell nuclei, such as size and shape, degree of chromosome condensation, and metaphasic figures (**Figures 6(b)** and **10**). In zebrafish, leptotene/zygotene spermatocytes have a larger nucleus (~ 5.5µm) and are more round than in the last type B spermatogonia; the chromatin is clear and shows small dots of heterochromatin outlining the nuclear membrane (**Figures 6(b)** and **10**). Pachytene spermatocytes are the most frequent meiotic cells due to the long duration of this stage. They have a large (~6.5 µm) and dense nucleus, with the chromosomes appearing as bold lines from the nuclear membrane to the center of the nucleus. Diplotenic primary spermatocytes are often found together with metaphasic figures (metaphase I); the chromosomes reach their maximum degree of condensation and are found close to the nuclear membrane that, however, starts to disappear at this stage. The secondary spermatocytes, resulting from meiosis I, are rare because they quickly enter meiosis II. They are small cells with a dense nucleus (~4 µm), usually found together with metaphasic figures from the second meiotic division (**Figures 6(b)** and **10**). A fine description of meiotic germ cells using light and electron microscopy has been reported for several species of fish.

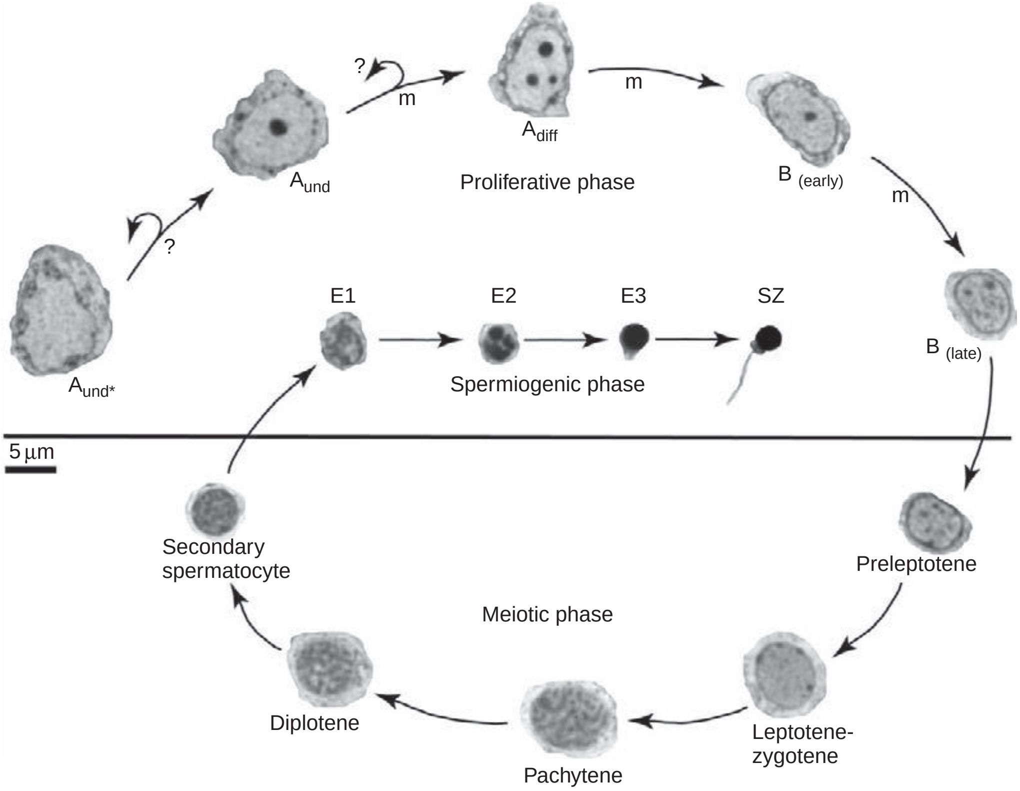

Figure 10 Step-by-step representation of zebrafish spermatogenesis from type A undifferentiated spermatogonia to spermatozoa, throughout the three phases of the spermatogenic process: proliferative or spermatogonial, meiotic or spermatocytary, and spermiogenic. The spermatogonial micrographs show the most characteristic features of each cell type, although there is a range of their morphology and size. A_{und}*(stem cell?), type A undifferentiated* spermatogonia; A_{und}, type A undifferentiated spermatogonia; A_{diff}, type A differentiated spermatogonia; B, type B spermatogonia; curved arrows, self-renewal; m, mitosis; E1, early spermatids; E2, intermediate spermatids; E3, final spermatids; SZ, spermatozoa. A_{und}* and A_{und} are single cells, whereas A_{diff}, B (early), and B (late) are grouped. The first question mark (?) indicates a doubt if A_{und}* and A_{und} are separated by a mitosis or represent different stages of the same cell cycle, while the second question mark indicates uncertainty as regards the stemness of A_{und}. From Schulz RW, de França LR, Lareyre JJ, *et al.* (2010) Spermatogenesis in fish. *General and Comparative Endocrinology* 165(3): 390–411 (doi:10.1016/j.ygcen.2009.02.013).

Spermiogenesis, that is, the differentiation of spermatids into spermatozoa without further cell divisions, consists of series of morphological changes, such as condensation of the nucleus and its DNA, elimination of superfluous organelles and cytoplasm (discarded as residual bodies), flagellum formation, and the rearrangement of remaining organelles in the remaining cytoplasm. Three types of spermiogenesis (types I, II, and III) have been described based on the orientation of the flagellum to the nucleus, and on whether or not a nuclear rotation occurs. These patterns are reflected in the spermatozoa structure, are highly conserved within taxonomic units, and can be used for clarifying the phylogenetic position of fish species. The increasing nuclear condensation together with the decreasing nuclear size can be used to subdivide spermiogenesis. In zebrafish, three types of spermatids were described in this regard: early, intermediate, and final spermatids **Figures 6(b)** and **10**). Fish spermatozoa usually have no acrosome; a micropyle gives access to the membrane of the oocyte. Spermatozoa often show a spherical nucleus with homogenous, highly condensed chromatin, a nuclear fossa, a midpiece of variable size containing the mitochondria, and one or two long flagella.

At the end of spermiogenesis, the intercellular bridges between the spermatids are broken and the germ cells are individualized. The cyst-forming Sertoli cells lose contact with each other upon opening of the cyst to release spermatozoa into the tubular lumen (**Figure 6(b)**). In some species, the release of germ cells occurs at the spermatid (or even the spermatocyte) stage itself, and spermiogenesis is completed in the tubular lumen. This is called semicystic spermatogenesis and is found in different taxonomic groups (e.g., Bleniidae, Corydoradinae, Opheliidae, Scorpaenidae, and Soleidae). In semicystic spermatogenesis, Sertoli cells form, earlier than in other species, an epithelial lining of the spermatogenic tubules. There are cases, however, where spermatozoa are kept together during release, and sperm bundles are formed within the cyst when Sertoli cells secrete a capsule around a group of spermatids, thereby creating spermatophores.

Glossary

Paracrine signaling Refers to the observation that signaling molecules (e.g., hormones and growth factors) can exert effects in the (close) vicinity of their site of production.

Pituitary gonadotropins Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are pituitary glycoprotein hormones that regulate the two main functions of the gonads, germ cell and sex hormone production.

Sex steroids A group of lipophilic, small (~300 Da) signaling molecules that are produced from cholesterol in the gonads under the influence of gonadotropins. Androgens are male sex steroids, and progesterones; estrogens are female sex steroids.

Spermatogenesis A cellular development during which spermatogonial stem cells give rise, via proliferation and differentiation steps, to a large number of sperm cells or spermatozoa. The germ-cell types formed successively during spermatogenesis are spermatogonia, spermatocytes, spermatids, and spermatozoa.

Spermiation Describes the release of spermatozoa from the germ-cell-supporting Sertoli cells. In fish, this is associated with the opening of the spermatogenic cysts formed by cytoplasmic extensions of the cyst-forming Sertoli cells.

Introduction

Another article presents the testis in its function as a germ-cell-producing tissue (**see also The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis). In the present article, we focus on the testis as an endocrine organ. Both functions are intimately related, since hormones and growth factors produced by the testis are required for regulating germ-cell production (**Figure 1**). Testicular hormones also regulate the development of secondary sexual characteristics or reproductive behavior (**see also Hormones in Communication**: Hormonal Pheromones), and they feed back on the endocrine systems in the brain and the pituitary (**Figure 1**) that regulate pubertal maturation and adult reproductive cycles (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction).

The testis is composed of two main compartments, the interstitial and the tubular compartment. The interstitial compartment houses the steroidogenic (i.e., steroid-hormone producing) Leydig cells (**Figures 1** and **2**). The tubular compartment contains germ cells and Sertoli cells. The germ-cell-supporting Sertoli cells also produce signaling molecules, although they do not release steroids but growth factors, many of which work in a paracrine (short-range, cell-to-cell signaling) manner to regulate spermatogenesis (**Figure 1**).

Regulation of Testis Functions by Pituitary Gonadotropins

In many species living at higher latitudes, reproduction is a seasonal event related to environmental cues, such as changes in the photoperiod. However, some tropical species do not display apparent seasonal variations in reproductive activity and once pubertal maturation is completed, reproductive activity is seen throughout adult life. Pubertal or seasonal activation of spermatogenesis is closely associated with the activation of testicular hormone and growth-factor production. Surgical removal of the pituitary demonstrated that both production of hormones/growth factors and spermatogenesis require

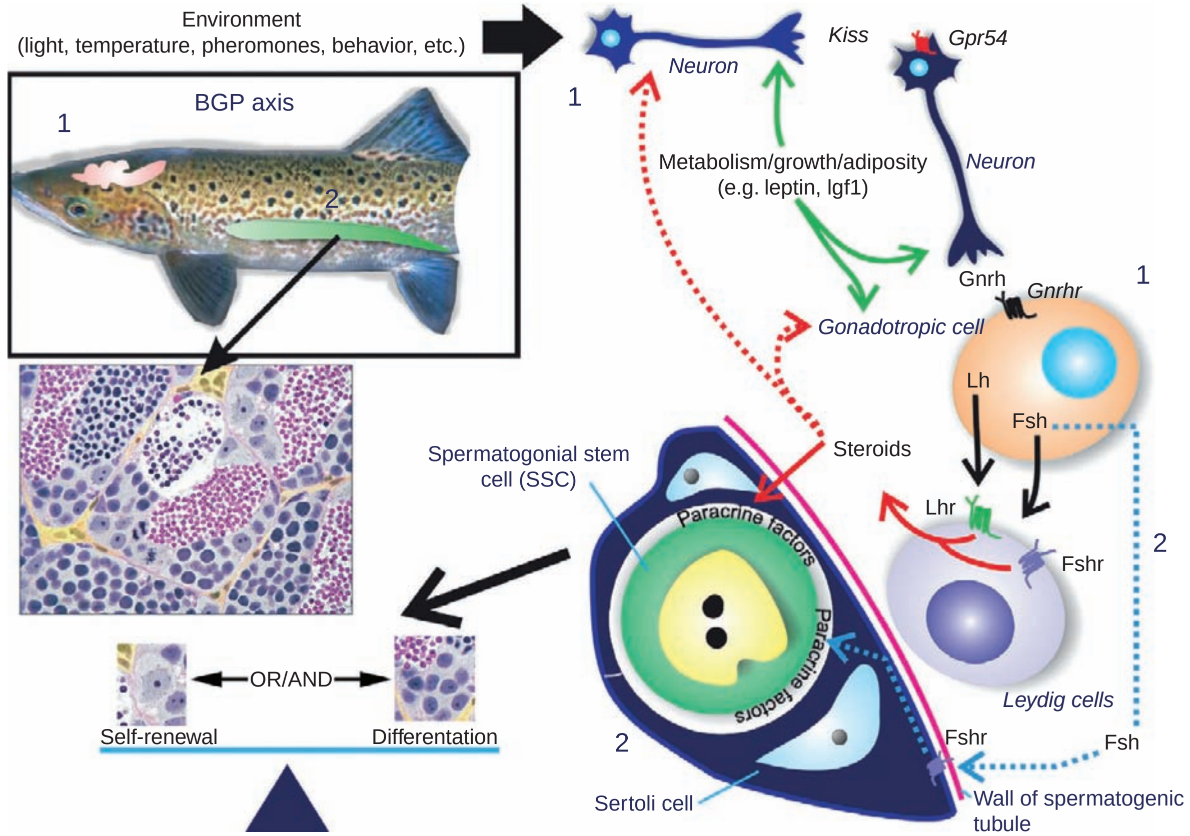

Figure 1 Schematic representation of the endocrine system regulating reproduction, the brain–pituitary–gonad (BPG) axis. In the brain–pituitary segment of the axis (1), Kiss producing neurons regulate via the Kiss receptor Gpr54 (red) the activity of the Gnrh-producing neurosecretory neurons. Gnrh interacts with its receptor Gnrhr (black) on the two gonadotropic cell types of the pituitary, which produce either LH or FSH. Both hormones reach the testis (2) via the blood stream and stimulate sex-steroid production by the interstitial Leydig cells by interacting with the LH receptor (green) or the FSH receptor (pink). FSH can also activate (blue stippled line) the FSH receptor expressing Sertoli cells, which moreover express steroid hormone receptors. Sertoli cells envelop developing germ cells and following steroid and/or FSH action, modulate the release of growth factors that influence the self-renewal, proliferation, and/or differentiation behavior of germ cells in a paracrine manner. Sex-steroid hormones feed back to the brain–pituitary system (red stippled line) and modulate, together with other internal messengers (e.g., reflecting the metabolic state, green arrows) and external signals (e.g., photoperiod, large black arrow), the activity of Kiss and Gnrh-producing neurons.

regulatory input from the pituitary. The pituitary, in turn, is controlled by neuro-endocrine centers in the brain (**Figure 1**).

The two most important pituitary hormones regulating testicular physiology are luteinizing hormone (LH) and follicle-stimulating hormone (FSH), collectively referred to as gonadotropins or gonadotropic hormones. In mammals, FSH and LH interact with their membrane-associated, G-protein-coupled receptors, FSHR and LHR, in a highly specific manner at physiological hormone concentrations. Leydig cells express the LHR gene (**Figure 1**). Accordingly, LH regulates Leydig-cell sex-steroid production. Sertoli cells express the FSHR gene and FSH regulates the structural, nutritional, and regulatory (paracrine) support that Sertoli cells provide to germ cells. In fish, the FSHR is less selective and binds, next to FSH, to LH as well. Moreover, the FSHR is not only expressed by Sertoli cells, but also by Leydig cells. These traits lead to the impression that the biological activities of fish gonadotropins are less clearly separated compared with those in higher vertebrates. However, cross-activation of the FSHR requires a rather high LH concentration that, if at all relevant physiologically, is restricted to the brief period with peak LH plasma levels during actual spawning events. FSHR expression by Leydig cells, on the other hand, explains the steroidogenic potency of FSH fishes, which is particularly relevant for understanding the regulation of sex-steroid production when LH plasma levels are very low or undetectable. Hence, in fish, Leydig-cell steroid production is directly regulated by LH and by FSH, while Sertoli cell functions are predominantly regulated by FSH.

Data on plasma levels of the gonadotropins during a complete reproductive cycle are available for a few salmonid species only. In rainbow trout (*Oncorhynchus mykiss*), LH plasma levels were low or undetectable during the start of

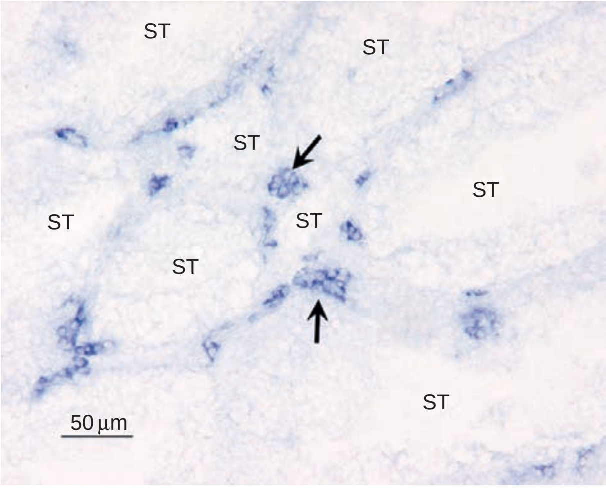

Figure 2 3β-Hydroxysteroid dehydrogenase (3βHsd) activity (blue staining) is demonstrated on a 5-μm thick cryosection from an adult African catfish (*Clarias gariepinus*) testis using an enzyme-histochemical technique. The enzyme is localized in the cytoplasm of Leydig cells that are arranged in cell groups (black arrow) in the interstitial compartment of the testis, between the seminiferous tubules (ST). Air-dried cryosections were treated with xylene for 2 min, and then incubated for 1 h at 37 °C in 3βHsd staining medium (containing 0.1 mg·ml^{-1} 5α-androstan-3β-ol-17one, 0.5 mg·ml^{-1} β-nicotinamide adenine dinucleotide, 0.2 mg·ml^{-1} nitroblue tetrazolium chloride, and 10% 7 dimethylformamide in 0.1 M phosphate buffer pH 7.4).

testis development (proliferation of spermatogonia), became detectable when meiosis started, and reached peak levels in the spawning season. FSH plasma levels, on the other hand, showed a transient increase at the beginning of spermatogonial proliferation, re-increased with the start of spermiation (opening of spermatogeneic cysts to release spermatozoa in the lumen of the tubules), and decreased before the spawning season was completed. In Chinook salmon (*Oncorhynchus tshawytscha*), FSH and androgen blood levels were elevated when spermatogonial proliferation started. In Japanese eel (*Anguilla japonica*), FSH-stimulated spermatogonial proliferation was prevented by blocking the steroidogenic activity of FSH. Hence, the present knowledge about fish indicates that FSH stimulates androgen production, which in turn initiates spermatogenesis. However, future work may uncover other aspects of FSH effects on spermatogenesis.

As in other vertebrates, fish Leydig cells express the LHR. When LH binds to its receptor, steroid production is upregulated by transporting cholesterol into the mitochondria, thereby fueling the steroidogenic pathway (**Figure 3**). Biochemically, all steroid hormones are derived from cholesterol, and are formed in a suite of reactions catalyzed by steroidogenic enzymes. The first step, the conversion of cholesterol to pregnenolone (**Figure 3**), is catalyzed by an enzyme located in the mitochondria. This is also the rate-limiting step, the bottleneck being the transport of cholesterol into the mitochondria. Cholesterol uptake by mitochondria is greatly enhanced by the steroidogenic acute regulatory protein, and its expression is stimulated by pituitary hormones inducing steroid production. The product of the first reaction is pregnenolone, which diffuses into the cytoplasm where most of the ensuing steps (production of progesterone, androgen, and estrogen) are catalyzed by enzymes associated with the endoplasmic reticulum. The type of steroid metabolites released by Leydig cells depends on the type and quantity of steroidogenic enzymes present. Expression of the respective enzyme genes changes during puberty or at different stages of the annual reproductive cycles. Enzyme expression is regulated by LH and FSH (mainly stimulatory), and by steroid hormones (mainly inhibitory). In mammals, Sertoli cell-derived growth factors can also participate in the regulations of Leydig-cell enzyme expression, but information is unavailable in fish.

The main Leydig-cell products in fish are androgens, in particular 11-ketotestosterone (11-KT) and testosterone (T). Apart from androgens, other sex steroids are produced in the fish testis, such as a progesterone (in many species 17α,20β-dihydroxy-progesterone; DHP), and also small amounts of the estrogen 17β-estradiol (E2). All three types of sex steroids have specific functions in the regulation of testis physiology, which are discussed later. First, however, a closer look at Sertoli cells is provided (**see also Hormonal Responses to Stress**: Hormone Response to Stress; and Impact of Stress in Health and Reproduction).

Sertoli Cells

Sertoli cells provide physical, nutritional, and regulatory (via growth factors) support for developing germ cells. Moreover, Sertoli cells are the only phagocytotically active cell type in the spermatogenic tubules, and they remove apoptotic germ cells and cellular remnants discarded by developing germ cells. Sertoli cells express receptors for sex steroid hormones as well as FSH receptors (**Figure 1**). One of the effects of steroids on Sertoli cells is to modulate growth-factor release (see below). Information on FSH effects on Sertoli-cell functions, such as growth-factor production, is unavailable in fish.

An aspect of great relevance for spermatogenesis is Sertoli-cell proliferation. In particular, during the period of mitotic proliferation of the spermatogonia, the cyst-forming Sertoli cells also proliferate to exactly the number required for supporting the growing germ-cell clone (**see also The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis). This tailored Sertoli-cell proliferation is very important for the quantity and efficiency of sperm production, since germ cells can neither survive nor develop without Sertoli-cell support. Hence, if

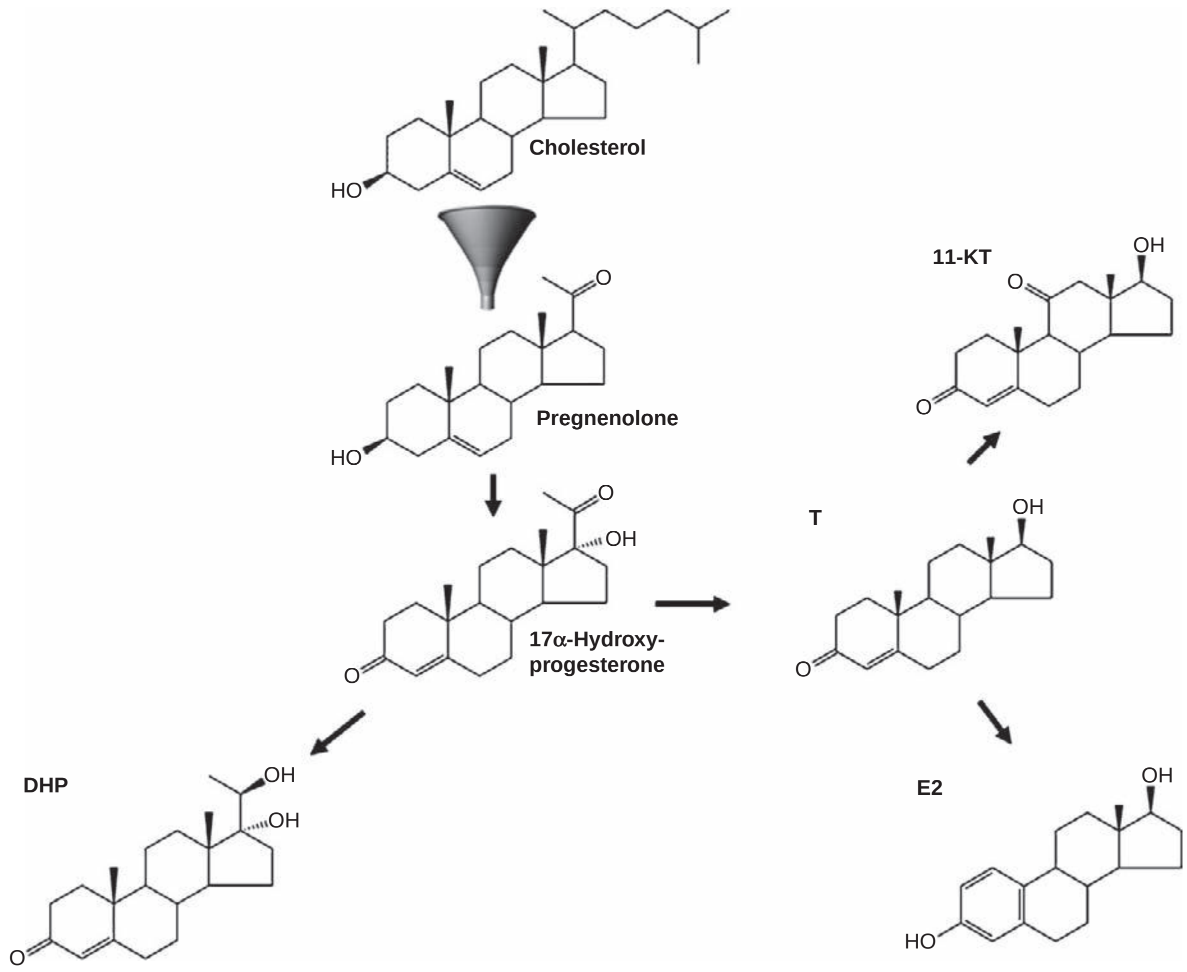

Figure 3 Schematic, simplified representation of the steroidogenic pathway in fish Leydig cells. Cholesterol is taken up from the blood or synthesized in Leydig cells. The first step in steroid production, the conversion of cholesterol to pregnenolone, is rate limiting (indicated by a funnel) and takes place in the mitochondria. Most subsequent steps take place in the cytoplasm, where pregnenolone is converted to 17α-hydroxyprogesterone. The latter is the substrate for androgen synthesis. The main product of the mature fish testis is 11-ketotestosterone (11-KT) that is produced in a number of steps from testosterone (T). T, in turn, is also the substrate for the production of 17β-estradiol (E2). Finally, in the spawning season, 17α-hydroxyprogesterone is also used as substrate for the production of 17α,20β-dihydroxyprogesterone (DHP).

Sertoli cells numbers are too low, increased germ-cell apoptosis and reduced sperm production will follow. Elevated FSH blood levels were observed during the start of seasonal testis growth, that is, when the numbers of spermatogonia and their accompanying Sertoli cells start expanding. In mammals, FSH is the most important stimulator of Sertoli-cell proliferation. The availability of recombinant fish FSH or synthetic FSH analogs allows more functional studies on FSH in fish, in the near future.

Steroid Hormone Blood Levels

Plasma levels of sex-steroid hormones change greatly during puberty or annual/seasonal reproductive cycles in adults. Estrogens are generally considered female hormones, but small amounts are formed in males as well. In rainbow trout, for example, E2 plasma levels increase transiently at the beginning of testis growth. The androgens 11–KT and T increase gradually as spermatogenesis proceeds, and reach peak levels shortly before or at the beginning of the spawning season. The progesterone DHP shows two peaks in salmonid fish, a small peak after the start of spermatogonial proliferation when the first meiotic germ cells are formed, and a prominent peak in the spawning season. These examples suggest that steroid hormones have distinct roles in controlling spermatogenesis. Indeed, as discussed later, estrogens modulate spermatogonial stem cell (SSC) self-renewal proliferation, androgens stimulate the rapid, differentiating proliferation of spermatogonia, and progesterone triggers the entry of spermatogonia into meiosis, that is, it promotes the development from spermatogonia to spermatocytes. Later on, DHP also supports final maturation of spermatozoa and sperm hydration.

Estrogens

Estrogens, like other steroid hormones, bind to nuclear receptors that function as hormone-activated transcription factors and modulate target-gene expression. Up to three estrogen-receptor (ER) subtypes can be found in fish. Testis tissue expresses the estrogen receptors in Sertoli cells and in spermatids. Estrogen treatment changed the expression of numerous genes in the testis of maturing sea bream (*Sparus auratus*). Some of the estrogen-regulated genes seem relevant for spermatogenesis since they are involved in lipid or protein metabolism, cellular communication, or proliferation.

Two types of germ-cell proliferations are observed at the beginning of spermatogenesis: on the one hand, the slow self-renewal proliferation of SSCs that produces new, individual SSCs; and on the other hand, the rapid, clonal proliferation of differentiating spermatogonia toward meiosis (**see also The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis). In immature Japanese eel testis, E2 induced in Sertoli cells the expression of platelet-derived endothelial cell growth factor (PD-ECGF) that in turn stimulated SSC self-renewal (**Figure 4**). In the fruit flie (*Drosophila melanogaster*), a number of different growth factors participate in the regulation of SSC proliferation, and future work will likely elucidate the roles of other factors regulating SSC proliferation in fish as well (**see** section Androgens). The stimulatory effect via PD–ECGF occurred at very low estrogen concentrations, while higher concentrations inhibited spermatogenesis via negative feedback effects on the brain and the pituitary, involving downregulation of the testicular androgen-production capacity.

Androgens

Androgens are required for spermatogenesis in all vertebrates. Depending on the fish species, one or two androgen receptor (AR) subtypes have been described, which are prominently expressed in the testis. AR expression is found in Sertoli cells (and other somatic cells), but not in germ cells. Therefore, androgens stimulate spermatogenesis in an indirect manner, for example, via the AR-expressing Sertoli cells. As can be expected in context with the molecular mechanism of action of steroid hormones, androgens strongly influence testicular gene-expression patterns. Detailed studies have been carried out in Japanese eel and in rainbow trout. With regard to androgen-sensitive Sertoli cell genes, for instance, the expression of the transforming growth factor β (TGFβ) family member anti-Müllerian hormone (AMH) is downregulated by androgens. AMH has two known biological activities in fish. It stimulates self-renewal proliferation of SSCs (demonstrated in medaka (*Oryzias latipes*)), and it prevents differentiation of SSCs into rapidly proliferating clones of spermatogonia (observed in Japanese eel (*Anguilla japonica*)) (**Figure 4**). Therefore, the observation that androgens stimulate the start of spermatogenesis is in line with the downregulatory effect of androgen on AMH gene expression, hence relieving the inhibition of SSC differentiation (**Figure 4**). Once the clones of differentiating spermatogonia have been formed, their further development toward meiosis continues to be stimulated by androgen-regulated, Sertoli-cell-derived growth factors, such as activin, another TGFβ family member (**Figure 4**).

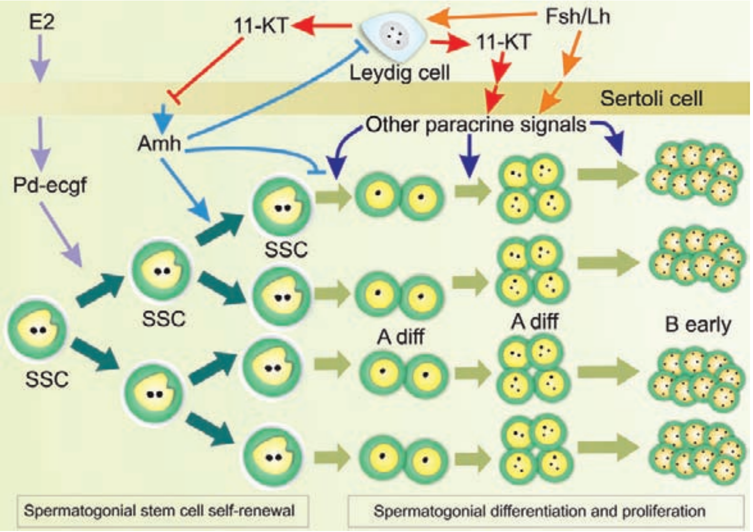

Figure 4 Schematic representation of the balance between spermatogonial stem cell self-renewal and differentiation. Spermatogonial stem cell (SSC), differentiating type A spermatogonia (Adiff), early type B spermatogonia (B early), 17β-estradiol (E2), platelet-derived endothelial cell growth factor (Pd–ecgf), 11–ketotestosterone (11–KT), anti-Müllerian hormone (Amh), follicle-stimulating hormone/luteinizing hormone (Fsh/Lh), stimulatory signal (→) and inhibitory signal (⊥).

In rainbow trout (*Oncorhynchus mykiss*), it was possible to compare changes in testicular gene expression after sex-steroid treatment with those occurring during natural testis maturation. For example, distinct subgroups of genes responsive to androgen treatment are highly expressed before the start of spermatogenesis, at the initiation of rapid spermatogonial proliferation, and during meiotic/post-meiotic stages, respectively. These gene groups therefore may play important roles during specific phases of spermatogenesis. Many of the maturational changes in gene expression are correlated with the changes in androgen levels in the blood. For instance, some genes are upregulated when androgen levels increased moderately at the beginning of spermatogenesis. Others are overexpressed in parallel to the prominent increase in androgen blood levels, in fully mature males. Interesting examples are genes coding for ion or water transporters, supporting the relevance of androgens for sperm hydration.

Progesterones

Testis tissue expresses nuclear and membrane-associated progestin receptor types in fish. Progesterone blood levels increase toward, and are high during, the spawning season. Progesterones are involved in the regulation of several testicular functions. For example, treatment with progesterone (DHP in freshwater species; 17α,20,21-trihydroxy-4-pregnen-3-one in marine species) induced spermiation, increased milt production, and stimulated spermatozoa motility in different fish species. Moreover, the involvement of DHP in triggering meiosis was recently reported.

Upon completion of the mitotic proliferation phase, type B spermatogonia differentiate into primary spermatocytes, thereby entering meiosis (**see also The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis). DHP plasma levels show a small peak during this period. Incubating immature testis tissue with DHP induced the expression of proteins typically associated with meiosis in eel. One of the proteins induced by DHP treatment was identified as trypsin that, secreted by Sertoli cells, mediated the DHP-induced entry of spermatogonia into meiosis. DHP also induced meiosis in oogonia in huchen (*Hucho hucho*) and carp (*Cyprinus carpio*) ovarian-organ-culture experiments. Together, these data show that DHP is an essential factor for the initiation of meiosis in both spermatogenesis and oogenesis.

Final Maturation of Male Gametes

During the actual spawning season, several plasma hormone levels show remarkable changes in male fish. LH secretion induces an increase in the testicular androgen and progesterone production. Androgen injections induced spermiation in goldfish (*Carassius auratus auratus*) and salmonids; progesterone injections had similar effects in salmonids and eels. While LH and these steroids are clearly involved in regulating spermiation in fish, the mechanism of action of these hormones on milt hydration, sperm migration from the spermatogenic tubules to the sperm duct, or sperm capacitation (see below), are still unclear.

After completion of spermatogenesis, Sertoli cells release the spermatozoa (spermiation) which are often not yet capable of fertilizing eggs, however. In some salmonid fish, for example, dilution with freshwater induces motility of spermatozoa collected from the sperm duct while testicular spermatozoa remain immotile. Thus, spermatozoa acquire the motility response to dilution during their passage through the sperm duct. Sperm maturation, the phase during which nonfunctional gametes develop into mature spermatozoa (fully capable of vigorous motility and fertilization), involves physiological but no morphological changes. In salmonids, sperm motility can also be induced by increasing the seminal plasma pH value to ~8, which in turn results in an elevation of cyclic adenosine monophosphate (cAMP) levels in spermatozoa. In Japanese eel, DHP triggered the expression of an enzyme in the efferent duct system that increases seminal plasma pH, in turn increasing the cAMP content, and hence sperm motility. Finally, progestins also may have a direct action on sperm motility. In Atlantic croaker (*Micropogonias undulatus*), progesterone bound to a membrane-bound receptor on the mid-piece (region rich in mitochondria) of the spermatozoa and induces vigorous motility.

The different phases of spermatogenesis and the role of steroid hormones are summarized schematically in **Figure 5**.

Germ Cell Autonomous Regulation of Spermatogenesis

While hormones exert the master control over spermatogenesis, regulation of spermatogenesis also operates on an intracellular level in germ cells, independent of external signals. This is elegantly demonstrated by transplanting germ cells between species that show differences in the amount of time required for spermatogenesis. For example, transplanting germ cells from rat (duration of one spermatogenic cycle is 14 days) to mice (10 days) showed that the timing of spermatogenesis was determined by the germ-cell genome, that is, it reflects (rat) germ-cell autonomous processes that are not influenced by the recipient's (mouse) endocrine system. We can conclude that endocrine signaling does not mediate a step-wise regulation of germ-cell development, but rather brings about the creation of different microenvironments that the germ cells require for proceeding through the

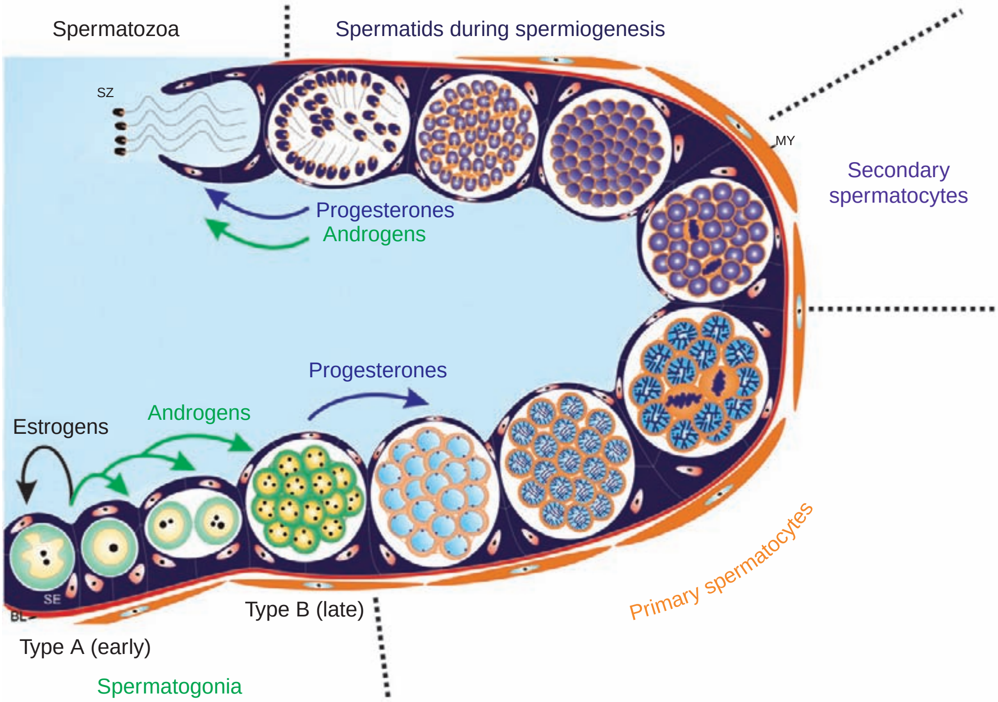

Figure 5 Schematic representation of the main phases of spermatogenesis starting from spermatogonia type A (early generations) through type B (later generations), primary and secondary spermatocytes, spermatids and spermatozoa). Estrogens stimulate self-renewal of spermatogonial stem cells (black curved arrow). Androgens (green arrows) stimulate differentiation and rapid proliferation of spermatogonia. Progesterones (blue arrows) trigger entry into meiosis and, together with androgens, spermiation (opening of the spermatogenic cysts). The germinal epithelium contains Sertoli (SE) and germ cells, delineated by a basal lamina (BL) and peritubular myoid cells (MY).

successive phases of the developmental program (stem cell, spermatogonial, meiotic, and spermiogenic phases) that constitute spermatogenesis.

The complexity of these germ-cell autonomous processes is exemplified in yeast. From the ~6200 genes in the yeast genome, ~1600 are expressed differentially during meiosis. When deleting a subset of these genes one by one, ~10% of them (~160 genes) were found to be required for just one process, the segregation of the meiotic chromosomes. In vertebrates, other spermatogenesis-specific genes function during the mitotic and spermiogenic phases. Indeed, in several cases, compromised or lost gene function was responsible for a failure of spermatogenesis, and many of these defects concern germ-cell autonomous processes, often based on germ-cell-specific (variants of) cell-cycle regulators, transcription factors, or enzymes. Some information in this regard is also available in fish.

The *mlh1*gene operates during meiosis. In spermatocytes, a large number of DNA double-strand breaks are generated in the chromosomes. One or two breaks per pair of chromosomes are repaired through homologous recombination with a non-sister chromatid of the homologous chromosome, resulting in crossing-over sites. The mutL protein complex consists of two proteins, Mlh1 and Mlh3. The complex is present at the sites of crossing over, and stabilizes the recombination sites until their repair. In zebrafish (*Danio rerio*) lacking a functional Mlh1 protein, males are sterile and lack fertile spermatozoa. Spermatogenesis stops at the metaphase of the first meiotic division, where completion of recombinatory DNA-break repair fails. Primary spermatocytes accumulate at this point, become apoptotic, and are finally phagocytized by Sertoli cells.

In addition, a new class of small, noncoding RNAs (so-called piRNAs) is involved in germ-cell autonomous differentiation processes. Loss-of-function mutations of the enzymes generating the piRNAs result in a loss of all germ cells before they can reach meiosis.

Synopsis and Outlook

Hormones of the brain–pituitary system control spermatogenesis. This endocrine master control of puberty and adult reproduction provides numerous evolutionary advantages, such as silencing of the reproductive system until somatic development and/or until seasonal conditions are sufficiently favorable to afford reproduction. Moreover, integrating activation of spermatogenesis, via its dependency on sex steroids, with reproductive behavior and secondary sexual characters, allows for sexual selection to have an impact. Seemingly wasteful (ornamental or behavioral) competitive traits, often in males, reflect the individual's competence to recruit resources from the environment, involve several genes spread over the genome, and therefore serve as genome-quality indicators. When used in mate choice, this efficiently removes deleterious alleles, while rapidly fixing advantageous ones in a population.

What are the most important steps in spermatogenesis under control of the endocrine system? Reproductive hormones seem to play a critical role at three points:

- the balance between self-renewal and differentiation of SSCs;
- the transition of type A spermatogonia to rapidly proliferating type B spermatogonia, and
- the entry into meiosis.

During later developmental stages, on the other hand, the endocrine system seems to assume a permissive rather than stimulatory role, enabling Sertoli cells to generate the environment germ cells needed to proceed through meiosis and spermiogenesis. After completion of spermatogenesis, the endocrine system is again important for spermiation and milt hydration in the context of spawning.

Knowledge about the mechanisms regulating SSC proliferation and differentiation are not only very interesting with regard to basic and comparative biology, but also with regard to applied aspects of science. For example, the early stages of spermatogenesis in fish are of great relevance for aquaculture biotechnology and ecotoxicology (**see also Hormonal Responses to Stress:** Impact of Stress in Health and Reproduction). Surface freshwater bodies contain compounds (referred to as endocrine-disrupting chemicals, EDCs) that function as agonists/antagonists of nuclear receptors involved in regulating the reproductive system. Detrimental effects of EDCs have been described in wild populations of fish as well as in experimental models, and are an important ecotoxicological concern. In aquaculture biotechnology, precocious sexual maturation, particularly in males, is a commonly observed problem, with adverse effects on growth, flesh composition, disease, and survival. Obtaining detailed knowledge about the underlying processes triggering pubertal testis maturation will be of great relevance not only for developing approaches to control male puberty, but also for estimating the impact of, and the requirement for, monitoring/regulating the presence of EDCs in surface freshwater bodies.

Glossary

Egg The fully grown and ovulated female gamete, competent to undergo fertilization. After ovulation oocytes become eggs. Also called an ovum.

Follicular growth The period after onset of meiosis from the time when prefollicle cells envelop the oocyte to the end of vitellogenic oocyte growth.

Oocyte The female germ cell (gametocyte) from which an egg develops. After the onset of meiosis, oogonia become oocytes.

Oogenesis Process by which oogonia become mature eggs (or ova), the female gametes.

Ovarian follicle The basic unit of female gametogenesis, composed of a spheroid aggregation of cells found in the ovary. Follicles are comprised of an oocyte surrounded by a monolayer of granulosa cells overlain by a basement membrane (or basal lamina) and then a peripheral layer of theca cells and associated connective tissue and vasculature. During the reproductive cycle, these structures grow and develop, culminating in ovulation of the oocyte as a competent egg.

Ovarian maturation The series of events beginning with fully yolked (postvitellogenic) oocytes encapsulated in their follicles and culminating with the ovulation of fertilizable eggs.

Vitellogenesis The stage of oocyte growth characterized by the formation of egg yolk proteins and their accumulation in the ooplasm (Latin *vitellus* (yolk) and Greek *genesis* (production)). Vitellogenesis is characterized by five events: hepatic synthesis of the vitellogenin yolk precursors, which is induced by estrogen, delivery of vitellogenins to the growing oocyte via the bloodstream, selective uptake of vitellogenins by the oocyte through receptor-mediated endocytosis, processing of vitellogenins into their derivative yolk proteins, and storage of the yolk proteins in yolk granules, globules, or platelets.

Vitellogenins Precursors of the major egg yolk proteins comprised of up to five different domains, each of which corresponds to one of the stored yolk proteins (see also yolk proteins). Vitellogenins are large (>350 kDa), homodimeric phospholipoglycoproteins. Common abbreviations for vitellogenin are Vg, VG, and Vtg.

Yolk The content of the ooplasm of the egg, which serves as the nutrient source for the developing embryo. Yolk components of endogenous or maternal origin may include proteins, carbohydrates, lipids, vitamins, minerals, ions, and various other nutritive materials required to sustain embryogenesis, as well as nucleic acids encoding proteins essential for oogenesis and embryonic development.

Yolk proteins Proteolytic derivatives of the yolk precursors, vitellogenins, that are stored in the yolk granules, globules, or platelets, or fluid yolk of the ooplasm and comprise the major protein component of the egg yolk. There are five different yolk proteins, which may occur singly or as conjugates in pairs or groups: lipovitellin heavy chain, lipovitellin light chain, phosvitin, β'-component, and carboxy-terminal component.

Introduction

Ovarian follicle growth can be divided into previtellogenic (primary growth) and vitellogenic (secondary growth) stages, during which the major lipid and protein nutrients required for embryonic and larval development are stored within the oocyte (**Figure 1**). During previtellogenesis, oocytes begin accumulating neutral lipids, which are stored as lipid droplets in the ooplasm. During vitellogenic growth, oocytes also accumulate

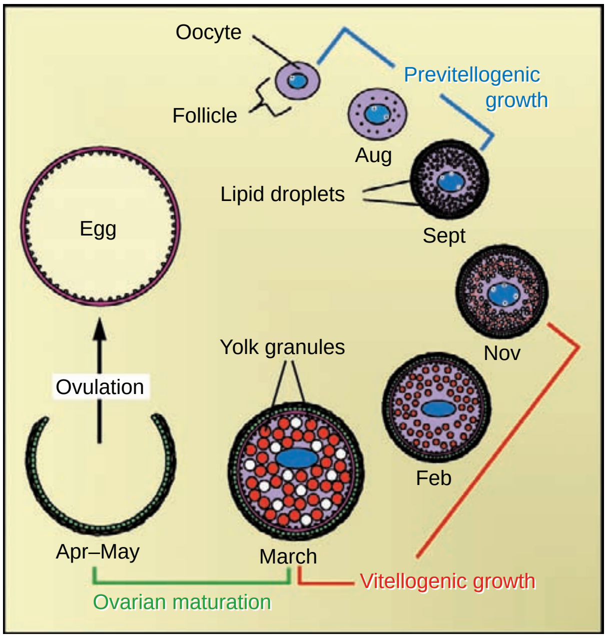

Figure 1 Model depicting oogenesis in a temperate perciform fish, the white perch (*Morone americana*). The oocyte along with its surrounding somatic tissues (the granulosa cells and theca layer) is called a follicle. The previtellogenic, primary growth oocyte accumulates neutral lipids that are stored in the ooplasm as lipid droplets. During vitellogenic growth, lipid deposition continues and the oocyte accumulates yolk proteins, which are stored in yolk granules. After vitellogenic growth is completed, the follicle undergoes maturation, which includes resumption of meiosis and cytoplasmic maturation by the oocyte, culminating in ovulation of an egg that is competent to undergo fertilization.

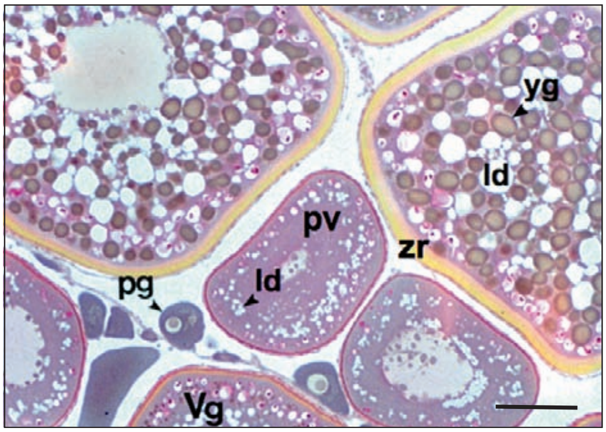

Figure 2 Light micrograph of a section through white perch ovarian follicles containing large, late vitellogenic oocytes (upper left and right) among small primary growth oocytes (pg), previtellogenic oocytes undergoing lipid deposition (pv), and early vitellogenic (Vg) oocytes. This section is typical of white perch ovaries collected just before the spawning season. The large vitellogenic oocytes contain abundant yolk granules (yg) and lipid droplets (ld) as inclusions in their ooplasm, and they have a well-developed egg envelope or zona radiata (zr). The previtellogenic oocytes contain only lipid droplets as ooplasm inclusions and their zona radiata is relatively undeveloped. Scale = 150 μm.

phospholipid-rich yolk protein (YP) precursors termed vitellogenins (Vtgs). Vtgs are synthesized by the liver and transported through the bloodstream to the ovary, where they are taken up by oocytes and processed into their derivative YPs. When vitellogenesis ends, the ovary is filled with fully yolked oocytes that subsequently undergo maturation and ovulation. The contribution to oocyte growth of Vtg-derived yolk can be substantial, comprising up to 80–90% of the dry mass of an ovulated egg in some species. The histological structure of vitellogenic ovarian follicles from white perch (*Morone americana*) is shown in **Figure 2**.

Chemistry of Vitellogenins and Egg Yolk

Vitellogenins are dimeric proteins, consisting of two identical subunits with phosphate, lipid, carbohydrate, and protein components. They are members of the large lipid transfer protein superfamily, which includes other serum lipoproteins such as low-density lipoprotein (LDL). The Vtgs are large lipoproteins (~350–600 kDa) and ~20% lipid by weight. They also are specialized carriers of important ions, such as calcium, magnesium, iron, zinc, copper, and various minerals and vitamins, such as retinoids and carotenoids. In addition, regulatory compounds found in fish egg yolk, including lipid soluble steroid and thyroid hormones, may be transported in part by Vtgs.

For fishes that spawn demersal (sinking) eggs that lack prominent oil droplets, Vtgs are major carriers of lipids into growing oocytes, most of which (~80%) are phospholipids, often phosphatidylcholines (**Figure 3**). In marine fishes that spawn pelagic (floating) eggs with no large oil droplet(s), phospholipids, triacylglycerides, and wax- or steryl-esters can account for >70%, ~8–12%, and ~4% of total egg lipids, respectively. Other teleosts produce pelagic eggs with large oil droplets comprised of neutral lipids (e.g., triacylglycerides and wax- or steryl-esters) that can occupy >50% of the ooplasm. As the deposition of neutral lipids is initiated before, and can occur independently from, accumulation of Vtg-derived YPs, Vtg is not a major source of neutral lipids in oocytes of these species. The neutral lipids must be delivered to the oocyte via a different mechanism, perhaps by LDL or related lipoproteins.

Alanine is the most abundant amino acid comprising Vtg polypeptides (~11–12% of total residues). In addition, Vtgs in some species (e.g., anguillid eels) contain polyalanine regions. It is suggested that the alanine serves as an important intermediary of carbohydrate metabolism, especially embryonic gluconeogenesis.

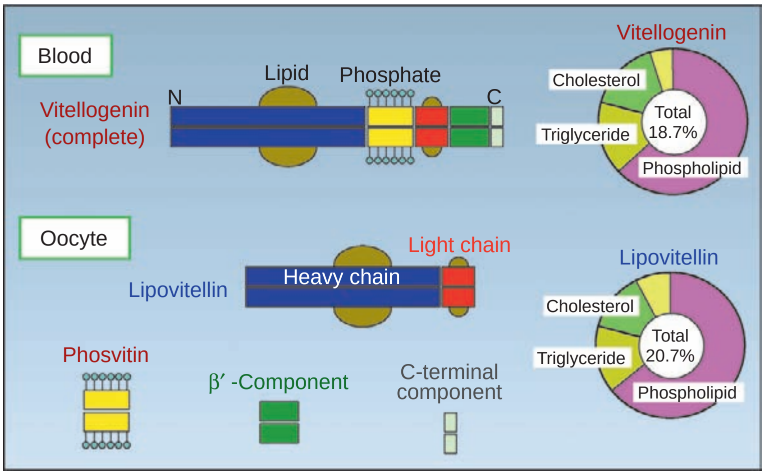

Figure 3 Model showing the pentapartite domain organization of native complete vitellogenin (dimer) in the blood and its corresponding dimeric yolk protein products in growing oocytes. The yolk protein products include: lipovitellin (Lv) heavy chain (LvH), Lv light chain (LvL), phosvitin (Pv), β'-component (β'-c), and C-terminal component (Ct). Phosphate groups attached to Pv are indicated by the aqua blue circles, and lipids bound to vitellogenin (Vtg) and Lv are indicated by the half-ovals shaded in brown. The amino (N)- and carboxy (C)-termini of Vtg also are indicated. The average percentage of total teleost Vtg and Lv lipid (by weight) is indicated within the white circles to the right (total %); the proportional composition of lipids by class (phospholipid, triglyceride, and cholesterol) is shown as colored wedges, with phospholipids being the dominant lipid class.

Vitellogenin Structure and Product YPs

Native Vtg monomers consist of covalently linked YP domains that are proteolytically processed into corresponding YPs after being taken up by the oocyte (**Figure 3**). Complete Vtg molecules consist of five linear YP domains from the amino-terminus: lipovitellin heavy chain (LvH), phosvitin (Pv), lipovitellin light chain (LvL), β'-component (β'-c), and C-terminal peptide (Ct).

The largest YP is the LvH lipoprotein that supplies offspring with amino acids and phospholipids, which can serve as catabolic energy substrates or in anabolic synthesis of membrane or protein structures, respectively. Teleost LvH has an average mass of ~114 kDa predicted from deduced amino acid sequences and resolves close to this position by acrylamide gel electrophoresis in most species. The LvH polypeptide consists of largely amphipathic secondary and tertiary structures that form a basket with a lumen of hydrophobic residues required to accommodate lipids. This characteristic structure is similar to vertebrate apolipoprotein B, the primary protein scaffold of other lipid-transporting particles such as LDL. Almost universally included in the LvH domain is a short sequence known to bind oocyte Vtg receptors. The LvL domain, which is smaller than LvH (~25 kDa), also forms part of the lipid-basket of Vtg and has chemical and structural characteristics similar to LvH. The LvH and LvL domains of Vtg usually contain one or more glycosylation sites to which carbohydrate moieties are attached and the LvH also contains a site that may bind zinc ion.

The Pv is a metalloprotein, consisting largely of serines (>50% of total residues), to which phosphates may be covalently attached prior to secretion by the liver. The negatively charged phosphates attract calcium, magnesium, zinc, and other multivalent metal cations (e.g., ferric iron) via ionic interactions occurring in the bloodstream or oocyte. In freshwater fishes, such as masu salmon (*Oncorhynchus masou*) and mosquitofish (*Gambusia affinis*), metal ions delivered by Pv are crucial for embryo survival, since they are not abundantly available for uptake from the environment. The egg yolk of marine fishes, such as barfin flounder (*Verasper moseri*), red seabream (*Pagrus major*), and Pacific herring (*Clupea pallasii*), contains less of the metal ions abundantly present in seawater (e.g., calcium and magnesium), suggesting that Pv plays a less significant role in maternal provision of these ions in marine fishes. The Pv also usually contains several potential glycosylation sites. Thus, Pv acts to transport important metabolic ions and carbohydrates into the yolk and, in doing so, helps maintain aqueous solubility of the largely hydrophobic Vtg particle. In addition, Pv may aid in stabilizing Vtg structure through interaction with the basket enclosing lipid cargo formed by LvH and LvL.

It is technically difficult to precisely resolve Pv by acrylamide gel electrophoresis, since it does not stain by traditional protein dyes and all species of Pv do not migrate to the same position in the gel (size range ~6–20 kDa) due to high and varying degrees of phosphorylation and to the presence of various Pv–Lv conjugates in the yolk. The size of Pv also is highly variable among fishes and the Pv domain may even be lacking in some incomplete forms of Vtg. The Pv-containing Vtgs from Ostariophysian and Protacanthopterygian fishes generally contain shorter Pvs with fewer serines (~24–34) than those from acanthomorph teleosts, which contain ~50 serines. In contrast, Japanese eel (*Anguilla japonica*) Vtgs have massive Pvs with 87–91 serines. Why this size variation occurs is unknown.

The remaining two small YPs (β'-c and Ct) are devoid of lipid and phosphate but together contain 14 highly conserved cysteine residues, which are known to be involved in disulfide linkages required for complex folding of the Vtg polypeptide and possibly for dimerization of native Vtg. This carboxy-terminal end of Vtg is highly similar in structure to cysteine-rich von Willebrand factor (vWF)-type D2 domain located in the short propeptide of vertebrate vWF. In addition, a conserved CGxC motif found in both vWF-type D2 domain and the carboxy-terminus of β'-c may be involved in facilitation of disulfide bond formation during peptide folding and/or adhesion when Vtg binds its oocyte receptor. The β'-c may have a glycosylation site and, like Pv, also has high aqueous solubility with many of its hydrophilic residues exposed on the surface of the Vtg particle. Although β'-c is known to be released from the carboxy-terminal end of Vtg as an ~16 kDa YP in a number of fish species, presence of Ct as a bona fide YP has only been verified in barfin flounder and deduced in Atlantic herring. The molecular weight of β'-c in the oocytes of several fishes indicates that Ct is cleaved from its carboxy-terminus; however, it may be degraded as opposed to stored as yolk, since a Ct YP typically cannot be detected (predicted size ~13 kDa).

Nomenclature and Classification of Vitellogenins

Fish Vtgs have a complex evolutionary history and they exhibit considerable variation in structure and function. The currently accepted Vtg nomenclature developed by R.N. Finn and associates is based on multiple types of Vtg having arisen via whole genome duplications (WGDs) during the evolutionary history of vertebrates. According to this scenario, the ancestral chordate Vtg (VtgABCD, present in silver lamprey, *Ichthyomyzon unicupsis*) gave rise to two forms of Vtg, VtgAB (chondrostean vitellogenin; present in chondrostean fishes and amphibian and avian species) and VtgCD. The VtgAB subsequently gave rise to VtgA (universally present in teleosts) and to VtgB, which is extinct. VtgCD gave rise to teleost vitellogenin type C (VtgC; also called Vtg3 or phosvitinless Vtg) (present in teleosts from diverse phylogenetic lineages) and to VtgD, which is extinct. Additional Vtg gene duplications, not always involving WGD, have occurred within different lineages of fishes. Dual or multiple A-type Vtgs are present in Protacanthopterygii (salmonids, VtgAsa, and VtgAsb), Ostariophysi (Ostariophysian vitellogenin type 1 (VtgAo1) and type 2 (VtgAo2)), and Elopomorpha (Elopomorph vitellogenin type 1 (VtgAe1), type 2 (VtgAe2), and type 3 (VtgAe3)). In a late round of WGD, the VtgA gave rise to two paralogous forms of Vtg (acanthomorph vitellogenin type Aa (VtgAa; also called Vtg1 or VtgI) and type Ab (VtgAb; also called Vtg2 or VtgII)), which are present in acanthomorph teleosts.

The various forms of fish Vtg may be either complete or incomplete and their phylogenetic distribution is shown in **Table 1**. Incomplete Vtgs are subdivided into those that contain Pv and those that lack or have severely reduced Pv domains (Pv-less). The VtgC is incomplete, being Pv-less and also lacking β'-c and Ct domains, and consists only of lipovitellin (LvH and LvL). Incomplete Pv-containing Vtgs occur only in Ostariophysian fishes (VtgAo1) and contain three YP domains: LvH, Pv, and LvL. A protein dendogram showing classification and domain structure of various types of Vtg present in diverse fish species for which full-length Vtg sequences are available is shown in **Figure 4**.

Endocrine Control of Vitellogenesis

Vitellogenesis is a seasonal or cyclic process depending on gonadotropins. The production of gonadotropin-releasing hormone (GnRH) by the brain (hypothalamus) is mediated

Table 1 Classification of multiple fish vitellogenins (Vtgs)

Taxon	*Complete Vtgs*	*Incomplete Pv-containing Vtgs*	*Incomplete Pv-less Vtgs*
Acanthopterygii	VtgAa and VtgAb	–	VtgC
Paracanthopterygii	VtgAa and VtgAb	–	VtgC
Protacanthopterygii	VtgAsa and VtgAsb	–	VtgC
Ostariophysi	VtgAo2	VtgAo1	VtgC
Elopomorpha	VtgAe1, VtgAe2, VtgAe3	–	?
Chondrostei	VtgAB	–	?
Primitive chordates	VtgABCD	–	?

A dash (–) indicates a Vtg type that is absent in a taxonomic group of fishes and a question mark (?) indicates not evaluated or described to date. The nomenclature is based on Finn and Kristoffersen, *PLoS ONE*, 2(1): e169.doi:10.1371/journal.pone.0000169, 2007.

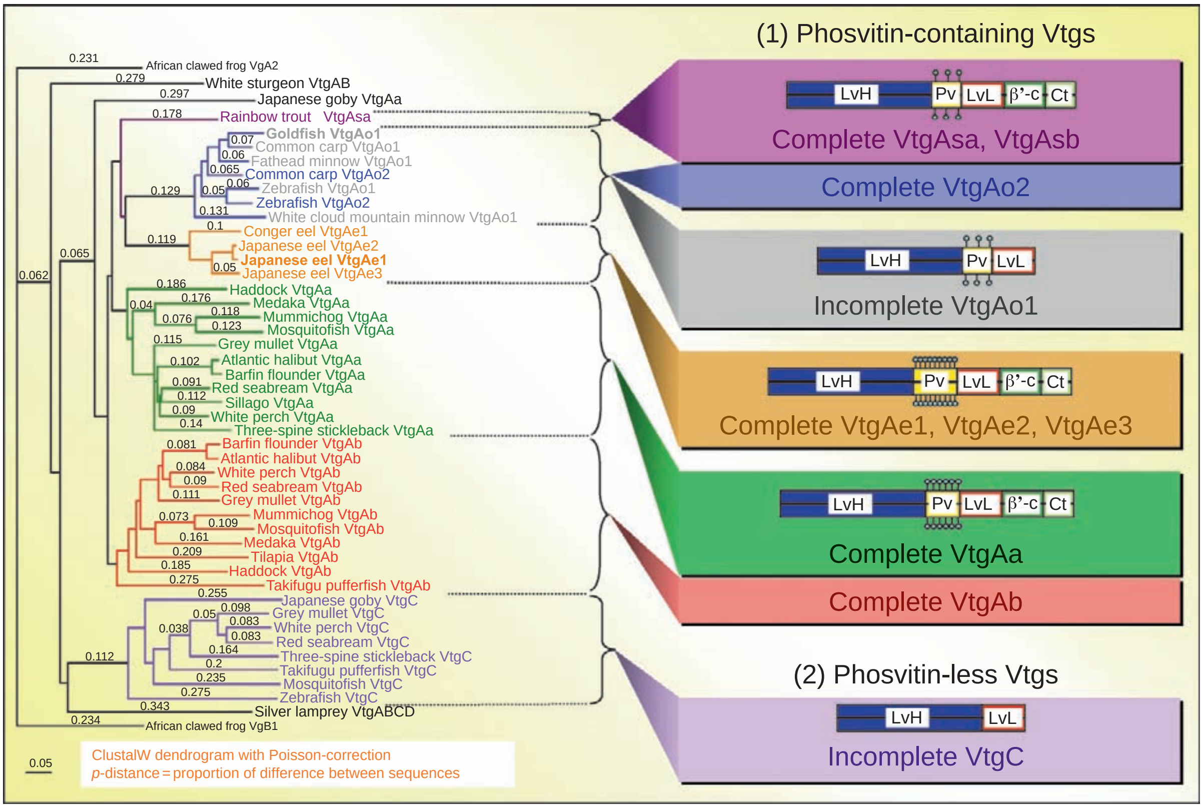

Figure 4 Protein dendrogram, nomenclature, and domain structure of vitellogenins (Vtgs) present in a diverse array of teleosts for which full-length Vtg cDNA and deduced polypeptide sequences are available. See text for details and abbreviations. The protein dendrogram was generated using the ClustalW (v 1.83) algorithm and MacVector™ (Oxford Molecular Ltd.) software with multiple alignment parameters: open gap penalty = 10.0; extended gap penalty = 0.2; delay divergent = 30%; gap distance = 4; and similarity matrix = gonnet. The Vtg polypeptide sequences were deduced from cDNA. Adapted from Reading BJ, Hiramatsu N, Sawaguchi S, *et al*. (2009) Conserved and variant molecular and functional features of multiple egg yolk precursor proteins (vitellogenins) in white perch (*Morone americana*) and other teleosts. *Marine Biotechnology* 11:169–187.

by a variety of endogenous and environmental factors, including innate biorhythms, nutritional status, and seasonal changes in day length and water temperature. In response to GnRH, follicle-stimulating hormone (FSH) is secreted by pituitary gonadotrophs and induces the theca and granulosa cells of the ovarian follicle to secrete estradiol-17β (E2), which instructs the liver to synthesize Vtgs and secrete them into the bloodstream (**Figure 5**). In some species, luteinizing hormone produced by the pituitary in response to GnRH also elicits follicular production of E2. Growth hormone, thyroid hormone, cortisol, androgens, and other estrogenic steroids, such as estrone, may also contribute to induction of hepatic vitellogenesis in some species (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction).

Vitellogenin Synthesis and Secretion

Circulating E2 enters liver cells and binds to one of three estrogen receptors (ERs), likely estrogen receptor alpha in tilapia, *Oreochromis mossambicus* (**Figure 5**). Once the E2 is bound, conformational changes occur, which allow the ER to bind protein factors involved in targeted transcriptional activation. The ER is translocated to the nucleus where it dimerizes and binds specific genomic DNA sequence motifs called estrogen response elements nearby basal *vtg* gene promoters and transcription is initiated. Ribosomes on the rough endoplasmic reticulum translate Vtg-encoding mRNAs and the polypeptides are translocated to the endomembrane system. The Vtgs undergo substantial posttranslational modification. They must be properly folded and dimerized, their Lv domains lipidated, Pv domains phosphorylated, 15–16 residue signal peptides cleaved, and carbohydrate moieties attached to their glycosylation sites. Mature Vtgs are exported to the *trans*-Golgi network where they are packaged into secretory vesicles and released into the circulatory system.

Rates of hepatic synthesis differ between Vtg types and some Vtgs are more sensitive to induction by E2. In Japanese goby (*Acanthogobius flavimanus*), VtgC has a lower sensitivity to induction by E2 and, in most species, is a minor form of Vtg based on transcription rate, plasma protein levels, and/or yolk composition. In contrast,

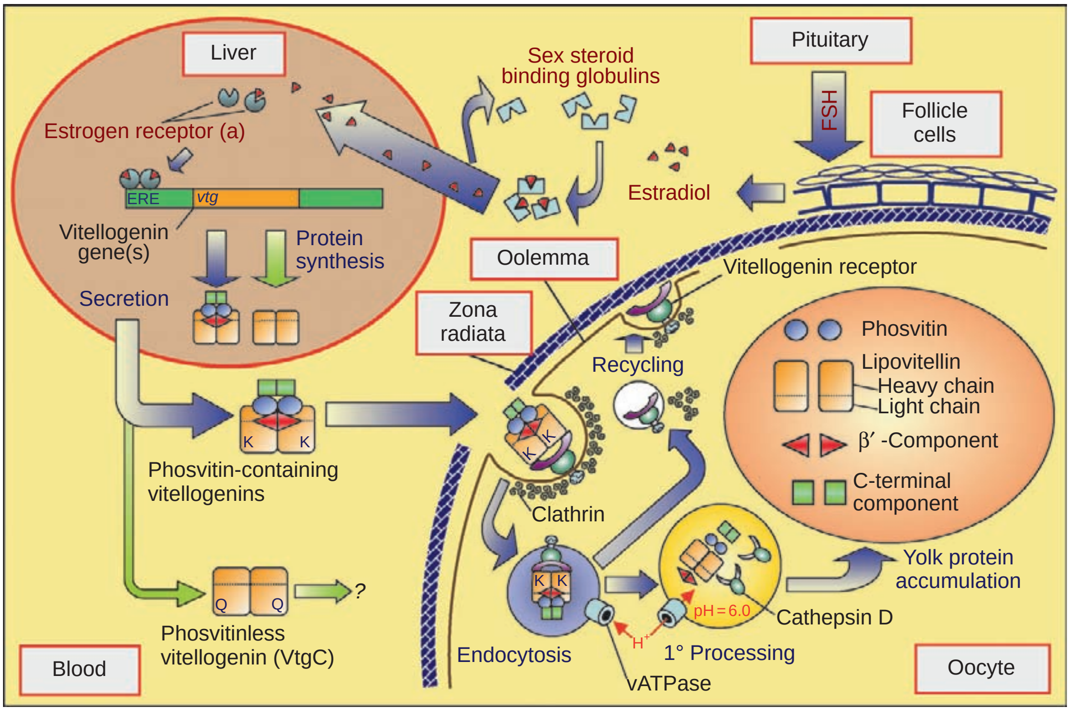

Figure 5 Model of vitellogenesis and oocyte growth. See text for details and abbreviations. Redrawn from Hiramatsu N, Cheek AO, Sullivan CV, Matsubara T, and Hara A (2005) Vitellogenesis and endocrine disruption. In: Mommsen TP and Moon TW (eds). *Biochemistry and Molecular Biology of Fishes*, vol. 6, pp. 431-471. Amsterdam: Elsevier.

VtgAb and VtgAa are the dominant types in barfin flounder and goldsinny wrasse (*Ctenolabrus rupestris*), respectively. Rates of hepatic secretion may also differ between Vtg types, as shown in barfin flounder. In this species, VtgAb is present at low levels in the liver compared to VtgAa and VtgC. However, VtgAb levels in the serum are relatively high, indicating that it is secreted at a higher rate than VtgAa and VtgC (see also **Figure 9**).

Vitellogenin Uptake and Processing into YPs

Circulating Vtgs travel through capillaries in the follicle theca and pass through the basement membrane and intercellular spaces among granulosa cells to enter the extracellular matrix of the granulosa epithelium where it contacts the oolemma. Here, Vtgs enter growing oocytes via selective endocytosis mediated by specific membrane receptors (vitellogenin receptors (Vtgrs)) (**Figure 5**). Once bound to Vtg, the Vtgrs cluster in clathrin-coated pits that invaginate and are endocytosed. In the peripheral ooplasm, the clathrin coat is stripped and Vtg dissociates from the Vtgr due to mild acidification of the vesicle. Vesicles are then sorted into a population of early endosomes that fuse with lysosome-like organelles to form multivesicular bodies. Inactive cathepsin D zymogens are co-localized with the imported Vtgs, and V-class vacuolar ATPases (i.e., proton pumps) further acidify the lumen of the multivesicular bodies. The resulting drop in pH (to ~6.0) activates cathepsin D, which cleaves Vtg into its product YPs, including LvH, LvL, Pv, β'-c, and Ct (**Figure 5**). Proteolytic variants of YPs have been demonstrated in some species, whereby the Pv domain either remains covalently linked to the carboxy-terminus of LvH or the amino-terminus of LvL, or whereby LvH–Pv–LvL conjugates remain largely intact. Smaller proteolytic fragments of LvH and β'-c have been reported in some fishes and may possibly result from incomplete or nonspecific cleavage of Vtgs.

This initial proteolytic event is termed 'primary YP processing'. Acidification may also strip calcium ions from Pv. The YPs are stored as noncovalently linked homodimers in yolk granules, globules or platelets, or as fluid yolk, in the ooplasm. In addition, noncovalent association of LvH with LvL to form lipovitellin (Lv), presumably as a result of the similar lipophilic characteristics of these YPs, has been demonstrated in many species.

Disparate accumulation of different types of Vtgs by the oocyte has also been reported. In grey mullet (*Mugil cephalus*), an acanthomorph species that spawns pelagic eggs, the accumulated ratio of VtgAa:VtgAb:VtgC in oocytes is 4:13.3:1 and in barfin flounder it is 9:15:1. Thus, a system for differential uptake of Vtgs exists and may be receptor mediated.

Vitellogenin Receptors

The teleost Vtgr is a member of the lipoprotein receptor superfamily characterized by eight ligand-binding repeats (LR8), a feature typical of other vertebrate Vtgrs and of the very low density lipoprotein receptor (VLDLR) (**Figure 6**). The LR8 receptors are ∼100–110 kDa and generally exist as splice variants either containing [LR8(+)] or lacking [LR8(–)] a serine- and threonine-rich O-linked sugar domain. The LR8(–) Vtgr is the dominant lipoprotein receptor in the ovary of fishes, whereas the LR8(+) may be a somatic VLDLR also expressed in the ovary of some species. Highest Vtgr mRNA expression occurs during previtellogenesis and expression is very low or absent in late-vitellogenic follicles or ovulated eggs. However, Vtgr-binding activity is not detected until transition to vitellogenic growth. The Vtgr transcripts are translated during vitellogenesis and Vtgrs are recycled back to the oocyte membrane throughout vitellogenic oocyte growth (**Figure 5**). The first three ligand-binding repeats of the Vtgr recognize a short motif rich in basic amino residues (HLTKTKDLN) in tilapia (*Oreochromis aureus*) VtgAb, to which it binds. Similar, but not identical, sequences are located in LvH of other fish Vtgs, usually between residues 172 and 191. The VtgC lacks this sequence.

Three distinct Vtgrs that specifically bind VtgAa and VtgAb have recently been discovered in the acanthopterygian white perch (**Figure 7**). One of these (>200 kDa) binds specifically to VtgAa (the vitellogenin Aa receptor (VtgAar)), whereas two other receptors (110 and 116 kDa) bind VtgAb (the vitellogenin Ab receptors (VtgAbrs)). It is hypothesized that these receptors may direct the different forms of Vtg into discrete populations of early endosomes resulting in disparate degrees of storage and proteolysis of their derivative YPs during ovarian maturation (see below). The disparate uptake of different Vtg types by the oocyte in barfin flounder and grey mullet may also relate to this discovery. Multiple ovarian receptors that bind Vtg have been detected in the rainbow trout (*Oncorhynchus mykiss*); however, disparate binding to the different Vtg ligands (Protacanthopterygian (salmonid) vitellogenin type a (VtgAsa) and type b (VtgAsb)) was not demonstrated.

Maturational Proteolysis of YPs

After vitellogenesis, oocytes undergo maturation, which, in addition to resumption of meiosis, includes lipid droplet coalescence, ooplasm clarification, and oocyte

Figure 6 Model depicting typical structures of teleost oocyte lipoprotein receptors with eight ligand-binding repeats (LR8). Motifs present in each domain are indicated at the left and the linear organization of the defined receptor domains present in the receptor polypeptide sequences is shown on the right (**see** section Vitellogenin Receptors for details and abbreviations). The LR8 receptors contain four (Vtgr) or five (VLDLR) domains from the N-terminus: a ligand-binding domain, comprised of eight class A ligand-binding repeats; a domain that shares high homology with epidermal-growth factor precursor (EGFP) comprised of three class B repeats (A–C) and five YWxD repeats that form the β-propeller; an O-linked sugar domain which is present in the VLDLR [(LR8(+)], but is absent in the Vtgr [LR8(–)]; a transmembrane domain; and a short cytoplasmic domain that contains endocytosis signals (NPxY and YxxØ). Clusters of acidic residues (DxSDE) impart a negative charge at the surface of each ligand-binding repeat, indicated by the (–), which is required for their electrostatic interaction with specific positively charged residues in Vtg or other ligands.

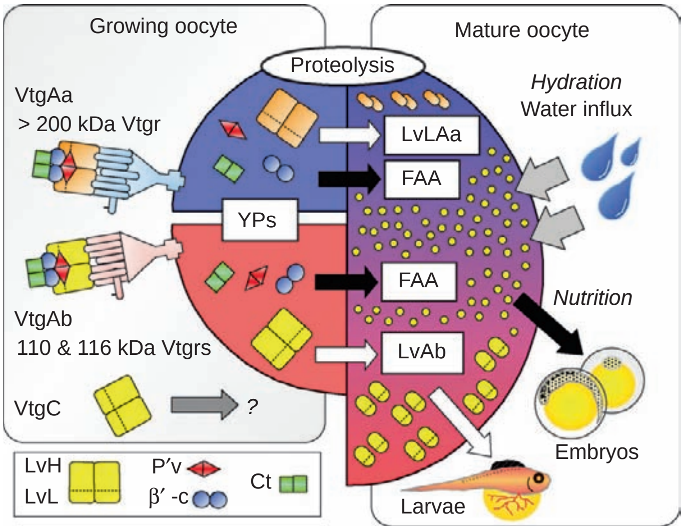

Figure 7 Hypothetical model of oocyte growth including recent findings on ovarian receptors for vitellogenins (Vtgrs) in white perch (**see** section Vitellogenin Receptors for details). One of these receptors specifically binds VtgAa (>200 kDa Vtgr), whereas the two other receptors bind VtgAb (110 and 116 kDa Vtgrs). During oocyte growth, these receptors may direct the different forms of complete Vtg into discrete populations of early endosomes (blue and red compartments) where they are cleaved into product yolk proteins (YPs): lipovitellin (Lv) heavy chain (LvH), Lv light chain (LvL), phosvitin (Pv), β'-component (β'-c), and C-terminal component (Ct). The YPs derived from the different forms of complete Vtg are later subjected to disparate degrees of maturational proteolysis yielding free amino acids (FAAs) and lipoprotein products that play different roles in oocyte hydration and embryonic and larval nutrition (**see** section Maturational Proteolysis of YPs for details). In white perch, VtgC does not bind any Vtgr; therefore, its method of entry into the oocyte is unknown and indicated with a question mark.

hydration. Collectively, these latter changes are termed ‘cytoplasmic maturation’. In acanthomorph teleosts that spawn pelagic eggs in marine or brackish water, a ‘secondary proteolysis’ occurs during this time, whereby most Vtg-derived YPs are degraded into free amino acids (FAAs). However, the major YP derived from VtgAb (LvHAb) persists largely intact (**Figure 8**), although it may dissociate from its native dimeric state into monomers (~170 kDa). In barfin flounder, the YPs derived from VtgAa (representing ~87% of the entire VtgAa polypeptide) are extensively cleaved into FAAs, whereas the proteolysis of YPs derived from VtgAb (representing only ~33% of the VtgAb polypeptide) is quite limited. A similar phenomenon has been described in haddock (*Melanogrammus agefinus*) and in Atlantic halibut (*Hippoglossus hippoglossus*). The VtgC has been shown to survive maturational proteolysis in grey mullet, mosquitofish, and white perch. The β'-c also survives this degradation in striped bass (*Morone saxatilis*), although it is degraded in barfin flounder, red seabream, and Atlantic halibut. In barfin flounder, LvL remnants, perhaps derived from Lv–Pv conjugates or from incomplete degradation of LvLAa, along with Vtg-derived yolk lipids, are reconstructed into novel, highly lipidated particles.

Maturational proteolysis of YPs requires acidification of yolk vesicles, which activates cathepsin proenzymes therein (**Figure 9**). Yolk vesicle pH decreases to ~5.0–5.5 due to the activation of bafilomycin-sensitive vacuolar H^+-ATPase in concert with chloride channels in the organelle membranes and of the chloride antiporter SLC26 (pendrin) in the oolemma (**Figure 9**). In mummichog (*Fundulus heteroclitus*), cathepsins B, F, and L have all been implicated in this process. However, cathepsin F is only found in yolk granules during vitellogenesis and, therefore, it may play a catalytic role in the activation of cathepsins B or L. The proteolytic activities of cathepsins B and L related to their roles in degradation of YPs may also be species specific. In barfin flounder, cathepsin B mediates this degradation; however, in seabream (*Sparus aurata*) cathepsin L does. Concomitant with the proteolysis of YPs, inorganic phosphates are liberated from Pv by phosphatase, which is activated by yolk vesicle acidification.

The small peptides and FAAs generated during secondary YP processing, along with inorganic intraoocytic ions, such as Pv-derived phosphate (and calcium) and potassium transported into the oocyte by oubain-sensitive Na^+, K^+-ATPase, act as osmotic effectors that drive the influx of water. Water diffuses through aquaporin channels transiently expressed in the oocyte membrane, resulting in oocyte hydration and in acquisition of proper egg buoyancy. Oocyte hydration also provides for dilution of embryonic wastes

Figure 8 Model showing molecular alterations of the three types of vitellogenins (Vtgs) during vitellogenesis (1° processing) and ovarian maturation (2° processing) in barfin flounder. Structures of Vtgs and their product yolk proteins in serum of vitellogenic fish, vitellogenic oocytes, and ovulated eggs are shown (**see** sections Vitellogenin Uptake and Processing into YPs and Maturational Proteolysis of YPs for details and abbreviations). The yolk proteins (YPs), including LvH, LvL, Pv, β'-c, and Ct, are illustrated as in **Figure 1** with the exception that the Vtg-of-origin of each yolk protein (VtgAa, VtgAb, or VtgC) is indicated following the abbreviation for that YP (Aa, Ab, and C, respectively). The percentage of total Vtg comprised by VtgAa, VtgAb, and VtgC in liver and serum, and by the YPs products of each form of Vtg in fully yolked oocytes is also indicated (percent of total Vtg or YP). Although processing of LvHC during ovarian maturation was not evaluated in barfin flounder, in several other species this yolk protein remains largely intact. Compiled from Matsubara T and Swano K (1995) Proteolytic cleavage of vitellogenin and yolk proteins during vitellogenin uptake and oocyte maturation in barfin flounder (*Verasper moseri*). *Journal of Experimental Zoology* 272: 34–45; Matsubara T and Koya Y (1997) Course of proteolytic cleavage in three classes of yolk proteins during oocyte maturation in barfin flounder *Verasper moseri*, a marine teleost spawning pelagic eggs. *Journal of Experimental Zoology* 278: 189–200; Matsubara T, Ohkubo N, Andoh T, Sullivan CV, and Hara A (1999) Two forms of vitellogenin, yielding two distinct lipovitellins, play different roles during oocyte maturation and early development of barfin flounder, *Verasper moseri*, a marine teleost that spawns pelagic eggs. *Developmental Biology* 213: 18–32; and Sawaguchi S, Ohkubo N, Amano H, *et al*. (2008) Controlled accumulation of multiple vitellogenins into oocytes during vitellogenesis in the barfin flounder, *Varasper moseri*. *Cybium, the International Journal of Ichthyology* 32(2): 262.

(e.g., ammonia) and adjusts the spatial volume of the egg for embryonic development. The YP-derived FAA pool is later used as a source of diffusible nutrients by embryos at early developmental stages, while the remaining LvHs serve as lipoprotein nutrients for late-stage embryos and larvae, in which structures required to process large macromolecules (e.g., yolk syncytium) have formed.

In acanthopterygian teleosts spawning demersal eggs, such as mummichog, and those in less derived taxa, degradation of YPs into FAA is not as extensive and some major YPs (notably LvHAa) are only partially hydrolyzed or nicked to yield smaller peptides. For example, there is only a nearly threefold increase in absolute FAA content in maturing oocytes of the mummichog, which spawns demersal eggs, as compared to the barfin flounder, a pelagic egg spawner in which a ~12-fold increase in FAA content is observed. In addition, disparate hepatic production or oocytic accumulation of different types of Vtg (e.g., VtgAa:VtgAb ratios) may influence this phenomenon.

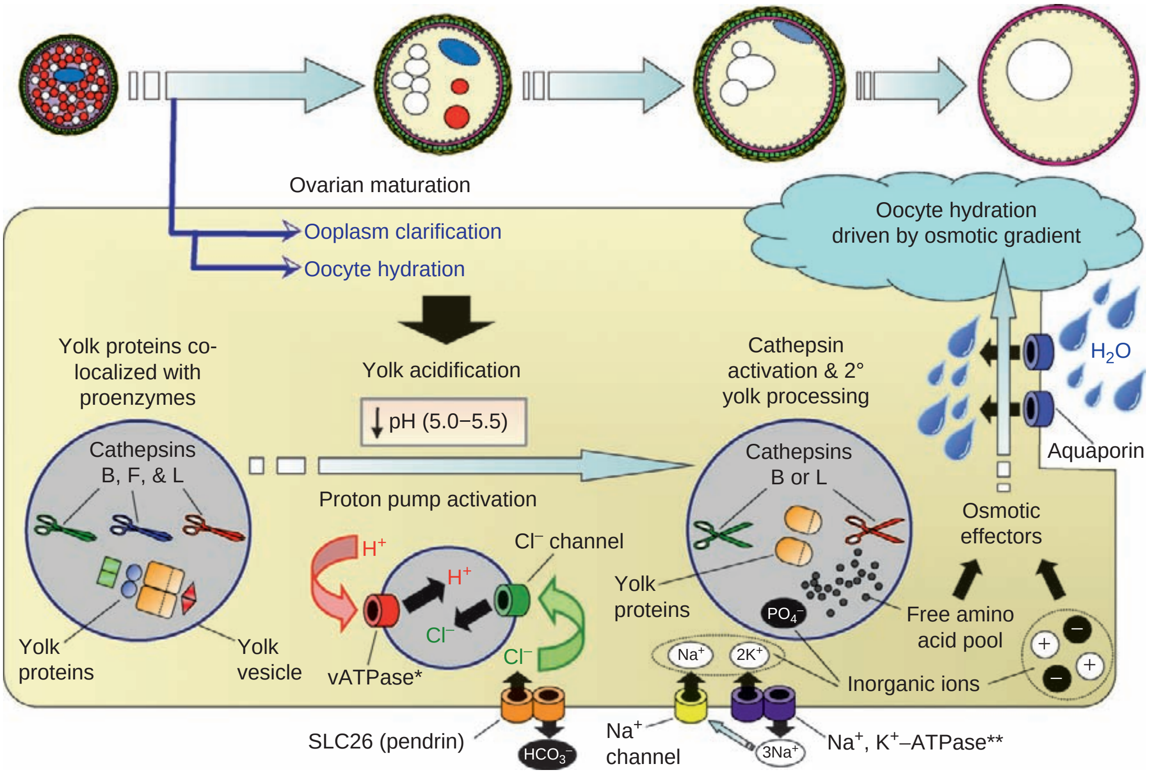

Figure 9 Model of ovarian maturation showing mechanisms of maturational proteolysis of yolk proteins (YPs) and ion transport during oocyte hydration (**see** the section Maturational Proteolysis of YPs for details and abbreviations). Ooplasm clarification and oocyte hydration are related to the proteolysis of vitellogenin (Vtg)-derived YPs, which requires acidification of the yolk vesicles to activate cathepsin proenzymes, yielding free amino acids (FAAs) that act as osmotic effectors influencing oocyte hydration. The single asterisk (*) and double asterisk (**) indicate bafilomycin- and oubain-sensitive ATPases, respectively.

Phosvitinless Vitellogenin: The Oddities of VtgC

The nearly universal presence of VtgC and its characteristic lack of some typical YP domains raise questions as to its physiological functions. The VtgC usually makes a minor contribution to the yolk. In grey mullet and barfin flounder, LvHC represents only 5.4% and 4.0% of the total LvH accumulated by oocytes, respectively. However, in mosquitofish a corresponding value as high as 25% has been reported. The VtgC has an aberrant Vtgr-binding site in its LvH domain and, in the white perch, it does not bind to any oocyte receptor, indicating a potentially different mechanism of oocyte entry, perhaps in the fluid endocytotic phase. This linkage between lack of receptor binding and the absence of oocytic proteolysis emphasizes receptor targeting of Vtgs to specific endocytotic compartments as an important mechanism regulating their proteolytic fates. In addition, the synthesis of VtgC appears to be less dependent on, and less sensitive to, E2 induction and it has been reported to begin accumulating in oocytes much earlier than the complete Vtgs in medaka (*Oryzias latipes*) and tilapia (*Oreochromis niloticus*). In mosquitofish, LvHC is consumed as a nutrient by late-stage larvae. Thus, VtgC may provide a mechanism for enriching the supply of large lipoprotein nutrients for late-stage larvae without altering the osmotic balance of oocytes or eggs.

Vitellogenesis in Livebearing Fishes

Livebearing fishes (**see also Social and Reproductive Behaviors**: Nutritional Provision During Parental Care) also produce Vtgs and utilize their derivative YPs as nutrients that support embryonic development. The ovoviviparous mosquitofish and the viviparous redtail splitfin (*Xenotoca eiseni*) produce VtgAa, VtgAb, and VtgC and deposit them in oocytes as YP nutrients. Although mosquitofish embryos develop in a closed system (egg), with the mother contributing no additional nutrients during gestation, *Xenotoca* embryos form vascular attachments with their mother called trophotenia, which function analogously to a placenta. This mode of embryonic development, termed matrotrophy, in which nutrients are supplied directly by the mother, has arisen independently in many fish lineages. However, the extent to which Vtg-derived YPs contribute to embryonic nutrition after formation of trophotenia remains to be verified, and direct transfer of Vtgs from mother to offspring via trophotenia also is unexplored.

Alternative Functions of Vitellogenins

In the rosy barb (*Puntius conchonius*), Vtg(s) have been shown to have hemagglutinating functions in blood clotting and males produce Vtgs in response to bacterial exposure. The basis for the hemagglutinating properties of Vtg is unclear at present; however, the vWF-like β'-c may be involved, since vWF is important in platelet and collagen adhesion during clotting. The Vtg(s) of greeling (*Hexagrammos otakii*) and carp (*Cyprinus carpio*) have been shown to exhibit multivalent pattern recognition, binding to various pathogen-associated structures including bacterial lipopolysaccharide, peptidoglycan, and lipoteichoic acid in a bacteriostatic fashion. Interaction of purified greeling Vtg(s) with lipopolysaccharide and lipoteichoic acid in the cell wall is actually bacteriocidal. Therefore, Vtgs may serve as antimicrobial agents in some species.

Vtgs have also been demonstrated to regulate their own synthesis in some fishes. Vitellogenesis in female walking catfish (*Clarias batrachus*) has been induced by administration of heterologous Vtg(s) purified from Indian mrigal carp (*Cirrhinus mrigala*). In rainbow trout, high concentrations of Vtg(s) inside the oocyte can alter Vtg synthesis in the liver, through suppression of E2 production by the ovary.

The specific types of Vtgs possessing these various alternative functions have not yet been identified.

Applications and Perspectives of Vitellogenesis

Circulating Vtgs have served as markers for onset of puberty and progression of gonad maturation in female fishes, especially in aquaculture. The presence of Vtg in blood, mucus, and muscle has also been used to identify the gender of fishes that do not exhibit sexual dimorphism (**see also Social and Reproductive Behaviors**: Sexual Behavior in Fish). Assessment of the proper maturational proteolysis of Vtg-derived YPs, or of expression of cathepsin transcripts and proteins, has also been used as a marker of egg quality. In addition, Vtgs are frequently used to assess exposure of animals in aquatic environments to endocrine-disrupting chemicals (EDCs), specifically to EDCs that mimic the action of estrogens (**see also Toxicology**: The Toxicology of Organics in Fishes). Since Vtgs are produced in response to endogenous E2, they are potentially ideal markers for assessment of estrogenic EDCs. However, as disparities exist between the different types of Vtgs (or *vtg* transcripts) with regard to their sensitivity to induction by estrogen(s), the specific type of Vtg being measured to detect EDCs should be taken into account.

Animal behavior Any action or reaction of an animal in the field or in a laboratory setting.

Ethology The study of animal behavior derived from the Greek word *ethos* meaning character. Ethologists study animal behavior.

The award of the Nobel prize for physiology or medicine in 1973 to three ethologists, Karl von Frisch, Konrad Lorenz, and Nikolaas Tinbergen, marked a turning point in awareness of the fundamental links between organism behavior and physiology. Although physiologists have long recognized the importance of behavioral factors in understanding the way organisms respond to their environment, traditionally physiology and behavior have been studied as two separate fields. We now find ourselves in an era of multidisciplinary research supporting an increasing trend toward combining behavioral and physiological approaches. In particular, the vast diversity of fish species combined with the myriad of life histories that they display make fishes excellent models for comparative studies linking behavior and physiology.

This section of the encyclopedia is particularly diverse, reflecting the enormity of the interface between behavior and physiology in fish. In general, the section can be divided into three areas where current research is investigating behavior/physiology interrelations. These are sensory systems, perception, and learning; interactions with the environment; and social and reproductive behaviors.

Sensory Systems, Perception, and Learning

Fishes obtain information about their surrounding environment through their sensory systems. Some fish senses, such as hearing, vision, taste, and smell, are very similar to that in humans, while others, such as electrocommunication, are completely alien. These senses, sound (**see also Sensory Systems, Perception, and Learning**: How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling and **Hearing and Lateral Line**: Acoustic Behavior), vision (**see also Sensory Systems, Perception, and Learning**: Communication Behavior: Visual Signals and **Vision**: Behavioral Assessment of the Visual Capabilities of Fish), taste, smell (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior), and electrocommunication (**see also Sensory Systems, Perception, and Learning**: Shocking Comments: Electrocommunication in Teleost Fish), among others, play vital roles in fish behaviors, from aggression toward predators, competition with conspecifics, to attracting and courting potential mates. Like humans, fish are also known to enter the behaviorally quiet state of sleep where sensory systems are not easily aroused by mild environmental stimuli (**see also Behavioral Responses to the Environment**: Sleep in Fish).

Central to the use of sensory information is the ability to interpret and process information received from the sensory systems. For example, if a fish can visually identify a competitor with which it has previously lost a social encounter, then, being able to remember this information may allow avoidance of any subsequent encounters with the same individual (**see also Sensory Systems, Perception, and Learning**: Fish Learning and Memory). Losing aggressive encounters can be very costly to a fish and while the ability of fish to perceive pain in the same way that we do remains a widely debated topic (**see also Sensory Systems, Perception, and Learning**: Nociception or Pain in Fish), remembering and consequently avoiding unpleasant experiences can aid survival. Integration of sensory information gained about the surrounding environment is also vital for formation of spatial maps that fish can use to orientate and navigate through their environment (**see also Sensory Systems, Perception, and Learning**: Spatial Orientation: How do Fish Find their Way Around?).

Interactions with the Environment

Fishes have evolved many behavioral and physiological strategies ensuring that they acquire sufficient food from an environment, without becoming food themselves (**see also Behavioral Responses to the Environment**: A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food). Nevertheless, many fishes will experience periods of food deprivation with subsequent periods of compensatory growth having profound behavioral and physiological effects (**see also Behavioral Responses to the Environment**: Effects of Compensatory Growth on Fish Behavior). For those fish whose life-history requirements cannot be met by a single habitat, migration to alternative environments for reproduction or feeding may be essential (**see also Fish Migrations**: The Biology of Fish Migration).

Fish survival, like human survival, also depends on a supply of oxygen, which in many aquatic environments can become restricted on a regular basis. Fish that inhabit these environments display physiological and behavioral survival strategies (**see also Behavioral Responses to the Environment**: Behavioral Responses to Hypoxia). Along with levels of dissolved oxygen, temperature can have profound effects on the way fish behave (**see also Behavioral Responses to the Environment**: Temperature Preference: Behavioral Responses to Temperature in Fishes). Parasites, such as trematodes and cestodes, have the ability to manipulate both the behavior and physiology of their fish hosts (**see also Behavioral Responses to the Environment**: Manipulation of Fish Phenotype by Parasites), and the fragile link that exists between fish behavior and physiology is vulnerable to anthropogenic disturbance as well (**see also Behavioral Responses to the Environment**: Anthropogenic Influences on Fish Behavior). For example, release of estrogenic endocrine disruptors into aquatic environments is now well known to cause alterations in the sexual behavior and physiology of male fish, having a negative impact on reproductive success and population health.

Social and Reproductive Behaviors

The majority of fishes reproduce sexually, where effective transmission of genes to the next generation requires finding a suitable mate. In many instances, there may not be a sufficient number of attractive mates within a habitat and competition over resources will lead to the formation of social structures (**see also Social and Reproductive Behaviors**: Dominance Behaviors). Many fishes use elaborate courtship displays to attract mates (**see also Social and Reproductive Behaviors**: Sexual Behavior in Fish) and/or release attractive smells (pheromones) into the water (**see also Hormones in Communication**: Hormonal Pheromones). Reproductive strategies among fishes are amazingly diverse (**see also Reproduction**: The Diversity of Fish Reproduction: An Introduction); some species forming mating pairs between individuals that matured as either a male or female, while in other species individuals have the capacity to change from being male to female in a matter of seconds (**see also Social and Reproductive Behaviors**: Socially Controlled Sex Change in Fishes). Parental care is seen in a variety of fishes (**see also Social and Reproductive Behaviors**: Parental Care in Fishes) with some species providing their offspring with nutritional supplements during the pre- or post-hatch/birth period to enhance offspring survival (**see also Social and Reproductive Behaviors**: Nutritional Provision During Parental Care).

In conclusion, upon reading articles in this section of the encyclopedia on the links between fish behavior and physiology, it is hoped that the reader will be inspired to contribute to the ever-increasing body of literature that treats fish behavior and physiology as entities that are inextricably linked.

Glossary

Dominance The state of being dominant where dominant individuals obtain a high status within a social group.

Dominance hierarchy A social situation where one individual dominates all those below it, then the individual directly beneath it in social status dominates all those below it and so on (i.e., a pecking order). In a linear hierarchy, this relationship continues down to an individual dominated by all. Some social groups may have more complex dominance hierarchies that form networks rather than following a continuous linear relationship.

Hypothalamus Region at the floor of the forebrain (diencephalon) that controls several vegetative physiological processes, including food intake and secretion of hormones from the pituitary gland.

Interrenal cells These cells are found in the head kidney of teleost fish that synthesize and release cortisol.

Neuropeptide Any member of a class of protein-like molecules released by the nervous system. They consist of short chains of amino acids, functioning as neurotransmitters (direct synaptic effects) or hormones (indirect modulatory effects).

Neurotransmitters The signaling molecules released by nerves. This is a specialized form of paracrine signaling.

Pituitary An area of the brain involved with the release of certain hormones, including adrenocorticotropic hormone.

Preprohormone A precursor protein to a prohormone that is, in turn, a precursor of a peptide hormone.

Sclera The white of the eye.

Smoltification A series of physiological and morphological changes a fish may undergo when migrating from freshwater to seawater.

Social status Social standing or rank.

Dominance Hierarchies

To survive, an individual fish must, among other things, find food and avoid being eaten. To pass on its genes to future generations it must also find a mate and reproduce. However, in many instances, food supply may be limited, there may not be sufficient shelter within a habitat to support all individuals, and the number of available attractive mates may be restricted. Therefore, individuals may be left with no option but to compete among themselves for access to resources. Fighting can be costly to an individual. Minimally, it can be energetically expensive. It can result in serious or fatal injuries, and weakened individuals might be more prone to predators. Particularly, aggressive encounters also can distract an individual's attention away from any potential predators lurking nearby. Given the risks associated with fighting over resources, it is not surprising that many species form stable social structures, where once social status is established, direct competition is greatly reduced. In stable hierarchies, individual fish are likely to maintain their social position for long periods, although this will depend on stable environmental conditions and the absence of changes in population density.

The concept of dominance hierarchies was first developed through the observation of a 'pecking order' in chickens. Initial competition between pairs of individuals within a population results in winners and losers; winners of contests are termed 'dominant individuals' and losers as the 'subordinates'. A dominance hierarchy is then formed as a result of successive paired encounters within a group of animals. Dominance hierarchies have now been documented within many species of fish and described in particular detail for salmonids (e.g., salmon and trout). Juvenile salmonid fish often inhabit streams and rivers where water currents supply drifting food items and individuals will tend to orientate themselves in the water current accordingly. A section of stream may be inhabited by several individuals who will compete with each other for the most profitable position in the stream in terms of catching prey and providing access to shelter. In these instances, linear dominance hierarchies may form along the stream, with the most dominant fish upstream of its subordinate counterparts (**Figure 1**).

Many tropical fish form dominance hierarchies in which only the most dominant fish reproduces. For example, linear dominance hierarchies can be seen among individual clown fish (*Amphiprion percula*) co-inhabiting an anemone. Within an anemone, there will generally be one sexually mature male and female pair, which collectively dominates that anemone. Also living within the anemone will be a hierarchy of several more subordinate males that have no reproductive access to the female. When one of the breeding pair is eaten or dies, there is a progression up the hierarchy and the most dominant of the remaining males will take the breeding position. Of course, in the case of the clown fish, to replace the lost breeding female requires that one of the subordinate males within the group must change sex (**see also Social and Reproductive Behaviors:** Socially Controlled Sex Change in Fishes). A similar situation is observed in the freshwater African cichlid, *Neolamprologus pulcher*, which live in groups consisting of a breeding pair and several subordinate helpers who assist the breeding pair in caring for their young. Once one of the breeding pair is lost, the most dominant helper will take its place.

Dominance hierarchies are not only seen among groups of fish in the natural environment but also seen in groups of many fish species confined together in a laboratory environment and under aquaculture conditions. Here, aggressive interactions and unequal distribution of food among individuals is disadvantageous, resulting in mortalities, injuries (such as fin damage), and a reduction in fish quality. Therefore, much research has focused on reducing the formation of social hierarchies within aquaculture conditions. Large stocking densities may reduce the likelihood of formation of strong linear hierarchies and if food is distributed randomly rather than from a single, defendable point source, then food consumption is more likely to be equally distributed. Water flow, allowing fish to orientate and swim within a water current, can also reduce aggression. Holding fish of similar size together additionally reduces the opportunity for larger fish to aggressively target smaller fish.

How Is Dominance Measured?

With the vast amount of research that has explored the formation and consequences of dominance hierarchies, it is important to understand how dominance is measured.

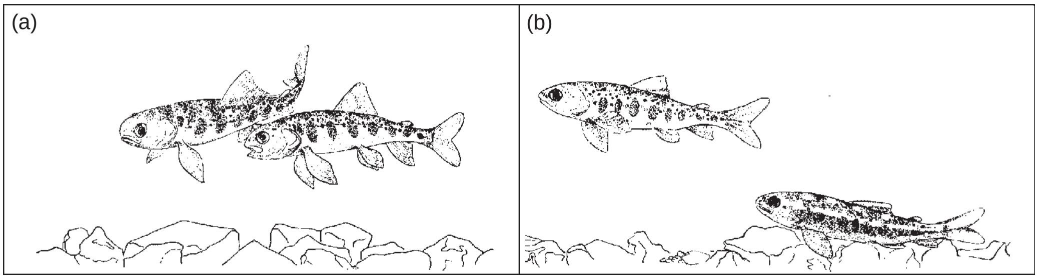

Figure 1 (a) Juvenile salmonid fish compete over limited resources and form dominance hierarchies as a result of pair-wise interactions. (b) Following hierarchy formation, dominant individuals will generally maintain position in the water column, while subordinate individuals take up a submissive posture on the bottom and may turn darker in coloration as a signal of defeat. Reproduced from figures 4 and 8 in Keenleyside MHA and Yamamoto FT (1962) *Territorial Behaviour of Juvenile Atlantic Salmon* (*Salmo salar* L.). The Netherlands: Brill, with permission.

Dominance is relative rather than absolute and in its simplest form can be tested by observing the interaction between two individuals when presented with a limited resource to compete over. The most dominant of the two individuals will be the one that wins the aggressive encounter and gains access to the resource. This test can be extended to investigate dominance hierarchies among groups of fish by allowing them to compete for a resource and by sequentially removing the most dominant individual. Each time the dominant fish is removed, the next most dominant individual will take its place and so on until all the individuals have been assigned a social ranking. This method of identifying the dominance hierarchy among a group of fish is known as the 'serial removal technique'. Dominance hierarchies can also be assessed by observing the interactions between individuals and by noting which individuals win aggressive encounters over others. However, as social hierarchies promote stability and reduce aggressive encounters, this is often easier to observe during the formation of hierarchies rather than after they have stabilized.

Causes of Dominance

The ability of one individual to win a competitive encounter and monopolize a resource at the expense of another individual relies inherently on individual variation in competitive ability. Therefore, what makes some individuals physiologically and behaviorally better at competing than others? Originally, it was believed that size was the main predictor of high dominance status with larger individuals consistently outcompeting smaller individuals. However, it appears that this only holds true when the size disparity is quite large. For example, in male green swordtails (*Xiphophorus helleri*) size uniquely determines dominance only when asymmetries in size greater than 20–30% occur. Thus, other factors may play more fundamental roles.

So far, the only physiological parameter that has reliably been demonstrated as a predictor of dominance status is metabolic rate. The success of salmonid fry at the outset of competitive interactions with conspecifics is determined based on a higher metabolic rate being correlated with greater competitive ability and dominance status. Whether the individual variation in metabolic rate that is responsible for varying competitive ability is genetically determined is unknown; however, approximately 70 genes have been identified so far that differ significantly between dominant and subordinate fish.

Prior residence of an area is also known to influence the outcome of competitive interactions. If an individual has prior experience of a habitat, then its chances of successfully outcompeting an individual unfamiliar to the area are increased. Under these conditions, an unfamiliar individual is likely to have to adjust to a new environment at the same time as competing with the resident individual, making success less likely. However, dominant individuals under certain environmental conditions may not necessarily prosper if the environment changes; fluctuations in water levels and flows have the potential to disrupt and alter existing social hierarchies. Thus, a physiology that suits one set of environmental conditions does not ensure dominance in another environment. Physiological condition may also affect the competitive ability of an individual. Elevated plasma concentrations of the stress hormone cortisol are known to be associated with a decrease in the competitive nature of individuals. In contrast, aggressive behavior of fish increases with administration of L-dopa, the immediate precursor of the neurotransmitter, dopamine.

A complication in predicting the outcome of dominance contests based on a combination of all the above is the additional ability of fish to learn and adapt their competitive tactics in successive aggressive encounters, that is, based on prior social experiences. In fact, there is positive feedback in this regard. Fish that have lost competitive encounters are more likely to adopt submissive behaviors in subsequent contests and become subordinate. Moreover, the simple observation of competitions between other individuals may influence the way that the observer will subsequently interact with either of these opponents. If the observer is subsequently required to compete with the observed loser, then the previous eavesdropping on its competitor's ability may bring confidence that adopting a dominant/aggressive tactic is likely to be successful in this instance. Alternatively, if the observer is required to compete with the observed winner, then it may decide that adopting a submissive role may be the least costly strategy. Thus, a whole myriad of innate and acquired physiological factors influence the competitive ability of an individual.

Physiological Consequences of Social Status

Growth

Access to premium resources is likely to result in advantages to dominant individuals. One of the most obvious advantages where a food source is monopolized is a higher growth rate compared to more subordinate animals. Many studies have documented lower growth rates in subordinate fish under culture or laboratory conditions. For example, among groups of green sunfish (*Lepomis cyanellus*), growth is directly correlated with social rank. Growth also correlates with dominance among groups of salmonids and among groups of *N. pulcher*. In field studies, however, investigations into the effects of social status on growth are equivocal. In groups of masu salmon

(*Oncorhynchus masu ishikawai*) living in a mountain stream, there was a clear correlation between a high dominant status and higher daily growth increments but in Atlantic salmon (*Salmo salar*) several studies have failed to find a clear relationship between dominance and growth in the natural environment. It is, therefore, likely that the effect of social status on growth is strongly influenced by environmental conditions.

Although short-term changes in growth rates have been documented in relation to position in a social hierarchy, we know very little about prolonged physiological effects of social status. Even so, there is evidence that among juvenile salmonids social status can have a profound effect on life history strategy as a consequence of initial short-term changes in growth. Within the freshwater stream environment, dominant Atlantic salmon grow faster than their subordinate counterparts and are more likely to undergo smoltification (**see also Fish Migrations:** The Biology of Fish Migration) and migrate to sea a year earlier. Subordinate individuals enter a 4–6-month period of anorexia and postpone seaward migration. Not only has this phenomenon been documented in laboratory studies, but there is strong evidence for bimodal size distribution seen in some natural salmon populations. A few male individuals may adopt an alternative reproductive strategy (**see also Social and Reproductive Behaviors:** Socially Controlled Sex Change in Fishes) and mature in freshwater without migrating to sea. These fish, known as precocious parr, reach sexual maturity at a much smaller size, bypassing the usual increase in size associated with transition from a juvenile to adult stage.

Clown fish are another species in which subordinate individuals are believed to suppress their growth rates. As mentioned above, groups of clownfish living within an anemone form a queue for a breeding position. By maintaining a size smaller than a more dominant individual, subordinate individuals avoid the potential aggression they might attract if they were seen as a competitive threat. The exact mechanism of appetite suppression in fish awaits discovery, but is likely to be under the control of brain neurotransmitters. In the cichlid, *Haplochromis burtoni*, subordinate fish have larger neurons containing the neuropeptide somatostatin, which is known to inhibit the release of growth hormone.

Differences in growth rates among individuals of different social status, particularly under laboratory conditions, clearly do not appear to be solely explained by monopolization of a food resource by dominant individuals. In fact, in studies where fish of different social status are fed equal rations, subordinate fish will still exhibit lower growth rates and be less motivated to feed even when excess food is available. Furthermore, suppression of feeding in subordinate salmonids may be sustained for several days after removal of the dominant and appetite suppression can be linked to a stress-induced anorexia.

The Endocrine System, Brain Neurotransmitters, and Dominance

Stress in teleost fish results in an immediate activation of the sympathetic nervous system and release of the catecholamine hormones epinephrine and norepinephrine from chromaffin cells in the head kidney into the circulation (**see also Hormonal Responses to Stress:** Catecholamines). Catecholamines optimize cardiovascular and respiratory function and release stored energy to allow an individual to respond immediately to stress in the traditional fight-or-flight response. Because catecholamines are released so quickly into the circulation in response to stress, it makes accurate determination of plasma levels of catecholamines very difficult as the usual methods of obtaining a blood sample from a fish are stressful in themselves (e.g., capture, anesthetization, and withdrawal of blood by caudal venipuncture). Therefore, whether the levels of circulating catecholamines differ between dominants and subordinates is currently unknown.

Subsequent to the release of catecholamines under stressful situations is the activation of the hypothalamus–pituitary–interrenal (HPI) axis (**see also Hormonal Control of Metabolism and Ionic Regulation:** Corticosteroids). Here, the hypothalamus releases corticotrophin-releasing factor which causes the pituitary to release adrenocorticotropic hormone (ACTH), resulting in the synthesis and release of the stress hormone cortisol from the interrenal cells of the head kidney. Because of this hormone cascade, cortisol takes longer time to enter the circulation than the catecholamines.

Elevated cortisol concentrations elicit a myriad of physiological changes (**see also Hormonal Responses to Stress:** Stress Effect on Growth and Metabolism). In general, cortisol maintains the release of stored energy by breaking down carbohydrate, lipid, and protein stores to allow an individual to cope with a longer-term stress. If cortisol remains elevated for long periods of time (e.g., chronic elevation over days to weeks), it can often be associated with more deleterious effects, such as immunosuppression and deterioration in brain function.

A considerable number of studies have examined the effects of social status on activation of the HPI axis. During an aggressive encounter, both opponents will experience an increase in plasma cortisol and, for the eventual dominant individual, this increase in cortisol is transient. However, plasma cortisol concentrations are likely to remain chronically elevated for days to weeks in the subordinate individual, resulting in many physiological changes associated with chronic stress (**Figure 2**). Elevated concentrations of circulating cortisol have

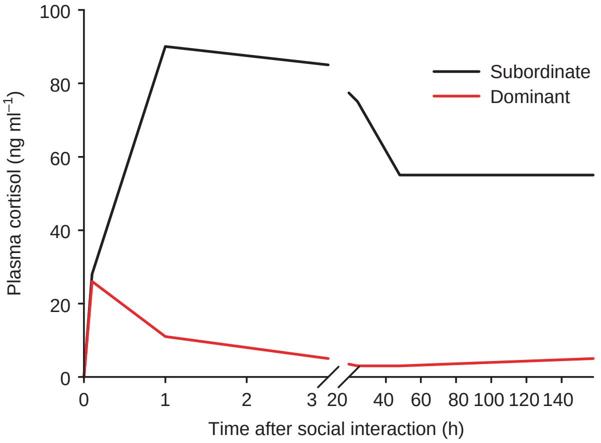

Figure 2 Typical plasma cortisol profile for dominant and subordinate rainbow trout held in pairs and allowed to establish a dominance hierarchy. Both individuals show an initial rise in plasma cortisol. While this elevation is transient in the dominant individual, concentrations of plasma cortisol remain chronically elevated in the subordinate individual.

been measured in the subordinates of many fish species including rainbow trout (*Oncorhynchus mykiss*), brown trout (*Salmo trutta*), coho salmon (*Oncorhynchus kisutch*), European eel (*Anguilla anguilla*), Arctic charr (*Salvelinus alpinus*), Gulf toadfish (*Opsanus beta*), and the cichlid (*H. burtoni*). The changes in interrenal-cell diameters that occur in conjunction with this chronic elevation of cortisol are likely to be associated with increased cortisol synthesis.

Elevated cortisol concentrations can also affect the functioning of the HPI axis through hormone feedback loops. Desensitization of interrenal cells to further stimulation by ACTH appears to occur in subordinate rainbow trout as they display a lower rate of cortisol secretion when stimulated *in situ* with ACTH than their dominant counterparts. This would suggest a decreased ability of subordinate animals to respond to further stressors as their endocrine system is already substantially challenged.

Cortisol is closely associated with the serotonergic system and levels of the brain neurotransmitter serotonin. Changes in brain monoamine neurotransmitters during social encounters have been documented in many fish species. These neurotransmitters include serotonin (5-hydroxytryptamine (5-HT)) and 5-hydroxyindoleacetic acid (5-HIAA, a metabolite of 5-HT). In particular, substantial activation of the serotonergic system has been associated with subordinate status. In dominant and subordinate salmonids, serotonergic activity (often measured as 5-HIAA/5-HT ratios) is observed to increase during aggressive encounters. As with cortisol, this increase is transient in dominants but persists in subordinates. In the bicolor damselfish (*Pomacentrus partitus*), higher serotonergic activity is seen in nonterritorial males. An antiaggressive effect of brain serotonin has been documented in fish along with a decrease in locomotor ability. Thus, long-term activation of the brain serotonergic system may perpetuate behavioral submission.

Social status may also influence levels of other circulating hormones. In juvenile Arctic charr, subordinate individuals show elevated levels of plasma α-melanocyte-stimulating hormone (α-MSH). The release of α-MSH is controlled by the HPI axis being derived from the same preprohormone, preopiomelanocortin, as ACTH. In fish, α-MSH is known to cause a darkening in skin coloration and a darker color is often observed in subordinate salmonids (**Figure 1**). In Atlantic salmon, overall body coloration and also sclera of the eye is seen to darken in subordinate individuals. It has been noted that immediately following this change in coloration, aggression is reduced between pairs of fish, suggesting that it may act as a signal of defeat.

Social dominance in fish has been associated with high levels of circulating androgens. In teleost fish, 11-ketotestosterone (11-KT) is the predominant androgen (**see also Hormonal Control of Reproduction and Growth:** Endocrine Regulation of Fish Reproduction); and in Arctic charr, elevated levels of 11-KT were found in dominant males. Similarly, in *Brienomyrus brachyistius*, a weakly electric fish, dominant males had high levels of 11-KT. In rainbow trout, dominant males have elevated levels of testosterone and another reproductive hormone 17α,20β-dihydroxy-4-pregnen-3-one (17,20β-P) (**see also Hormonal Control of Reproduction and Growth:** Endocrine Regulation of Fish Reproduction), but in male redbelly tilapia (*Tilapia zilli*), elevated levels of androgens were absent in dominant males. In male swordtails, living in stable social communities, there was no relationship between aggressive behavior and androgens. However, when instability occurred, aggression was androgen related. Therefore, although there is the potential for dominance to be associated with elevated androgens, this is likely to be both context- and species-specific.

Metabolism and Disease

Chronic elevation of stress hormones will eventually become disadvantageous. During stressful encounters, energy stores are mobilized and energy is diverted toward fuelling the stress response and away from basic needs such as growth and maintenance. There is evidence that social position can compromise ionoregulatory ability. Subordinate freshwater salmonids leak sodium ions across both the kidney and gills at a faster rate than dominants and, as a result, require higher rates of sodium uptake from the water to maintain their osmotic balance. More energy may, therefore, be directed to ionoregulation in subordinate individuals.

Not surprisingly, chronic stress is also associated with a compromise in immune response and a decreased resistance to disease. Under captive conditions, competitive interactions among European eels result in increased levels of plasma cortisol, glucose, and lactate along with decreased hepatic glycogen stores and lower numbers of leukocytes in subordinate individuals. Subordinate salmonids are more susceptible to a wide range of diseases; subordinate rainbow trout exposed to the opportunistic ubiquitous bacterium, *Aeromonas hydrophila*, were 50% more susceptible to infection.

Susceptibility to Aquatic Toxicants

Because of the wide variety in physiological profiles of individuals of different social status, it is not surprising that social position has an effect on the susceptibility of individuals to aquatic toxicants. In bluegills (*Lepomis macrochirus*), subordinates were found to be more susceptible to a lethal concentration of zinc, dying significantly earlier than their dominant counterparts. In this study, addition of a shelter increased the survival of subordinates suggesting that refuge from the aggressive attention of a dominant reduces stress and susceptibility to a contaminant.

Differential accumulation of metals can occur in fish of different social status (**see also Behavioral Responses to the Environment:** Anthropogenic Influences on Fish Behavior). For example, when salmonid hierarchies are exposed to waterborne copper, the subordinates will take up more copper from water than the dominants. A similar pattern is observed when hierarchies are exposed to waterborne silver. Both copper and silver ions are taken up across the gills, and, in salmonid fish, it is believed that this process occurs through sodium channels. Therefore, it is possible that the higher uptake of sodium seen in subordinates as a result of their social status concomitantly drives a higher uptake of copper and silver. Similar patterns of uptake are not observed with metals such as cadmium and lead which do not cross the gills via sodium channels.

In contrast to the increased susceptibility of subordinates to some waterborne toxicants, dietary toxicants may be more problematic for dominant fish. Monopolization of a food resource can become deleterious if it is contaminated by a toxic substance. Among groups of fish fed a copper-contaminated diet, dominant fish are likely to experience toxic effects earlier than more subordinate fish and, consequently, lose their ability to monopolize a food source. The next most dominant fish will out-compete the dominant individual and gain greater access to the food source but will eventually suffer a similar fate. Dietary contaminants are, therefore, likely to destabilize hierarchies and the impacts of dietary toxicants on social hierarchies warrants further study.

Why Study Dominance?

Dominance hierarchies play an integral role in the structure of many fish populations and will also form under artificial conditions in the laboratory and in aquaculture. Understanding how behavior and physiology interact during social encounters is important if we are to understand how populations will respond to environmental change and to predict welfare implications of hierarchy formation in captivity. We still know very little about the potential long-term consequences of social stress and the majority of techniques used for quantifying social stress remains invasive. Developing noninvasive assays for stress and techniques that can be readily applied to field situations is a priority for furthering our understanding of dominance hierarchies in natural fish populations.

Glossary

Agonist/antagonist An agonist produces an action. It is the opposite of an antagonist, which acts against and blocks an action.

Androgen Any natural or synthetic steroid hormone that is principally involved in growth, development, and maintenance of the male reproductive system and secondary sexual characteristics.

Bower A construction usually made by the male bowerbird for courtship display (i.e., not as a nest); the term may also be used to describe a sandcastle structure made by male cichlids that is used to attract females.

Estrogen Any natural or synthetic steroid hormone that controls female sexual development, secondary sexual characteristics, and stimulates egg production. Together with progesterone (another steroid hormone), it regulates the development and function of sex organs.

Hormone A chemical substance, often a peptide or steroid, released from endocrine glands that controls and regulates a range of physiological activities.

Neuropeptide Any member of a class of protein-like molecules released by the nervous system. They consist of short chains of amino acids, functioning as neurotransmitters (direct synaptic effects) or hormones (indirect modulatory effects).

Oviposition The act of laying eggs by oviparous animals (animals laying eggs that develop outside the female's body).

Prostaglandin Any member of a group of lipid compounds that are 20-carbon fatty acid derivatives containing a 5-carbon ring. They mediate a wide range of physiological functions, such as, in fish, ovulation (follicular rupture), and female sexual behavior, and also act as pheromones in some species.

Sex steroids (or gonadal steroid) Steroid hormones that are produced and secreted by the gonads (testes and ovaries). By interacting with androgen and estrogen receptors, they control reproductive development and functions and influence behavioral patterns (sexual and others).

Sympatric Organisms occupying the same or overlapping geographic areas without interbreeding.

Vitellogenesis Synthesis of the yolk protein vitellogenin, the precursor and main component of egg yolk protein, vitellin, which is synthesized in the liver, transported in the blood stream, and incorporated into oocytes providing energy reserves for the development of embryos.

Overview of Sexual Behaviors in Fish

A series of behaviors consisting of several specific acts are performed by teleost fish during the process of mating. A variable terminology is used for the description of these acts depending on the pattern of movement (e.g., courtship, chasing, clasping, mating, spawning, egg release, sperm release, oviposition, and ejaculation). Collectively, these acts are called 'sexual behavior' or 'reproductive behavior' while 'spawning behavior' is a commonly used term reserved for teleosts whose gametes are fertilized in the external environment. It is often quite difficult to clearly define sexual behavior in fish largely due to the diversity of behavior patterns observed (**see also Social and Reproductive Behaviors:** Socially Controlled Sex Change in Fishes).

Some behaviors, usually performed after gamete fusion, can be classified as reproductive behaviors in a broader sense but are usually not referred to as a sexual behavior. For example, parental care is not generally classed as sexual behavior. In fish that demonstrate some sort of parental behavior (one or both sexes), two strategies can be discerned: building of a physical barrier for protecting the eggs (guarders) or morphological/physiological modifications to carry the eggs/young (bearers) (**see also Social and Reproductive Behaviors:** Parental Care in Fishes). Here, we consider pre-spawning nest-building and territorial behaviors as sexual behavior, important for successful spawning to take place. For some species, migration and preparation of a breeding site constitute the first phase of sexual behavior (e.g., salmonids; (**see also Fish Migrations:** Pacific Salmon Migration: Completing the Cycle)).

Construction (Nest-Building) Behaviors

The main function of a nest is to protect eggs from predators and adverse environmental conditions. Nest spawners show a great diversity in their building capacity, ranging from simple depressions or cavities in the sediment to hugely complex structures. Nest structures, however, may lead to secondary problems, such as low oxygen, that are overcome by further adaptations in behavior (e.g., fanning) or/and in the complexity of the structure. Some fish establish a territory around a nest or spawning site and defend it vigorously against other conspecifics such as the Mozambique tilapia, *Oreochromis mossambicus*, the bowfin, *Amia calva*, the three-spine stickleback, *Gasterosteus aculeatus*, and the Siamese fighting fish, *Betta splendens*. Fish that guard spawning sites tend to produce fewer numbers of eggs than those that do not (**see also Social and Reproductive Behaviors:** Parental Care in Fishes).

Most sunfish species, such as pumpkinseed *Lepomis gibbosus*, reproduce in shallow waters of slow rivers or lagoons and are not particularly choosy with respect to substrate type. Males construct a nest by sweeping the substrate, using their caudal fins much like brooms until they have made a clean, circular, slightly depressed, saucer-like area. Sunfish are usually colonial nesters, with nests in densely packed clusters. Many nests are so close that they touch each other, although males vigorously defend their individual nesting site. Another sweeping species is the bowfin, which prepares a nest in shallow, often poorly oxygenated water, by clearing a site from vegetation roots and creating a slight depression for the eggs to be deposited. The male also defends his nest very aggressively.

Some cyprinids, gobies, cichlids, tilefish, and wrasses are specialized in mound building. Some mounds can be quite impressive in comparison to the size of the fish. The male hornyhead chub, *Nocomis biguttatus,* achieves a total length of 90 mm and yet digs a depression up to 0.5 m in diameter and piles pebbles into the cavity to a height of 15 cm. After a female lays her eggs on the top of the mound, the male covers them with more pebbles.

Most anabantoids (labyrinth fish), for example, the gouramis (e.g., Siamese fighting fish) and species in the Callichthyiadae family (armored catfish), build characteristic bubble nests, an adaptation to an oxygen-depleted environment (**see also Behavioral Responses to the Environment:** Behavioral Responses to Hypoxia). The male blows air bubbles, coated with mucus through the gills, either at the water surface or under a leaf. The male incorporates the eggs, released by the females, into the mass of bubbles and guards them.

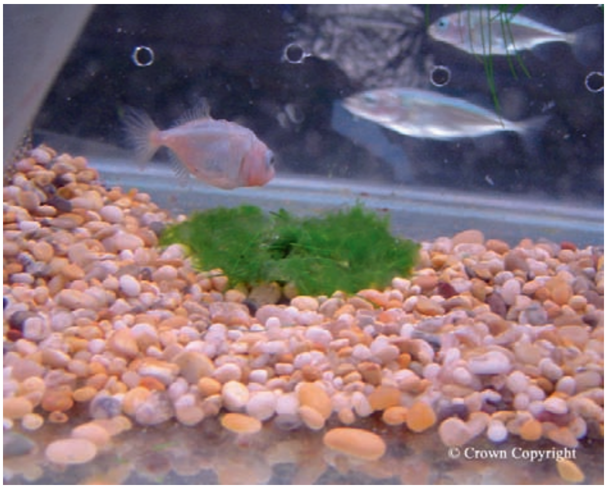

Figure 1 A male three-spine stickleback, *Gasterosteus aculeatus*, guarding his nest (an entrance is visible). Crown Copyright.

Finally, nests can be more elaborate in structure, such as an assemblage of pieces of vegetation. The most renowned example of such construction can be seen in the male three-spine stickleback (**Figure 1**). Once the male has established a territory, he tests several areas on the bottom by taking mouthfuls of sand and quickly ejecting them. Eventually he focuses on digging in one area, carrying the sand further away before spitting it out. This results in the formation of a pit where the nest will be built. The male collects nest material, for example, waterweed, and glues the pieces together with a mucus secretion of the kidney, a protein called spiggin from the Swedish name for stickleback. When a male performs the gluing behavior, he swims slowly over the nest with juddering movements of the pectoral and anal fins that result in both his head and his tail being raised while the cloacal region is pressed against the nest material to release spiggin (**Video Clip 1**). In the final stage, the last pieces of vegetation are glued together to form the nest entrance and the male performs a creeping behavior, swimming through the nest to form a tunnel and a more distinct entrance. After the female has spawned, the male takes care of the eggs alone by mainly fanning water currents through the nest for oxygenation.

Egg protection may not necessarily be the primary intention for nest construction. Some fish build houses predominantly for protecting themselves from predators; this is used secondarily for laying eggs, for example, mudskippers and the mouth-brooding jawfish (Opistognathidae). Mouth-brooding cichlids construct sand-scape bowers that they use mainly as a mating display and as egg-fertilization sites, but not for the protection of the young. Bower forms among different species range from huge craters 3 m in diameter (e.g., *Oreochromis* sp.) to small depressions of a few centimeters (e.g., *Copadichromis azureus*) and small sandcastles (e.g., *Lethrinops* sp.).

Fish that do not guard nests can also demonstrate spawning-site preparation. In these species, no parental care is provided and usually it is the female that displays site-preparation behavior. Female fish are generally considered nest diggers, preferring to dig down rather than build up a nest. After migration, female masu salmon, *Oncorhynchus masou*, use their tail to excavate gravel to form a nest or spawning bed, checking regularly the shape (depth and width) with their anal fins. Other female fish behave similarly; the smallmouth bass, *Micropterus dolomieui*, digs a nest up to 185 cm in diameter and both male and female lampreys excavate pits in streambeds using their mouths and tails. Shortly after high tide, on certain nights of the year, female California grunions, *Leuresthes tenuis*, swim as far as possible up onto a sandy beach using breaking waves and with their tails they drill their body into the sand up to their pectoral fins. They then wait for males to make their way up the beach and fertilize their eggs!

Courtship Behaviors

Courtship is, by definition, any communication behavior that occurs in order to initiate mating, and often includes elaborate displays. In fish, males usually display, while the role of females is mainly selective. In general, males prefer large females to small ones, a trait that is adaptive since brood size increases with female size. The state of arousal of a courting male is often (but not always) reflected in colored skin patches, the color intensity of which is under neural control. Together, female size (acting as the external stimulus) and internal arousal (signifying reproductive maturity) combine to determine the courtship acts of the male. Nuptial coloration patterns are very useful in the study of the motivation of courtship and can be examined in many species.

Expression of courtship behavior requires the occurrence of a number of signals in the following order: (1) visual recognition of the sexual status of the partner; (2) the expression of a state of sexual maturity by the male (male readiness); and (3) the willingness of the female to mate (female readiness).

Visual recognition (sexual dimorphism)

The more striking aspects of external appearance in fish are often associated with breeding. In most species, sexual characteristics are male specific and the male undergoes the most striking changes at sexual maturity. Alterations in female coloration are less common in fish. Some morphological changes are temporary, for example, nuptial coloration in the blenny and tubercles in the fathead minnow; others are permanent after sexual maturity is attained, for example, gonopodium in the guppy. The magnitude of sexual dimorphism is usually related to the mating system.

Sexual dimorphism in body size is known in a number of fish, for example, sunfish, blennies, sculpins, cyprinids, sticklebacks, gobies, labrids, guppies, salmonids, and an extreme example, anglerfish – for example, *Photocorynus spiniceps,* where the male measures less than a centimeter and lives as a parasite on a female, which can be up to five times bigger in size.

Sexual dimorphism in nuptial coloration can also be seen in a number of fish such as in cyprinids, cichlids, sticklebacks, greenlings, guppies, mollies, platies, and swordtails. Several males, such as the guppy, develop bright spots or bars on body and fins, as visual signals during the courtship display (**see also The Skin:** Coloration and Chromatophores in Fishes). There is a remarkable polymorphism of guppy color pattern with a great variation among individuals.

A special behavioral pattern occurs in the mouthbrooding cichlids *Haplochromis burtoni* and *Copadichromis virginalis*. The male develops egg-like spots on his anal fin. A receptive female lays her eggs in several batches within a site and collects them in her mouth. The male drags his egg-marked anal fin in front of her trying to tempt her to pick up the missed eggs; instead, she picks up his sperm and fertilizes the eggs in her mouth. Interestingly, the representation of the egg row on the male's fin is an exact one to the human eye.

Male readiness

A large range of courtship displays (from simple stimuli to a complex series of acts) exists among male teleost fish exhibiting both internal and external fertilization. Courtship behavior is commonly composed of a repetitive or rhythmic pattern in movement. These dance-like movements are often followed up by the male fish poking or butting the female in the flanks (Poeciliidae, Gasterosteidae, and genus *Phoxinus*), and in some species the male eventually curls himself around the body of the female (*Macropodus* sp., *Barbus* sp.).

The characteristic courtship behavior of the male guppy is the 'sigmoid' display, termed after the S-shape of the male's body when it is performed. The male guppy waits for a female to stop moving or slow down sufficiently for him to jump in front of her. When he performs the sigmoid display, he arches his body and quivers stiffly. Copulation may occur but the male could suddenly jump away from the female to test her responsiveness or/and to lead her away from a current position, especially away from a crowded male area.

The male three-spine stickleback is one of the best-studied examples of mating behavior. The courtship is composed of distinctive synchronized elements, which ensure that the male only mates with the females of his own species. The male first jumps away from and then toward the female with his mouth open and spines erect, performing the zigzag dance (**Video Clip 2**). If the female responds, the male interacts with her by a wide repertoire of moves including biting and dorsal pricking (where the male is below and across the female belly, pushing her with jerky movements with his erect spines toward the water surface). He then leads her to the entrance of the nest pushing his snout into and back from the nest to show the female. There are many variations in this courtship behavior both between individuals and populations. Pacific Ocean male three-spine sticklebacks perform the zigzag dance, while sympatric males of the Japan Sea perform a different dance, which is more like rolling. This different pattern of courting evolved over several thousand years of geographical isolation, and, while the two stickleback morphs now coexist, they do not interbreed. This difference in courtship behavior may have resulted in reproductive isolation; hence, courtship behavior is important for the ethological isolation of closely related species.

Sound (**see also Sensory Systems, Perception, and Learning:** How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling), olfaction (**see also Hormones in Communication:** Hormonal Pheromones), and electrocommunication (**see also Sensory Systems, Perception, and Learning:** Shocking Comments: Electrocommunication in Teleost Fish) may also be used during courtship behavior and are covered in more detail in other articles.

Female readiness

The female display of sexual receptivity is often less striking than that of the male, but maintains continuity through the female staying near the spawning ground or nesting site. It is important to emphasize that usually the females get to choose their mates; hence, there is not much point in developing attractive traits themselves. The logic behind this statement is simple. Males produce an enormous number of small cells (sperm) without investing too much energy, whereas females produce a few large and nutritious eggs that are very costly to them. If a male mates with several females, he increases the number of his progeny, but for females, it makes no difference. A female gains only a little from having a large number of egg fertilizations with different males. Therefore, males in general are promiscuous but females are choosy because they want their few progeny to be of highest possible quality.

The criteria for selecting a male mate vary enormously in the fish world and may include color, size, nest quality, aggressiveness, ability to win fights, relatedness (some species avoid inbreeding, others do not) and resistance to parasites. On choosing a mate, female readiness can manifest in a variety of ways. A sexually responsive female guppy displays a gliding motion, facilitating copulation. The displaying male moves in a circle around the female and attempts to inseminate the female with his gonopodium – this behavior may be accompanied by nips, that is, oral contacts with the female's gonopore. When both fish are successfully in contact, the pair rotates around each other rapidly. After mating, the male jerks his body up and forward several times; the significance of this behavior is not clear. Female guppies may mate with several mates and are able to store sperm so that sperm from different males may compete to fertilize their eggs. In this species, sneak copulation (a gonopodial thrust to an unwilling partner) occurs frequently, although most do not result in successful transfer of sperm.

In sticklebacks, receptive females adopt a characteristic head-up posture that serves as a stimulating clue to the male. When the female is interested in spawning, she will follow the leading male and inspect the nest before entering. If she is satisfied with the male courtship display and the nest quality, she will enter the nest. When inside the nest, the male stimulates her by giving a series of quick pushes on her flanks and caudal peduncle, a behavior that is called quivering (**Video Clip 3**). Finally, as soon as spawning is complete, she exits and moves away.

Hormonal Control of Sexual Behavior

As in other vertebrates, sexual behavior in fish is under hormonal control. For a number of years, hormones were seen as causal agents of behavior, acting directly on the expression of a given behavioral act; this view was supported by a number of studies that demonstrated that castration and hormone-replacement treatments could abolish and restore sexual behaviors, respectively. However, hormones are now considered major modulators of behavior, that is, they can modify the probability of the expression of a behavior but not necessarily the expression itself.

In fish, the actions of hormones in the occurrence of a particular sexual behavior have been classified into three categories. The first is a physiological trigger, which elicits sexual behavior in a relatively short time when other physiological and environmental conditions are appropriate. For example, in female goldfish the hormone prostaglandin (PG) F2α results in oviposition within several minutes of administration. Prostaglandin is produced in the ovary after ovulation (ovulated oocytes in the oviduct are the stimulus for its production) and acts on the brain of females, inducing this specific sexual behavior during natural spawning.

The second category of hormone action is as a requirement or primer; the hormone does not trigger sexual behavior *per se* but its presence is essential for the occurrence of the behavior. Testicular androgens often function in this priming manner. In many male teleosts, castrated males without circulating testicular androgens do not show any signs of an appropriate sexual behavior. Administration of androgens can restore male sexual behavior in castrated males, but merely administering the hormones does not trigger the behavior to occur. Likewise, a priming androgen injection in juvenile males allows male behavior to be triggered by external cues, such as pheromones or other behavioral signals from females.

The third category of hormone action is classed as 'potentiator'; it does not trigger the behavior and sometimes is not even essential for the actual occurrence of the behavior. However, the presence of this particular hormone enhances or increases the effect on the sexual behavior of the fish. Gonadotropin-releasing hormone (GnRH) is well known as a potentiator hormone in female goldfish. Without administration of GnRH, sexual behavior of female goldfish can still be triggered by PGF2α administration. However, PGF2α-induced spawning activity is enhanced by administration of a GnRH agonist and suppressed by a GnRH antagonist.

The equivalent hormone to progesterone in teleost fish is 17,20β-dihydro-progesterone (17,20β-P). Several functions for 17,20β-P have been proposed, including induction of oocyte final maturation and spermiation (milt production), enhancement of sperm motility (by alteration of the pH and fluidity of the seminal fluid), and acting as a pheromone.

Upstream migration in salmonids has been associated with a sharp increase in plasma cortisol levels, which is not associated with stressors such as long-distance migration and changes in salinity.

Regulation of the sexual behavior in fish has been extensively studied and is best understood in goldfish and salmonids. Some of these behavior regulators are produced by endocrine organs and are transported via the circulatory system where they act directly or indirectly on the brain, while others are produced in as well as act upon the brain. Although the neuroendocrine regulation of fish reproductive behavior has been the subject of many studies, our understanding of this modulation of sexual behavior remains incomplete. The relative importance of hormones and neuropeptides in modulating or controlling sexual behavior is different among species, reflecting the large variation observed in fish mating systems and is particularly complex in fish with alternate reproductive tactics (**see also Social and Reproductive Behaviors:** Socially Controlled Sex Change in Fishes). For this reason, we attempt a brief account of the most typical examples of hormonal regulation of sexual behavior described in fish thus far; these include sex steroids, prostaglandins, and neuropeptides.

Male Fish

Androgens, particularly testicular androgens, generally control sexual behavior (both nest building and courtship) in male fish, although variation exists between species. For example, castration abolished nest-building and courtship behaviors in the three-spine stickleback and the Egyptian mouth-brooder, *Pseudocrenilabrus multicolor multicolor,* but had no effect on the nest-building behavior of the blackchin tilapia, *Sarotherodon melanotheron melanotheron.* In addition, administration of androgen to the castrated Egyptian mouth-brooder or the three-spine stickleback restored male courtship behavior but the same treatment was ineffective in castrated rainbow trout, *Oncorhynchus mykiss.*

The functional androgenic steroid varies between species, although the main physiologically relevant androgens in fish are 11-ketotestosterone (11-KT) and 11-ketoandrostenedione (11-KA). 11-Ketoandrogens are not present in gobies or sardines where dihydrotestosterone and testosterone appear to be the major androgens. In goldfish, 11-KT is important in males in the release of the luteinizing hormone (LH) – that stimulates milt production – and sexual behavior (weak chasing). Similarly, androgens play an important role in the upstream migratory behavior of male salmonids.

There are many examples of androgens being the potentiator rather than the requirement for the expression of sexual behaviors. For example, in some cyprinids, androgen treatment increases olfactory sensitivity to sex pheromones, having a facilitating role in the initiation of sexual behavior.

Brain aromatase, an enzyme that converts androgens to estrogens, is possibly involved in the expression of male sexual behavior. Both the neuropeptide arginine vasotocin (AVT) and the hormone GnRH appear to control certain acts of male sexual behavior in some species.

In many species, the initiation of spermiation is accompanied not just by a sharp rise in plasma 17,20β-P concentrations, but also by a sharp drop in plasma 11-KT concentrations. There is an abundance of data (mostly on salmonids) suggesting that plasma concentrations of 17,20β-P are highly regulated by social factors, including hierarchy, territoriality, and courting. It has also been established that 17,20β-P concentrations increased in males only when in chemical contact with nesting females. Pheromones that have the ability to raise 17,20β-P concentrations in males were subsequently shown to be present in the urine of female salmonids including PGF2α and L-kynurenine.

Female Fish

In females, neuroendocrine studies have focused on female receptivity and oviposition. Estrogens do not seem to be a requirement for the female sexual behavior in many externally fertilizing teleosts. In fact, plasma estradiol levels appear decreased during the spawning period, which coincides with completion of vitellogenesis. Therefore, estrogens are controlling processes associated with oogenesis and do not appear to be essential for the female sexual behavior. In contrast, in internal-fertilizing fish, such as the guppy, estradiol synthesis appears to be in synchrony with sex pheromone production and maintains receptivity in females just as it does in internal-fertilizing tetrapods.

LH release plays a role in the production of the maturation-inducing steroid, 17,20β-P, that also has pheromonal properties.

Although in female masu salmon, a surge in plasma levels of testosterone is required for the induction of nest-digging behavior, there are no other reports showing a stimulatory effect of testosterone on female sexual behavior in fish. T is involved in LH release but not in sexual behavior in goldfish.

It is also interesting to note that sex steroids may regulate rheotaxis (swimming in response to a current of water) of fish. Fish without sex steroids, sexually immature or with their gonads removed, swim with the downstream current or do not exhibit upstream swimming behavior. In contrast, fish with high levels of sex steroids swim against the current, resulting in reproduction in the river (resident and upstream migration).

Female sexual behavior can be induced by PG injection in a number of fish species such as goldfish, paradise fish (*Macropodus opercularis*) medaka (*Oryzias latipes*) and dwarf gourami, *Colisa lalia.* In addition, AVT induces the spawning reflex in female killifish (*Fundulus heteroclitus*) – the same effect is observed in males – medaka, bitterling (*Rhodeus sericeus*) and flagfish (*Jordanella floridae*) – where it also occurs in males. Finally, GnRH is implicated in female spawning behavior in goldfish and salmon but has not been extensively studied in other species.

Conclusions

Fish present a unique collection of mating strategies and reproductive behaviors that in turn offer a great field for research into not only fundamental aspects of reproductive biology but also evolution and speciation. Of particular interest, and as yet a field that is far from being exhausted in terms of research, is the endocrine control of sexual behavior and mate choice. Here, there is scope not only for a better understanding of mechanisms involved in sexual behavior but also for applying knowledge to management of species conservation and aquaculture practice. In addition, since many cues controlling sexual behavior are chemical, it is anticipated that anthropogenic pollution might have an adverse effect on fish reproductive fitness, and hence deserves further investigation.

Glossary

11-Ketotesterone Potent androgenic steroid hormone in teleost fishes inducing the development of secondary sexual characters often associated with territoriality and courtship in large males.

Arginine vasotocin Neuropeptide homolog of arginine vasopressin found in mammals. These hormones are released at the posterior pituitary gland, and also widely in the brain where they act as neuromodulators.

Aromatase Enzyme belonging to the cytochrome P450 family of proteins and plays a key role in the biosynthesis of estrogens through metabolism of androgens such as testosterone.

Estradiol 17β The most important circulating estrogen in both teleost fishes and mammals, produced in the ovaries and also other tissues including brain.

Gonadotropin-releasing hormone Neuropeptide hormone produced in the hypothalamus, released at the anterior pituitary gland to regulate gonadotropin secretion and is a key regulator of reproduction.

Gonochorism Sexual pattern in which individuals mature as one sex and remain that sex.

Initial phase First sexual phenotype seen in many protogynous species, often characterized by relatively drab colors and relatively low displays of aggression and courtship behavior.

Monoamine neurotransmitter A group of neurotransmitters that contain one amino group in their chemical structure.

Protandry Sexual pattern in which individuals mature as males and can then later change functional sex to become female.

Protogyny Sexual pattern in which individuals can mature as females and then later change functional sex to become secondary males. In monandric (one male) protogyny, all secondary males first pass through a female stage. In diandric (two males) protogyny, individuals can mature as either males or females and both can change from the initial phase to become the larger and typically colorful and aggressive terminal phase males.

Simultaneous hermaphroditism Sexual pattern characterized by individuals possessing both mature ovarian and spermatogenic tissue within the same functional gonad.

Steroid receptors Proteins that bind steroid hormones and then function as ligand-activated transcription factors to regulate gene expression in target cells.

Testosterone Important androgenic steroid hormone in all classes of vertebrates; critically, this steroid often functions as a biosynthetic intermediate in estradiol or 11-ketotesterone production.

Introduction

This article focuses primarily on one of the more dramatic examples of reproductive adaptation to social environment seen in fishes and, indeed, any animal – socially controlled functional sex change. The adaptive significance (or why?) of sex change is generally better understood than the developmental and physiological mechanisms that underlie this process (i.e., how?). When individuals can reproduce more effectively as one sex when small or young and as the other sex when larger or older, then there is an obvious benefit in being able to change sex to maximize reproductive success for their body size. This is known as the 'size advantage model' of sex change and it has been quite successful in explaining patterns of sex change in many species.

While the size advantage model offers a compelling explanation for the presence of sex change in many species of fishes where this pattern is observed, it is equally striking that many species exhibit similar patterns of reproductive success across body size (especially mating advantages for large males) and should exhibit sex change according to the model, yet do not. This is true both within the fishes and especially for other vertebrate groups where sexual lability is both much rarer and restricted to early developmental periods if it occurs. What accounts for this variation?

In mammals, the sex of an individual is determined by sex chromosomes at fertilization and specifically the presence or absence of the gene SRY (for 'Sex determining Region of the Y' chromosome). The testis or ovaries then arise relatively early in development and their hormonal secretions (particularly testicular androgens) organize other tissues including the brain. By contrast, the gonads develop relatively late in fishes as compared with other tissues and often well after individuals have spent considerable time as independently living miniature adults. But why does this matter in terms of environmental control of sex determination?

When the gonads develop very early, the brain is neither capable nor has the opportunity to gather and interpret environmental information that might be used to adaptively guide sex determination. By contrast, fishes often have ample opportunity to collect such information prior to gonadal development and, in the case of social influences, possess a well-developed brain to interpret it.

Sexual Patterns in Fishes

Fishes show the broadest range of sexual patterns of any group of vertebrates. With respect to sex determination, this variation ranges from strict gonochorism, where sex is determined by sex chromosomes, to simultaneous hermaphroditism, where individuals can alternate male and female function on a second-to-second basis. Between these extremes are species where:

1. sex is determined by social or physical factors prior to maturation, but then fixed after maturation;
2. species that mature as one sex, either male or female, and then change to become the other sex following maturation either as part of an ontogenetic sequence dependent on age or body size or in response to changes in their social environment; and
3. species that can undergo serial adult sex changes in both directions in response to social environment.

The article primarily focuses on the latter two patterns where sex determination occurs in adults and is under social control. Many species that undergo sex change also exhibit alternate male phenotypes; these are fascinating reproductive adaptations, but a full treatment is beyond the scope of this article.

Socially controlled sex change was first described and is best characterized in tropical marine fishes associated with coral reefs. This is because sex change is relatively common in four families that are conspicuous and important parts of the reef fish community. These families are the wrasses (Labridae), parrotfishes (Scaridae), damselfishes (Pomacentridae including the anemonefishes, subfamily Amphiprioninae), and the gobies (Gobiidae). Socially controlled sex change is also found in some temperate species where studies have focused on wrasses and gobies.

Male-to-female adult sex change is termed protandry and is seen in several families of fishes. Socially controlled protandry is best described in the anemonefishes, an Indo-Pacific group of 26 species (25 in *Amphiprion* and one species of *Premnas*). The anemonefishes have been an object of fascination due to both the symbiotic relationship they show with large tropical sea anemones and their recognition as stars in the movie *Finding Nemo* that featured Nemo, a 'boy' anemonefish, being raised by his single father Marvin. However, had the movie been biologically accurate, Nemo's father would have likely changed sex to become female following the disappearance of Nemo's mother and Nemo would have been like other anemonefishes, developing as an immature female who would likely have matured into a functional male to form a breeding pair in the social group (**Figure 1**). This pattern of a breeding pair and up to several immature females forming social groups has now been described for several anemonefish species. The gonadal structure of males consists of peripheral active spermatogenic tissues surrounding immature ovarian tissue (oocytes in the previtellogenic stage of development, **Figure 2**). This pattern is interesting because it illustrates the fundamentally female-first pattern of development in sex changing fishes even when the adult sex change pattern is male-to-female (we can only speculate as to why the movie makers decided not to have Nemo's father change sex!).

The maturation of juveniles and sex change by breeding males appears to be prevented by aggressive dominance of large females in anemonefishes. In the cinnamon anemonefish, *Amphiprion melanopus*, dominant females rapidly and aggressively approach their male pair mates approximately 150 times a day. Disappearance or experimental removal of these females eliminates this inhibition and both the behavior and gonadal structure of the male begin to change rapidly. Male cinnamon anemonefish made experimentally dominant show significant increases in aggressive behavior within 1 day of the removal of their dominant female pair mates and extensive changes in gonadal structure with proliferation of oogonial-like cells by 10 days later. Replacement of spermatogenic tissue with ovarian tissue is complete by 20 days.

The most common form of socially mediated sexual plasticity seen in reef fishes is female-to-male sex change or protogyny. Protogyny can take two forms. In monandric (one male) protogyny, all individuals mature as females and only later potentially change to become males. In diandric protogyny, individuals develop initially as immature females, but may mature into the initial phase (IP) as either males or females and either of these

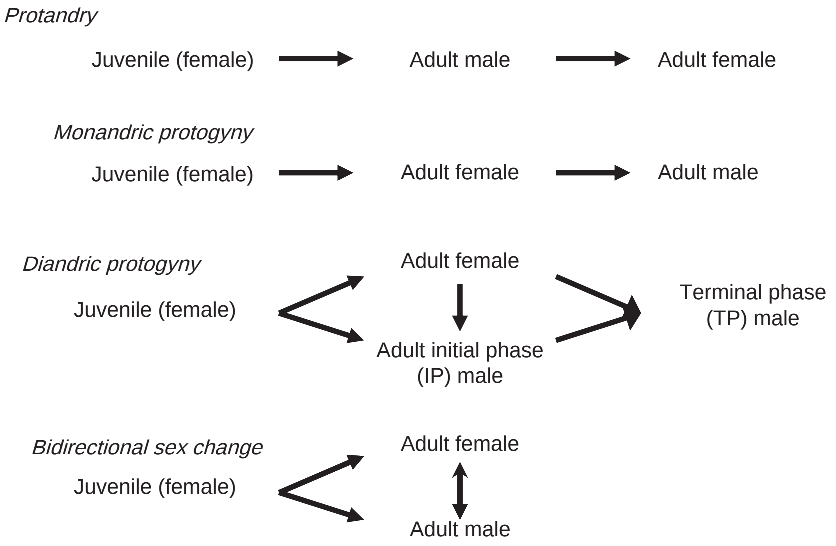

Figure 1 Sex change patterns in fishes. Modified from Godwin J (2010) Neuroendocrinology of sexual plasticity in teleost fishes. *Frontiers in Neuroendocrinology* 31(2), 203–216, with permission from Elsevier.

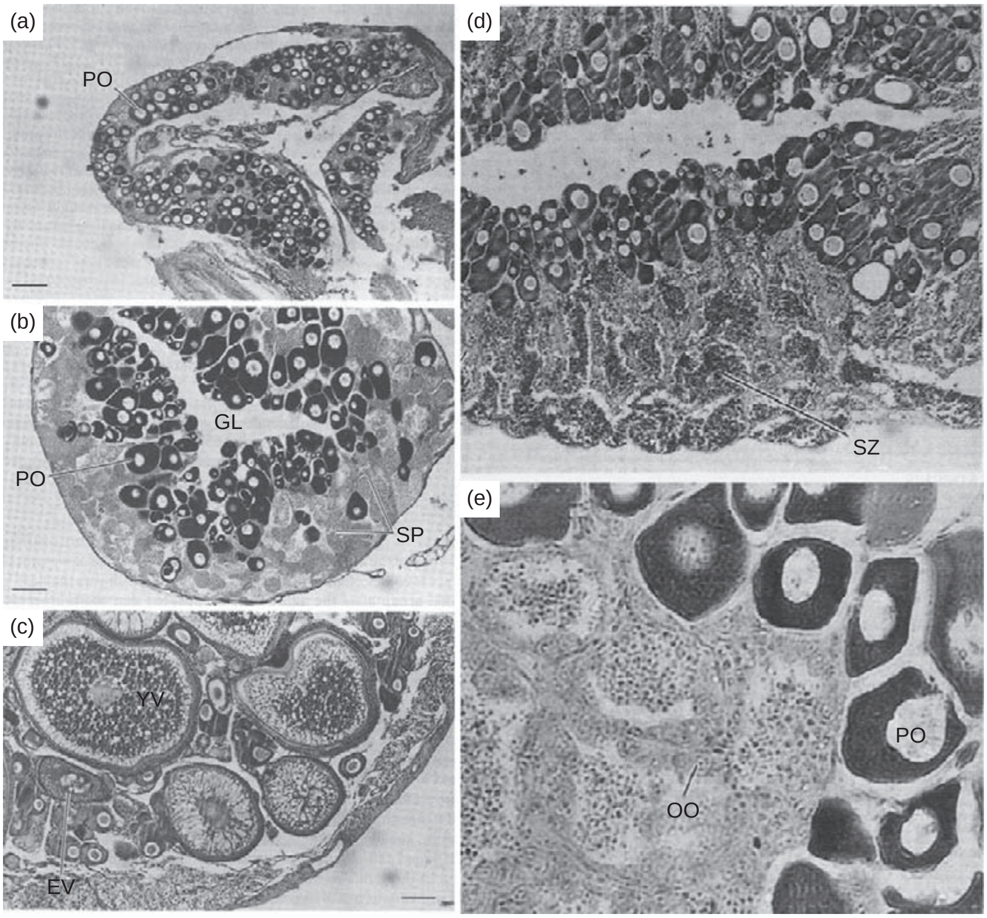

Figure 2 Gonad structure in the anemonefish *Amphiprion melanopus* for juvenile nonbreeders (a), breeding males (b), breeding females (c), and a sex changing fish 10 days after removal of the dominant female ((d) – low magnification, (e) – higher magnification). Abbreviations: EV, early vitellogenic oocyte; GL, gonadal lumen; PO, previtellogenic oocyte; SP, spermatogenic tissue (multiple stages); SZ, spermatozoa; OO, presumptive oogonia appearing as ovary develops during sex change. Scale bars = 100 mm. Figure 3 Initial phase and terminal phase males of the bluehead wrasse, *Thalassoma bifasciatum.*

phenotypes can then undergo change to the typically brightly colored terminal phase males (**Figures 1** and **3**). Monandric protogyny occurs in some damselfishes and is common in gobies and groupers with both monandric and diandric protogyny occurring in wrasses and parrotfishes. As predicted by the size advantage model discussed earlier, the adaptive significance of both monandric and diandric protogyny appears to be the high levels of reproductive success that accrue to large males who monopolize access to females or spawning territories.

Perhaps the most dramatic examples of sexual plasticity are seen in gobies and some serranid fishes. A number of serranid species are simultaneous hermaphrodites, maintaining both mature ovarian and testicular tissue in the same gonad. The hamlets (genus *Hypoplectrus*) are native to the Caribbean Sea and alternate female and male behavior and spawning on a second-to-second timescale in a behavior termed 'egg trading'. Other species of small serranid sea basses maintain gonads with mature tissue of both sexes and may lose the ovarian tissue when they become socially dominant members of social groups able to monopolize mating.

A number of goby species are protogynous. However, gobies also show an additional degree of flexibility in species that exhibit bidirectional sex change. Species of *Gobiodon* and *Paragobiodon* are obligate residents of branching corals in the west Pacific that can change sex in either direction. This flexibility allows any two individuals to form a mating pair on a coral, likely a strong advantage for a very small bodied species in which traveling large reef areas in search of mates could be very dangerous (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction; Endocrine Control of Sex Differentiation in Fish).

Steroid Hormone Patterns

The effects of androgens in a sex changing species were examined as early as 1962 in the wrasse *Coris julis*, but measurements of circulating levels of sex steroid hormones had to wait for the development of a technique termed 'radioimmunoassay' (RIA). Early studies using RIA showed that plasma levels of the primary estrogen in fishes (and mammals) 17-beta estradiol (E_2) were elevated in female saddleback wrasses (*Thalassoma duperrey*) and declined dramatically at the onset of sex change at the same time that oocytes in the gonad degenerated (**Figure 4**). Levels of E_2 remained very low across sex change and in terminal phase (TP) males. By contrast, a key androgen in fishes 11-ketotestosterone (11KT), was present at low levels in females and across sex change, only becoming elevated in TP males. Importantly, significant increases over female 11KT levels appeared to follow rather than precede or accompany the appearance of mature spermatogenic tissues.

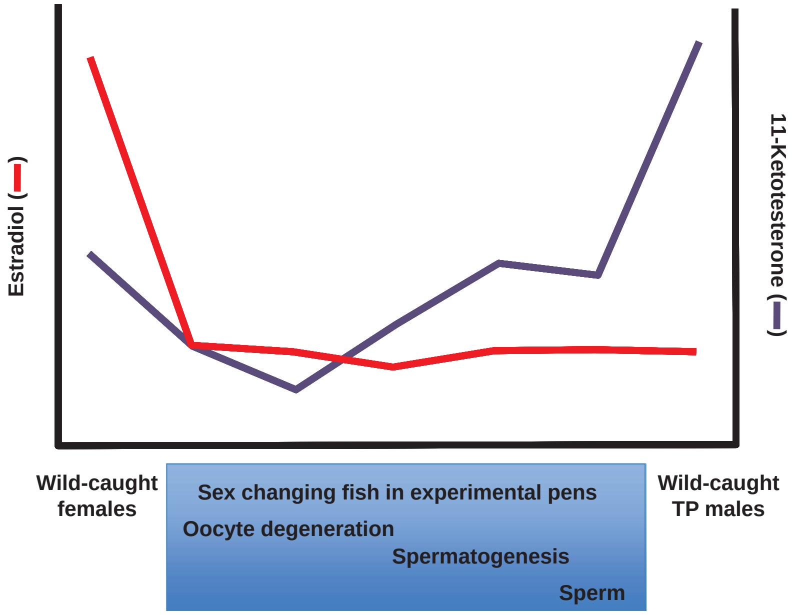

Figure 4 Relative steroid hormone levels in the plasma of saddleback wrasses shown for natural females and TP males as well as females undergoing socially induced sex change in experimental pens. Redrawn from Nakamura M, Kobayashi Y, Miura S, Alam MA, and Bhandari RK (2005) Sex change in coral reef fish. *Fish Physiology and Biochemistry* 31: 117–122.

Similar sex steroid hormone patterns are seen in the stoplight parrotfish (*Sparisoma viride*) and several other sex changing species that have been examined, including goby and grouper species. In an interesting twist, the anemonefish *A. melanopus* also shows higher plasma E_2 levels in females and higher 11KT levels in males despite the direction of sex change being male-to-female and females being the larger and aggressively dominant sex (**Figure 5**).

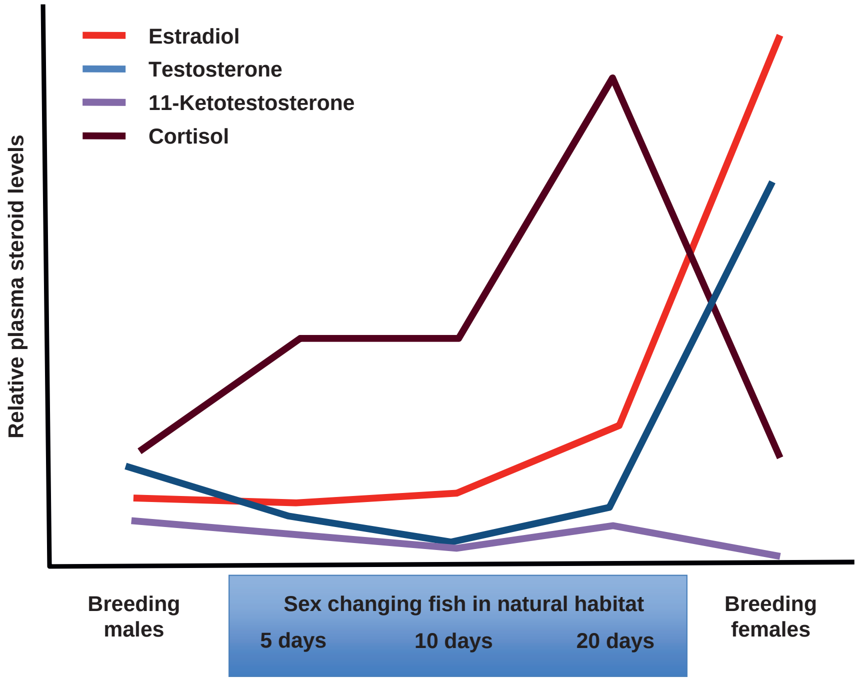

Figure 5 Relative steroid hormone levels in plasma of the anemonefish *Amphiprion melanopus* in natural males and females and as males underwent protandrous sex change following experimental female removals from social groups. Relative levels of different hormones are depicted approximately to scale except for cortisol, where levels were substantially higher. Redrawn from Godwin JR and Thomas P (1993) Sex change and steroid profiles in the protandrous anemonefish *Amphiprion melanopus* (Pomacentridae, Teleostei). *General and Comparative Endocrinology* 91(2): 144–157.

The role of steroid hormones in the control of sex change is supported by many experiments manipulating either steroid hormones directly or their synthesis. Androgen administration is effective for inducing male sex determination in a wide range of fishes and this approach is widely used in aquaculture to produce faster-growing males. Beginning in 1955 with bluehead wrasses, androgen administration has also been used to successfully induce sex change in a number of sex changing species. These include a number of wrasses, the stoplight parrotfish *S. viride,* the blackeye goby *Coryphopterus nicholsi,* and several species of groupers.

Blocking estrogen synthesis has similar effects to androgen administration in inducing female-to-male sex change. A key regulatory step in estrogen synthesis is the enzyme aromatase, a protein in the cytochrome P450 family of proteins. Fishes express two forms of this enzyme, known as gonadal and brain aromatase. Aromatase and estrogens generally appear to play key roles in sex determination in a range of species. Manipulations of estrogen signaling and aromatase activity are effective in manipulating the occurrence of sex change in several wrasse and grouper species as well as two goby species. For example, inhibiting aromatase action in the blackeye goby *C. nicholsi* induces sex change as effectively as 11KT implants. The bidirectionally sex changing gobies in the genus *Gobiodon* are especially interesting in this respect. As noted above, these gobies can change sex in either direction to form heterosexual pairs on the corals where they reside. Implants of the aromatase inhibitor fadrozole induce females to become males and males to remain male even when paired with a larger male. Conversely, E_2 implants induce sex change in males paired with other males while E_2-implanted females paired with other females do not change sex. Also consistent with a dominant role for estrogenic signaling in regulating sex change was a study where co-administering E_2 with androgens in three-spot wrasses blocked the female-to-male sex change that would otherwise occur. Taken together, these studies suggest that estrogenic inhibition may be the critical controlling factor for gonadal sex change.

The environmental cues for socially controlled sex change must clearly first be perceived in the brain. Consistent with this expectation, the more rapid decreases in brain aromatase activity seen in the brain compared to the ovaries of sex changing *Lythrypnus dalli* gobies suggest that a key early event in the sex change process is reduced estrogen signaling to neural structures.

Other Steroid Hormones and Sex Change

Because the social regulation of sex change is often closely related to aggressive behavioral dominance, there has been interest in the potential role of stress hormones. The key stress-related steroid in fishes is cortisol, as in humans, and is synthesized in the interrenal gland. Subordinate social status is quite often characterized by elevated cortisol levels in fishes and other species and elevated cortisol levels can inhibit reproductive function. These relationships led Perry and Grober to develop a model of the mediation of socially controlled sex change through the endocrine stress axis. This model was not supported in studies in anemonefish (*A. melanopus*) or the sandperch *Parapercis cylindrica*, where experimental increases in cortisol did not prevent sex change. However, stress effects can be exquisitely time sensitive and animals show physiological adaptation to chronic stressors in sometimes subtle ways, so more work remains to be done regarding the potential role of the endocrine stress axis in mediating sex change (**see also Social and Reproductive Behaviors**: Dominance Behaviors, **Hormonal Responses to Stress**: Impact of Stress in Health and Reproduction).

Neural Mechanisms of Sex Change

It has become clear that the often dramatic changes in behavior that accompany sex change are key parts of the change in sexual phenotype and may play an important role in stimulating the gonadal sex change process. This appreciation of the role of behavioral change as well as development of new techniques have shifted much of the focus in recent studies of sex change to neural and neuroendocrine mechanisms which may translate changes in social environment to changes in the gonads and other parts of the sexual phenotype.

The hypothalamus serves as a critical integrative center for both the reproductive axis and sexual behavior and is the site of gonadotropin-releasing hormone (GnRH) neurons which project to the pituitary gland. This brain region has, therefore, been a logical starting point for investigations of the neural mediation of sex change. Both correlative and experimental approaches support a role for the GnRH system in the sex change process. Working with bluehead wrasses in the early 1990s, Matthew Grober and colleagues described greater numbers of immunoreactive GnRH neurons in the hypothalamus of TP males than in that of females and that these numbers were increased in females by 11KT treatment. This pattern of greater numbers of GnRH neurons in males than females is also seen in the Ballan wrasse (*Labrus berggylta*) and in the protandrous anemonefish *Amphiprion bicinctus* (despite females being larger and aggressively dominant in anemonefishes). Expression of GnRH has not been closely monitored through the sex change process in any species, but findings from the cichlid *Astatotilapia burtoni* suggest that this would likely be informative. *A. burtoni* shows socially regulated sexual development that involves rapid activation of preoptic area GnRH neurons when changes in social conditions are perceived. This rapid activation of GnRH neurons underlies the rapid activation of the HPG axis when subordinate males ascend to social dominance.

What mechanisms might induce a change in the activity of GnRH neurons? Changes in neural estrogen signaling due to reductions in brain aromatase activity at the onset of sex change and a potential role for stress hormones were discussed above. Another intriguing possibility is the monoamine neurotransmitters – serotonin, noradrenaline, and dopamine which have been shown to vary in areas of the forebrain important for reproduction and sexual behavior, and their roles further confirmed by manipulation experiments.

Before leaving the discussion of neural mediation of gonadal sex change, this article discusses some recent work suggesting that the variation in target tissue responsiveness to gonadotropins is the critical change at the time of sex change. The bidirectionally sex changing goby *Trimma okinawae* expresses both ovarian and testicular tissues, but with only one type being mature and active at a given time. Kobayashi and colleagues found that the active portion of the gonad expressed gonadotropin receptors at much higher levels than the inactive portion and that this higher expression was associated with greater responsiveness to gonadotropin. Exposure to visual cues that induce a change to the opposite sex reversed the pattern of gonadotropin receptor expression within approximately 12 h.

Neural Bases of Behavioral Sex Change

Successful sex change requires coordinated changes in a suite of phenotypic features. Behavioral sex change in fishes is often very rapid, occurring within one to several days in anemonefishes and blue-banded gobies and within minutes of dominant male removal with cleaner and bluehead wrasses studied in nature. This short timescale suggests gonadal change does not drive behavioral change. Indeed, the reverse may be true. The role of the gonads, neural mediators of behavioral sex change, and potential connections between the behavioral and gonadal sex change are discussed in this section.

Surgically removing the gonads from female bluehead wrasses does not prevent behavioral sex change when those females are made socially dominant. While the gonads are not necessary for the behavioral components of sex change in this species, ovariectomized females do not develop TP male coloration on becoming dominant. This is presumably because they lack a source of 11KT, which can induce the development of these colors when administered even to subordinate, ovariectomized females. This lack of necessity for gonads in behavioral sex change is consistent with often very rapid time course of this process and highlights the fact that important changes in steroid hormone signaling do not need to occur in the gonad itself.

What neural mechanisms do mediate behavioral changes during the sex change process? Two areas of focus have been monoamine neurotransmitters and neuropeptide hormones. Changes in monoamines were mentioned above and in saddleback wrasses (*T. duperrey*) changes are especially pronounced during the first week of sex change when social dominance for sex changing females is being established. During the first week in experimental groups, dominance interactions develop accompanied by a number of alterations in monoaminergic signaling, although the patterns are complex across brain nuclei. In bluehead wrasses, serotonergic manipulations can decrease aggression in both laboratory and wild TP males, but no studies have closely examined the behavioral effects of manipulating monoamines during the sex change process in wrasses.

A second focus for studies of the neural mechanisms mediating behavioral sex change has been on neuropeptide hormones, especially arginine vasotocin (AVT). The first study to show differences in AVT neurons across sexual phenotypes in a sex changing fish was in the goby *T. okinawae*. In bluehead wrasse, TP males have significantly higher abundances of AVT mRNA in the preoptic area of the hypothalamus compared with females and these levels increase rapidly during experimentally induced sex change. Both the gonads and social interactions are changing as a female wrasse undergoes sex change; therefore, to tease these two factors apart, levels of AVT neurons in females changing sex with and without gonads and females that remain as subordinate females were compared. Social status affected AVT mRNA abundance, while gonadal status did not (**Figure 6**). Behavioral effects of AVT also appear to depend on sexual phenotype. Neither courtship nor territorial behavior could be induced by AVT injections in females or female-mimic IP males. However, injection of AVT increases courtship in TP males and induces nonterritorial TP males to establish territories.

This difference in responsiveness to AVT across sexual phenotypes is not surprising. In mammals, arginine vasopressin, the mammalian homolog of AVT, is more strongly implicated in male-typical socio-sexual behavior, while oxytocin, the homolog of the teleost isotocin, is implicated primarily in mediating female-typical socio-sexual behavior. The best data on the effects of isotocin in fishes come from an experiment by James Goodson and Andrew Bass, who examined neural responsiveness with a non-sex changing species, the plainfin midshipman *Porichthys notatus*. They found that the brains of large territorial males were strongly responsive to AVT while those of females and smaller nonterritorial type II males were not responsive at all. By contrast, the brains of females and type II males were strongly responsive to isotocin, while the large territorial type I males were completely unresponsive. The only data available

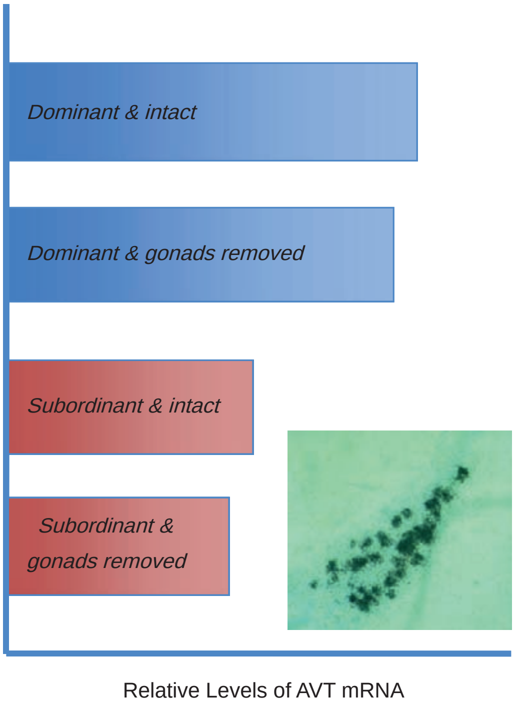

Figure 6 Social status influences AVT mRNA levels in the preoptic area of the hypothalamus in bluehead wrasses while gonadal status does not. Dominant individuals were the largest in their social groups while subordinants were not. Intact animals underwent sham operations to control for the surgical procedure. Inset shows AVT mRNA in the preoptic area visualized by the technique of *in situ* hybridization. Data from Semsar K and Godwin J (2003) Social influences on the arginine vasotocin system are independent of gonads in a sex-changing fish. *Journal of Neuroscience* 23: 4386–4393.

regarding isotocin neuron patterns in sex-changing species come from blue-banded gobies, where more isotocin neurons were found in females than males. Further exploration of isotocin actions in sex changing fishes would be valuable.

Summary

Our understanding of the physiological basis of sex change has increased rapidly in recent years. This is due to both technical advances in endocrine techniques and especially molecular biology as well as the identification and exploitation of powerful model systems such as sex changing wrasses and bidirectionally sex changing gobies. Estrogen synthesis through the aromatase enzyme and the actions of the neuropeptides GnRH and AVT appear especially important in regulating sex change, but other physiological mediators are undoubtedly important contributors to the process. The discovery of these mechanisms and development of synthetic models of the mechanistic basis of sex change from the perception of changed social environment to gonadal change should be the next stage in study of this fascinating reproductive adaptation.

Glossary

Androgen Any natural or synthetic steroid hormone that is principally involved in growth, development, and maintenance of the male reproductive system and secondary sexual characteristics.

Arginine vasotocin A neuropeptide homolog of arginine vasopressin found in mammals. These hormones are released not only at the posterior pituitary gland, but also widely in the brain where they act as neuromodulators.

Isotocin Homolog of the mammalian hormone oxytocin, known to influence social behaviors in fish.

Oviposition An act of laying eggs by oviparous animals (animals laying eggs that develop outside the female's body).

Phylogeny Modification of the structure and function of a species or group of species throughout their evolutionary history.

Prolactin A protein hormone primarily produced in the pituitary acting on ion balance and reproduction.

Sneaker male A male phenotype that sneaks into the territory of a conventional male to mate with a female.

Sperm competition The competition between sperm from two or more males to fertilize the egg of a female.

Viviparity The production of live young that develop before being released into the external environment.

Zygote The initial cell of a new organism, usually formed by the joining of an egg and sperm at fertilization.

Introduction

Parental care, the investment in young after fertilization, may not be a behavior that immediately jumps to your mind when you think of fishes. However, many fishes provide care for their young, and they care for the young in different ways. Which parent provides the care also varies greatly from fish species to fish species. The impressive variation in parental-care tactics has made fishes an excellent group for testing our understanding of how parental care evolves. Indeed, studies with bony fishes have helped shape our theoretical understanding of how sexual selection operates.

In contrast, the physiological mechanisms underlying parental behavior in fishes remain poorly explored. Although to a limited degree prolactin, isotocin, and androgens have all been investigated in the context of parental care, the behavioral physiology of parental care in fishes is very much in its infancy. In this article, we examine the major forms of care and the common patterns of care found in fishes. We then provide an explanation for these patterns based on the costs and benefits of parental care. Finally, we review the current available information on physiological underpinnings of fish parental-care behavior, albeit limited, and suggest areas for much-needed future research.

Before embarking on a review of parental care in fishes, it is necessary to clarify the terms used when describing behavior of parents toward their young. The term 'parental care' is used to describe any behavior performed by parents that appears likely to improve the survival and reproduction of the young. Robert Trivers coined a more restrictive term 'parental investment' to refer to any action by parents that increases offspring fitness at a cost to parental fitness (because it curtails their ability to invest in future mating, fecundity, survival, or further parental care). The terms parental effort or parental expenditure refer specifically to the time and effort spent on parental care of offspring, again referring to actions that are thought to increase offspring fitness, for example, defending offspring against predators. This measure is related to parental investment but does not necessarily imply fitness costs for parents, as the costs of parental care may change with an individual's age, status, or condition.

The question of which behaviors to include or exclude when using the terms parental care or parental investment can also be challenging. For example, building and defending a nest may not only increase the chances of attracting a mate (reproductive effort), but also have a positive impact on offspring fitness (parental effort). Many fish species provide eggs with large quantities of yolk before releasing them to the external environment (**see also Social and Reproductive Behaviors**: Nutritional Provision During Parental Care); the largest known fish egg belongs to the coelocanth (*Latimeria chalumnae*) with a diameter between 7.5 and 9.0 cm and a mass of 325 g. Whether or not such provisioning should be considered as parental care or parental investment has been much debated. Females vary considerably (within and across species) in the extent to which they provision eggs and such provisioning has profound effects on development time, survival of young, and the ability for a female to invest in future young.

Patterns and Diversity in Parental Care

Form of Care

Unlike birds and mammals where offspring require some form of parental assistance, most fish species do not provide parental care. However, in 25% of fish species, care has evolved, and the way care is performed is highly variable (**Figure 1**). Fish care ranges from hiding of eggs and then abandoning the area, to guarding young in elaborately prepared structures for up to several months, and from carrying young in or on the parent's body cavity to the feeding of young.

The simplest form of fish parental care is hiding of the eggs. Female salmon and trout, for example, will excavate nests (redds) by digging simple depressions with their tails; the eggs that are laid in these redds are fertilized and then buried by the female. In contrast to the simple pit built by the female salmonids, some fish species are amazing construction workers. Lake Malawi's cichlid, *Cytocara eucinostomus,* creates crater-shaped nests that are more than 3 m in diameter, while the three-spined stickleback, *Gasterosteus aculeatus*, constructs elaborate nests woven of plant material carefully glued together with a special kidney glycoprotein secretion known as spiggin (**Figure 1**(**a**); **see also Social and Reproductive Behaviors**: Sexual Behavior in Fish).

Guarders are fish species that take parental care a step further than nest builders, by tending and defending eggs, embryos, or larvae until they hatch. Some guarding species build their own nests, while others choose an area (cavity, cave or natural burrow, underside of a rock, or log) to use as a spawning and guarding site. Typically, fish species that significantly modify the substrate to receive eggs (nest builders), also guard eggs against predation (**Figure 1**(**b**)). The amount of time spent protecting young varies from 1 day in the Sacramento perch, *Archoplites interruptus,* to over 4 months in the Antarctic plunderfish, *Harpagifer bipinis.* Many fish species go beyond simple guarding by aerating the eggs using their pelvic or pectoral fins. By fanning the eggs with their fins, parents ensure that fresh, aerated water is passed over the eggs on a regular basis. Many parent fish also clean the eggs, placing their mouths against the eggs and sucking away detritus or removing dead or fungus-ridden eggs.

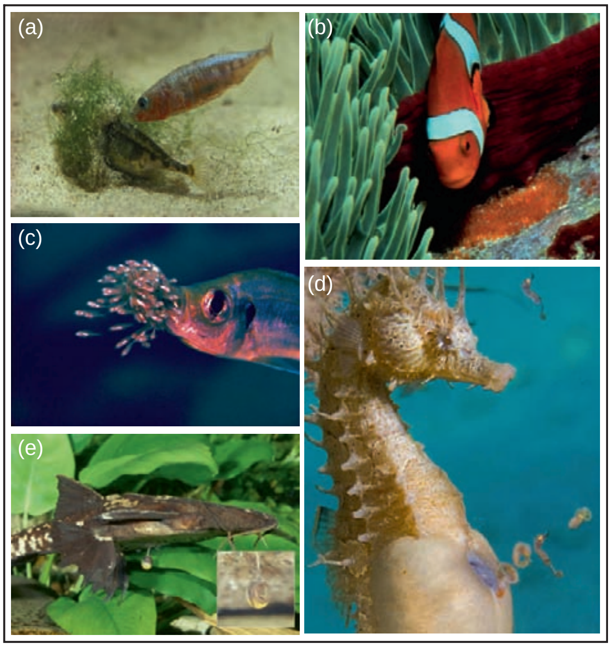

Figure 1 (a) A male three-spined stickleback (*Gasterosteus aculeatus*) observing a female entering his nest; (b) a male clownfish (*Amphiprion percula*), inspecting eggs in its nest; (c) a female mouth-brooding cichlid from Lake Tanganyika, *Haplotaxodon microlepis* collecting young in its mouth; (d) an unnamed seahorse, *Hippocampus* spp. giving birth to live young; and (e) A female eeltailed banjo catfish, *Platystacus cotylephorus,* carrying young embedded on the skin of her abdomen.

Although the terms 'brooding' and 'incubation' are commonly used by fish biologists when describing fish parental care, fish do not truly incubate eggs, as heat is not transferred to the eggs by parents. However, many fish species protect their young internally and some even have live births (known as live-bearing or viviparous species; **see also Social and Reproductive Behaviors**: Nutritional Provision During Parental Care). Species of fish that protect or incubate their young internally may do so in their mouths (e.g., marine catfishes and cichlids, **Figure 1(c)**), in ventral brood pouches (e.g., sea horses and pipefishes, **Figure 1(d)**), on hooks (e.g., *Kurtus* spp.), embedded in skin (e.g., American banjo catfish, **Figure 1(e)**), or in gill chambers (e.g., cavefish). Internal brooding is an extremely effective method of protection because the only way a predator can capture or kill young fish is to injure or kill the parent or force the parent to eject its young. For example, male seahorses, *Hippocampus wheitei*, receive eggs from their female partners, which the males internally fertilize and then aerate and nourish for a few weeks in an enclosed pouch. The dads eventually give birth (via a series of forward and backward muscular contortions) to young, one at a time.

The most complex or elaborate parental-care behaviors found in fishes are undoubtedly the feeding of young post-hatch and caring for nutritionally independent young. *Symphysodon discus* young as well as the young of some other cichlid species ingest the epidermal mucus from their parents' body. Both male and female parents of the Central American convict cichlid, *Cichlasoma nigrofasciatum*, carefully lift up fallen leaves for their young providing them with benthic prey underneath the leaf litter. Many cichlid parents appear to be able to signal imminent danger to their young by using a specific jolt or calling behavior that consists of open-and-shut snapping of the pelvic fins while swimming backward with the head pitched downward. The young respond to these warning movements by settling down into the substrate or swarming and entering the parents' mouths where they can be kept safely until the danger has passed. Finally, in Tanganyikan cichlids, such as *Neolamprologus brichardi and Neolamprologus pulcher*, sexually mature young continue to be vigorously guarded.

Sex of Caregiver

In fishes, care can be provided by the female alone (maternal or female-only care), by the father alone (paternal or male-only care), or by both parents together or in sequence (biparental care, **Figure 2**). About 30% of the 500 known fish families show some form of parental care, and most often (78% of the time) care is provided by only one parent (usually the male). Male care (50%, **Figure 2(a)**) is much more common than female care (30%) with biparental care accounting for about 20%, although a more recent comparative analysis suggests that male care may be more common (84%; **Figure 2(b)**). In some species, such as Galilee St. Peter's fish (*Sarotherodon galileaus*) and the brown bullhead (*Ameiurus nebulosus*), parental care is variable with male-only, female-only, and biparental care occurring in the same population.

Explaining the Patterns and Diversity of Fish Parental Care

Many interesting questions arise from the patterns observed in fish parental behavior. For example, (1) why do so many more freshwater fishes provide care (57% of freshwater fish families) compared to marine species (only 16%); (2) why is female-only (maternal) care typically associated with internal bearing in fishes; and (3) why is male-only (paternal) care so common? This section addresses these related questions about who should care, and it reviews the costs and benefits associated with parental care in fishes:

1. *Why so much more care in freshwater species?* The open ocean provides a relatively stable, safe, and homogeneous environment for egg development; egg predators are relatively rare and water conditions do not fluctuate quickly. In contrast, freshwater biotas, especially shallow ones where fish eggs are typically released, vary tremendously in time and space. Hence, selection of particular spawning locations combined with parental care can have massive impacts on egg development and survival. This benefit has led to male defense of the best or favored female spawning sites and to female egg clumping. Under these conditions (male territoriality and multiple females being attracted to the same spawning site), guarding eggs in addition to a territory would not be particularly costly.
2. *Why is female-only or maternal care associated with internal bearing in fishes?* Internal gestation is rare in fishes (11% of families) and is strongly associated with female care. Once internal fertilization has evolved, the retention of egg requires little re-organization and would confer a substantial survival benefit to young. A protracted association between females and the zygote is considered to be the basis for selection of internal fertilization. In families with internal fertilization and care, in 86% of the cases it is the female that provides the care; in contrast, when external fertilization and parental care co-occur, it is usually the male that provides care (76% of cases).
3. *Why so much male-only (paternal) care in fishes?* A lot of theory has centered on why, in contrast to other animals, in fish, it is the males that usually provide care. Initially, it was thought that higher rates of paternity, associated with external fertilization in fishes predisposed males to care. However, external fertilization does not protect against paternity loss; sneaker tactics and strong sperm competition have evolved many times in fishes and paternity certainly does not cause male care. Later, it was argued that the order in which gametes are released predisposes male fish to care, because in external fertilizing fishes, females shed eggs before males shed sperm, effectively providing females with an opportunity to desert their partners. Hence, male externally fertilizing

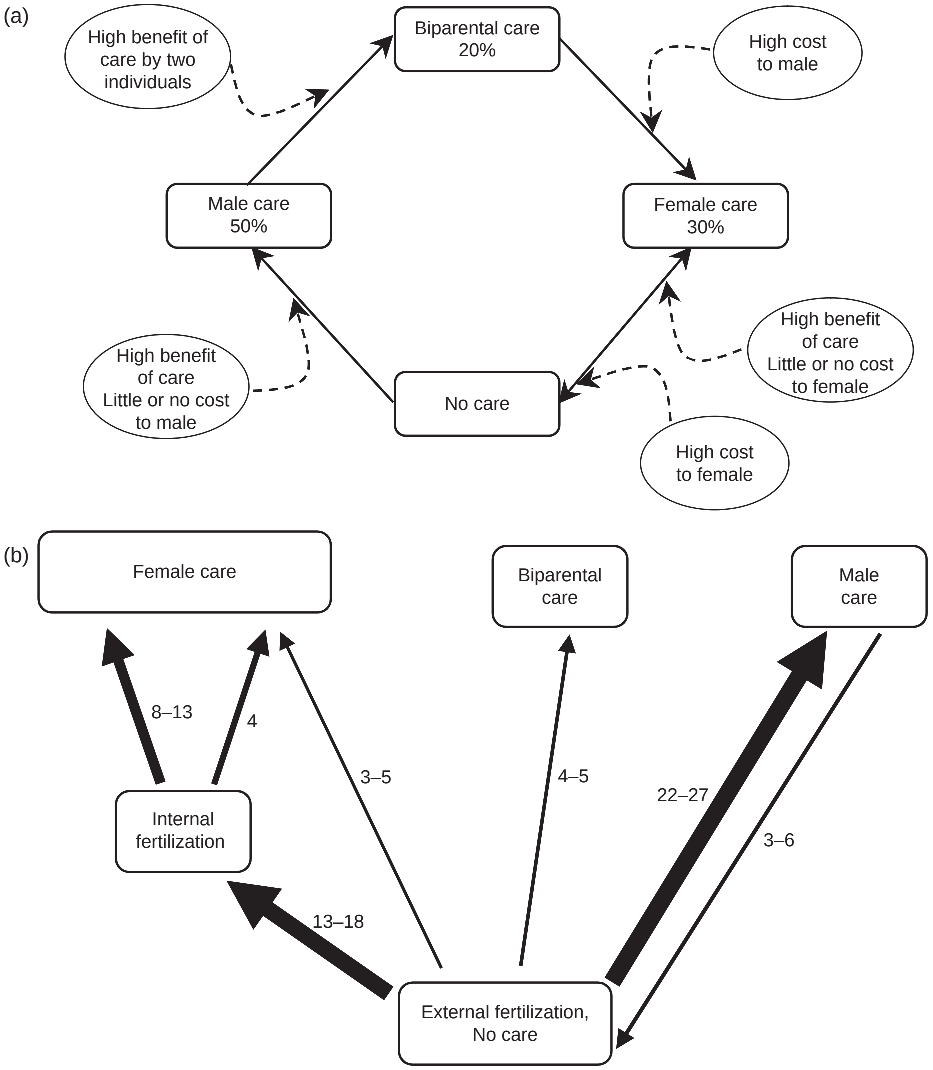

Figure 2 (a) The commonly accepted stepping-stone model of parental-care evolution in fishes with external fertilization (the data are based on 422 families of teleost fish families). There are four possible states of parental care: no care, male, female, or biparental care. The arrows show the likely direction of evolution among states. The dashed arrows refer to the selective factors promoting transitions in care. The percentage of teleost families in each state is shown, and families including species in more than one state are counted more than once. (b) An alternative evolutionary model for transitions among parental care states. Arrow size reflects the number of evolutionary transitions and the numbers by each arrow refer to the minimum and maximum number of possible transitions. The analysis is based on data for 228 families of ray-finned fishes (Actinopterygii). (a) Reproduced from Gross MR and Sargent RC (1985) The evolution of male and female parental care in fishes. *American Zoologist* 25: 807–822, by permission of Oxford University Press. (b) Reproduced from Mank JE, Promislow DEL, and Avise JC (2005) Phylogenetic perspectives in the evolution of parental care in ray-finned fishes. *Evolution* 59: 1570–1578, with permission of John Wiley and Sons.

fish are abandoned in the cruel bind of being left in charge of the babies. However, for the majority of externally fertilizing fishes, both males and females release gametes simultaneously. In some species (e.g., black gobies), caring males release sperm before females lay their eggs and in other species, females provide care even when males release gametes last.

A third hypothesis, known as the association hypothesis, is currently favored for explaining the preponderance of male care in fishes. The simple notion is that the sex with the lowest costs of care will provide care and that these costs of care are lower for the sex already associated with the young. This is the female for internal fertilizing fishes, while it is the male for external fertilizing species with male territory defense. Defending young does not represent a large energetic or time increase over and beyond the cost of defending a territory. Moreover, male reproductive rates are not necessarily curtailed by providing care, because multiple females may spawn with a single male. This is especially true when females are attracted to particular spawning areas because of reduced offspring mortality. In fact, in some fish species, females are most attracted to males that already have eggs in their nests. In contrast to males, the provisioning and protection of young can severely impact female growth and fecundity. Therefore, male care is more common in fishes because the costs of providing care are lower for males than for females.

Costs and Benefits of Parental Care

The answers to all of the above questions rely on understanding the costs and benefits of care. The benefit of parental care is that it improves survival and development of young. The three main costs of parental care are (1) decreased parental survival; (2) increased time until the next breeding attempt; and (3) reduced future fecundity (via suppressed feeding and growth). Experiments with various fish species have demonstrated these costs and benefits.

When parent sticklebacks and cichlids have been experimentally removed, eggs and young fail to survive. Experiments that have manipulated the benefits of parental care (relatedness and number of young) have shown that parents usually can dynamically adjust the level of care in relation to these changes in benefits.

Experimental manipulations have also quantified the costs of care. First, brooding male pipefish (*Syngnathus typhle*) have been shown to be 11 times less likely to survive than nonbrooding males. This may be because parents are more conspicuous or take bigger risks, or because caring is energetically costly while limiting foraging time, which in turn reduces body condition and makes parents more susceptible to predators, disease, and starvation. Second, in the cichlid fish, *Sarotherodon galileaus*, caring males and females have longer interspawn intervals (**Figure 3(a)**) and fewer opportunities to feed than noncaring fish. Caregivers also have a lower body mass, which reduces female fecundity as a result of smaller subsequent clutches compared to those that spawn eggs but do not provide care (**Figures 3(b)** and **3(c)**). Third, in another biparental cichlid, *Herotilapia multispinosa*, Miles Keenleyside showed by varying sex ratios that males desert their clutches far more frequently in female-biased areas, where their probability of mating again is high.

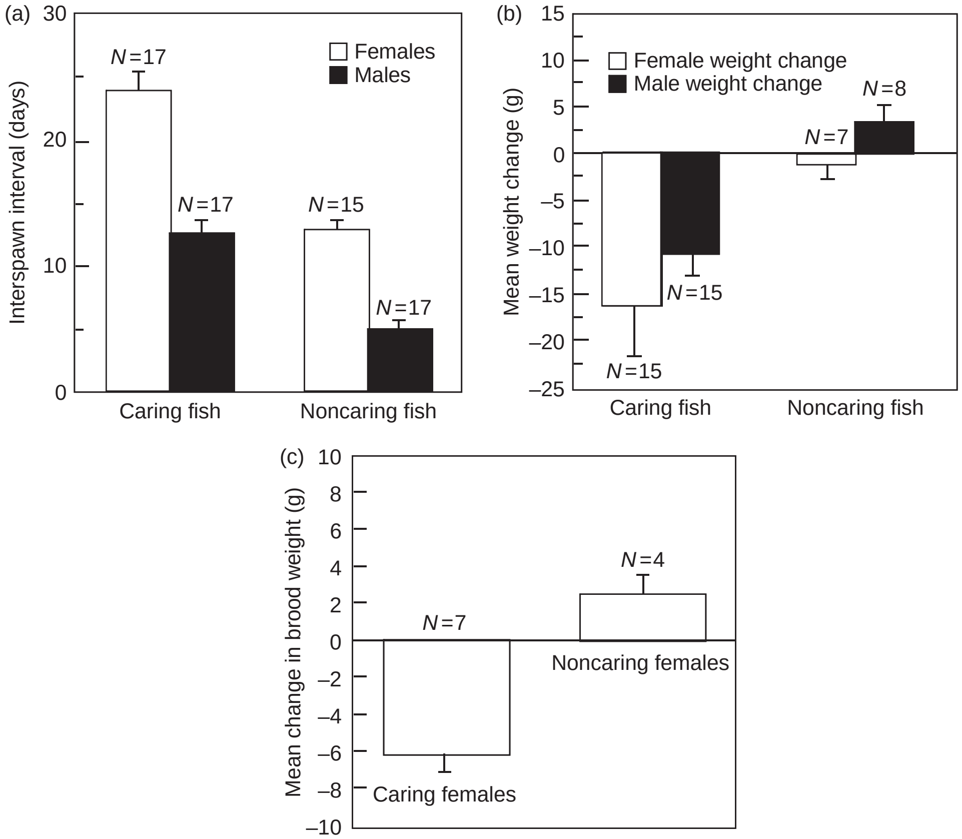

Figure 3 (a) The interspawn interval for caring vs. noncaring male (in black) and female (in white) Galilee St. Peter's fish. (b) Body mass change for caring vs. noncaring St. Peter's fish. (c) A decrease in fecundity was observed for caring but not for noncaring female St. Peter's fish. Evolutionary Trajectories of Parental Care among Fishes and Phylogenetic Comparisons

Parents and their young have often co-adapted to particular levels of care (constraining care tactics) so that sensible manipulative experiments to tease apart the causes and consequences of care are not always feasible. Fortunately, recent developments in fish phylogenies have allowed phylogenetic-based comparative studies to provide a complementary, powerful way to understand the evolution of parental care.

For 30 years, the most widely accepted hypothesis for the evolution of parental care in fishes has been a stepping-stone model in which care evolved from an ancestral state of no care to biparental care via two intermediate stages of female-only and male-only care (**Figure 2(a)**). While within-family phylogenetic-based comparative studies have largely supported this stepping-stone model, a recent cross-family comparison by Mank and co-workers, with representatives across 224 fish families, found no evidence for the stepping-stone model (**Figure 2(b)**). Instead, they showed that both female and male care have arisen from the precursor state of no care in fishes.

Transitions between care states are thought to have arisen via changes to the costs and benefits of parental care. For example, biparental care is thought to arise from male-only care when females lay very large eggs and the benefits of defense by two parents outweighs the female-fecundity costs of care. Biparental care is argued to lead to female-only care when male future mating opportunities increase. Female-only care is thought to have evolved from no care when the fecundity costs of providing care decrease and the benefits of care in terms of offspring survival surpass these costs. Comparative studies can test these ideas, examine what factors promote transitions in care, and explore the direction of change. For example, an analysis of 222 genera of cichlid fishes revealed 21–30 shifts from biparental to female-only care within the Cichlidae family. This removal of male care from the biparental state is related to a reduction in the need for biparental defense.

Physiological Mechanisms Underlying Fish Parental Care

There are still major gaps in our understanding of parental-care regulation in fishes. We know that a number of social, environmental, and physiological factors work together in a complex fashion to influence parental care. To date, few species have been physiologically studied and only a small handful of hormones and neuropeptides have been investigated in terms of how they mediate parental behavior.

Nest Building

Nest building can be considered a parental behavior because a well-placed, well-built nest can enhance the development of young. Nest building often occurs with territoriality and courtship in male fishes, and has been associated with high plasma androgen levels (0.85–400 ng ml^{-1}). For example, when male Siamese fighting fish, *Betta splendens*, build mucus-lined bubble nests and male three-spined sticklebacks weave vegetation nests together with glue from the special kidney protein spiggin, both of these actions are thought to be under the control of androgens (see **Figure 1(a)**; **see also Social and Reproductive Behaviors**: Sexual Behavior in Fish).

Defense

Male caring fishes, such as sticklebacks, damselfish, girabali, bluegill sunfish, plainfin midshipman, and the black-chinned tilapia, have high plasma androgen levels (testosterone and 11-ketotestosterone) during pre-spawning, when males compete for territories, construct nests, and court females. The androgen levels then gradually drop following spawning while males provide care. This was believed to indicate an androgen-mediated trade-off between aggression and parental care and a minimal role of androgens during parental care.

However, recent studies show that androgen levels often rise again to pre-spawning levels once eggs have hatched. Other studies even show that androgens remaining high in the early stages of care, correlated with the frequency of parental care/defense of young in the biparental cichlid *N. pulcher*. In addition, experimental elevation of androgen levels does not inhibit paternal behavior in a number of fish species, suggesting that an elevated androgen level is not necessarily incompatible with the expression of paternal behavior. This may be true of fish in general, but not other vertebrates. Male fish often continue to court and attract females even after they have begun to provide care, but in other taxa, the mating/courtship phase of reproduction is commonly temporally separated from the parental phase. Fish do not typically feed young, but instead defend young against predators (and sometimes fan the eggs); so, high androgen levels might, in fact, be beneficial and necessary for the aggression needed during parental care. More research is needed to clarify the role of androgens in mediating parental behavior with the importance of estrogen and mechanisms that modulate female care remaining particularly understudied.

Fanning and Brooding

The internal physiological mechanisms determining parental fanning behaviors remain largely unexplored.

Prolactin stimulates fanning behavior in the three-spined stickleback and in bluegills, where administration of a prolactin inhibitor reduces fanning and defense of offspring. In the mouth-brooding cichlid, *Oreochromis niloticus*, elevated levels of prolactin are seen in the brain and plasma during the brooding period, and in the cichlid, *Symphysodon discus*, injections of prolactin cause an increase in egg fanning and the production of mucus secretions on which newly hatched fry feed (**see also Social and Reproductive Behaviors**: Nutritional Provision During Parental Care). In *S. discus*, prolactin may, therefore, increase the production of mucus for young to feed from, in a manner similar to the role of prolactin in increasing milk production in mammals. Other hormones that have been associated with reproductive behaviors include arginine vasotocin (AVT) and isotocin (**see also Social and Reproductive Behaviors**: Socially Controlled Sex Change in Fishes) and investigations into their role during parental care are warranted.

Future Research Directions and Conclusions

This article makes two main points. First, nowhere in the animal kingdom is the diversity of parental-care habits greater than among fishes. This diversity has meant that fishes will continue as extremely useful model organisms for clarifying our theoretical understanding of the evolutionary origins of parental care (i.e., who cares?) and revealing key factors influencing the adaptive amount of care (i.e., how much to care?). The idea of reproductive trade-offs (the costs and benefits of care) has provided a rich theoretical test bed for exploring the evolution of parental care in fishes. This approach has moved parental-care research from a descriptive qualitative science into a strongly quantitative predictive one.

Fishes also offer a wonderful opportunity to explore parental care's strong and intimate link with sexual selection. Parental care promotes the survival and vigor of young (so will clearly be influenced by natural selection), but in fishes can be often strongly influenced by sexual selection as well. The best parent, the one providing the most vigorous care, is often preferred as a mating partner. A fruitful avenue for future parental-care fish research will be to clarify the interactions between natural and sexual selection and more specifically to investigate the degree to which parental care (egg tending, defense, and nest building) can be viewed as a sexual ornament enhancing mate attraction.

Second, we know little about the physiology modulating care behavior in fishes. The scarce research in this area has largely focused on androgens and paternal care while the neuroendocrinological mechanisms and genetics modulating biparental and female care remain largely unexplored. There is an urgent need to expand physiological studies to encompass a larger range of hormones, more model fish species, and different care behaviors (e.g., fanning, offspring retrieval, and feeding). New brain-imaging techniques and the sequencing of entire genomes may provide powerful new insights on the neurophysiological systems and molecular changes that occur during parental care. An integration between ultimate and proximate analyses will undoubtedly shed light on the how and why of parental care in fishes. Understanding the physiological processes of fish parental behavior and their link to population biology and the health of fisheries will arm us with a valuable roadmap to navigate the possible impacts of all too frequent anthropogenic changes to environments and ecosystems.

Glossary

Adelphophagy Where offspring feed on other embryos while still inside the mother.

Gestation The carrying of an embryo or fetus inside an ovoviviparous or viviparous parent.

Immunoglobulin An antibody playing a critical role in immunity.

Lecithotrophy Feeding on egg yolk or substances put into the egg by the mother.

Oophagy (egg eating) Where offspring feed on other eggs while still inside the mother.

Oviparity Production of eggs that develop and hatch after being released into the external environment.

Ovoviviparity Production of eggs that develop and hatch within the mother before being released as live young to the external environment.

Pseudoplacenta A structure which functions like a placenta, transferring nutrients from parent to offspring.

Trophotaeniae Vascular processes of an embryo that establish a placental relationship with the mother.

Vitellogenins Precursors of the major egg yolk proteins comprised of up to five different domains, each of which corresponds to one of the stored yolk proteins (see also yolk proteins). Vitellogenins are large (> 350 kDa), homodimeric phospholipoglycoproteins. Common abbreviations for vitellogenin are Vg, VG, and Vtg.

Viviparity Production of live young that develop before being released into the external environment.

Why Provide Nutrients?

A myriad of parental care strategies exist in fish (**see also Social and Reproductive Behaviors**: Parental Care in Fishes), ranging from the simple protection of eggs to more complex forms such as the provision of resources via a placental connection and offspring developing internally. In its broadest sense, parental care can involve any parental behavior that serves to maximize the survival of offspring. This can include behaviors whereby parents physically guard and protect both eggs and fry from predators through to the preparation of nests, and to mouth brooding. Besides providing physical protection to offspring, a number of strategies have also evolved to aid offspring survival through the parental provision of nutrients.

Fish hatch and begin development in what can be considered a hostile environment, frequently lacking an abundance of food and fraught with predators and pathogens. Newly hatched fish are often ill-equipped to deal with these problems due to a lack of development in immune organs and of locomotory systems that facilitate predation evasion and food capture; this period of early development is, therefore, considered one of the most delicate and dangerous periods of a fish's life where mortality rates are often highest.

One way parents can reduce the time offspring spend in this delicate period of development is to provide a form of nutrition to allow offspring to grow and develop quickly, thereby reducing their period of vulnerability. Parentally provided nutrition can be delivered to offspring during either the pre- or posthatch/birth period.

Prehatch/Birth-Provided Nutrition

The prehatch/birth provision of nutrients is the most common form of parental provision seen in fish. There are several variations including external development strategies such as the laying and provisioning of eggs with egg yolk, as seen in oviparous fish, to internal development strategies, such as the formation of a placental relationship between parent and offspring.

External development

Oviparous fish, those that lay eggs, provide their offspring with nutrients within the egg yolk, through a process known as lecithotrophy. Here, the majority of energy for development is derived from the yolk protein vitellogenin. Other non-nutritional factors such as hormones and immunoglobulins may also be present in the yolk, with recent work demonstrating the importance of maternally provided immunoglobulins for protection against pathogens. There are also trends, as seen in at least four families of oviparous fish (Cichlidae, Percidae, Salmonidae, and Centrarchidae), suggesting that egg size and the provision of egg yolk are positively correlated with the quality and duration of subsequent parental care – care which often involves egg guarding or mouth brooding of fry after hatch (**see also Social and Reproductive Behaviors**: Parental Care in Fishes).

Internal development

Besides providing offspring with a source of nutrition, internal development can be highly beneficial to the survival of offspring as it allows offspring to be released to the external environment at a more advanced stage of development; the vulnerability of very small embryos and larvae to predators is, therefore, reduced and parents can ensure that their offspring have an increased chance of survival at birth.

Fish that give birth to live young can be divided into ovoviviparous fish, where fertilized eggs develop and hatch inside the female, and true viviparous fish where embryos develop inside the mother (or father) without an egg case, most commonly with some kind of placental relationship. Nutrients may be provided either through direct parental contribution or through yolk stores (i.e., lecithotrophy) or a combination of both.

Oophagy and adelphophagy

Most elasmobranchs (sharks and rays) that display parental care are ovoviviparous. In this case, eggs hatch within the mother and are later released live into the environment. Developing embryos depend on their own yolk stores for energy but may also display a cannibalistic behavior where they feed upon sibling developing ova (oophagy) and embryos (adelphophagy). Oophagy is far more common than adelphophagy which has only conclusively been demonstrated in the sandtiger shark, *Carcharias taurus*.

In elasmobranchs where developing offspring supplement their energy reserves through oophagy, it is common for the female to continue ovulating during the gestation period to supply developing embryos with eggs. In the porbeagle shark, *Lamna nasus*, small developing embryos possess fangs designed for tearing open egg capsules (**Figure 1**). The embryos often have distended stomachs from the yolk they have ingested and in some cases the stomach may protrude between muscle layers and stretch the abdominal skin. Later in development, the stomach shrinks but leaves a characteristic scar on the abdomen, indicative of oophagy. The fangs possessed by the young embryos are present on both the upper and lower jaw and are progressively shed and replaced. The female continues to ovulate during the period when the embryos possess these fangs but appears to stop during the latter parts of gestation.

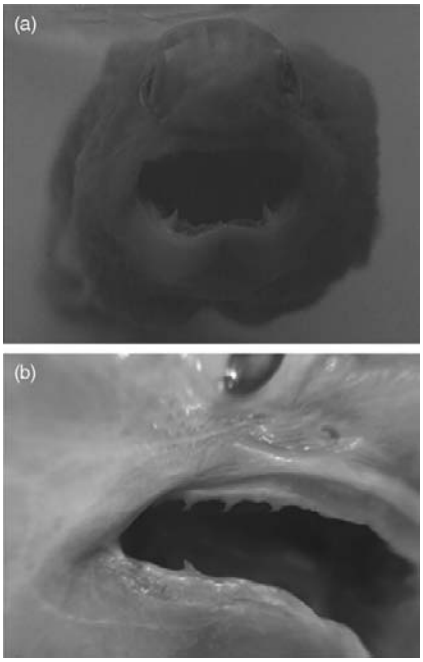

Figure 1 Anterior view of the heads of (a) 9.6-cm embryo and (b) 26.4-cm female *Lamna nasus* embryo showing the functional fangs. Photo (a) by G. Duhamel. Reproduction, embryonic development, and growth of the porbeagle shark, Lamna nasus, in the southwest pacific ocean, from Francis MP and Stevens JD (2000), Reproduced Fishery Bulletin 98: 41–63.

Oophagy has also been documented in the shortfin mako, *Isurus oxyrinchus*, the longfin mako, *I. paucus*, the great white shark, *Carcharodon carcharias*, and the thresher shark, *Alopias vulpinus*. The thresher shark has a gestation period of about 2 years with the young being released from the mother at about 60 cm in length and up to 10 kg in weight. Five or less individuals will survive until birth with many fertilized eggs being cannibalized during development. Searching behavior in the uterus when embryos are looking for eggs to eat is believed to occasionally result in injuries to other embryos within the uterus. This searching behavior may indicate the origins of adelphophagy.

Several ovoviviparous rays rely on histophagy as an additional source of nutrition for developing offspring. In this case, the uterus of the female develops vascularized appendages known as trophonemata which secrete a uterine milk-like substance rich in protein and lipid that can be ingested by the embryos. In some species of shark such as the smooth dogfish, *Mustelus canis*, nutrient provision to the developing embryo develops into a more direct placental relationship. Smooth dogfish embryos utilize yolk reserves for the first 3 months of gestation, at which point a placenta develops to provide energy until birth which occurs about 7–8 months later.

Placental relationships

Among the elasmobranchs, those species which show true placental relationships all belong to the family Carcharhinidae and tend to be tropical or subtropical. For example, in several species of hammerhead shark, *Sphyrna* spp., a placental cord develops between the mother and developing offspring with fine processes that aid in the absorption of maternal secretions.

There are also many teleosts where placental relationships develop between parent and embryo. For example, in the butterfly goodeid, *Ameca splendens*, embryos develop in the ovarian lumen of the female and develop a placental association with the mother. The placenta consists of an embryonic component known as the trophotaeniae and a maternal component derived from the internal ovarian epithelium. This joining of mother and embryo allows for nutritional provision to offspring during gestation.

Fish from the family Syngnathidae, the pipefish and seahorses, have a unique form of parental care that in some species involves a pseudoplacental relationship. Here, parental care is carried out by the male and during mating the female deposits her eggs on a brooding area or pouch where they are then fertilized by the male. The complexity of brooding structures in this family is very variable ranging from simple unprotected ventral areas to which the eggs are attached to well-defined pouches where the eggs are sealed from the external environment. In the pipefish *Solegnathus* and *Doryrhamphus* eggs are brooded in individual membranous compartments and in pipefish from the genus *Syngnathus*, a well-defined pouch partially or fully encloses the eggs. Seahorses, *Hippocampus* spp., display the most modified brood structures within this family consisting of sac-like fleshy pouches which are completely enclosed.

In seahorses, following intra-pouch fertilization, eggs implant into the brood pouch wall and form a pseudoplacental relationship with the father. The wall of the brood pouch undergoes morphological changes including a high level of vascularization (**Figure 2**), which is believed to aid gas exchange between the embryo and paternal blood supply. In sealing the brood pouch, the male is able to regulate the osmolality of the brood pouch environment to aid embryo osmoregulation. Gestation is variable in these species, lasting between 9 and 69 days depending on external temperatures. It has been noted that at birth the pseudoplacenta may be expelled along with juveniles.

There are several disadvantages of viviparity and placental relationships which include the reduced number of offspring that can be supported in this way and sometimes long gestation periods. Predation or disease in parents carrying offspring during gestation can potentially lead to the loss of both parents and offspring. However, placental relationships do allow a large amount of nutritional investment from the parent into their offspring, increasing the fitness and size of offspring at birth and, therefore, their survival chances. For example, the embryo dry mass of the butterfly goodeid increases remarkably by about 150-fold during the gestation period. This considerable energetic investment by the parent provides a remarkable fitness advantage to the offspring entering the competitive environment outside its parent.

Posthatch-Provided Nutrition

Oviparous parents may opt to supplement offspring nutrition after hatch. This can be extremely beneficial to the offspring during the first few weeks of development to ensure that nutritional requirements are met.

Mucus feeding

It is estimated that about 30 species of fish, predominantly from the family Cichlidae, provide nutrients to their offspring by allowing them to feed off their epidermal mucus secretions. The parent–offspring trophic transfer is associated with a parent-touching behavior. Examples of fish that display these parent-touching behaviors include the long-fin cichlid, *Cichlasoma longimanus*, the blue-eye cichlid, *C. spilurum*, the orange chromide, *Etroplus maculatus*, the midas cichlid, *C. citrinellum*, the red discus, *Symphysodon discus*, and the blue discus, *S. aequifasciatus*. It has also been suggested that some mouth-brooding cichlids may allow offspring to feed off mucosal secretions in their mouths. However, few studies have conclusively demonstrated a transfer of nutrients between parents and offspring. Parent-touching behavior of fry can be related to many other factors including a fear response and intraspecific communication, and it is also difficult to observe feeding in mouth-brooding cichlids. Here, we focus on the mucus feeding of the midas cichlid, discus fish, and some mouth-brooding *Tilapia* spp. where evidence exists for direct transfer of nutrients.

The midas cichlid is a substrate spawner where young begin free swimming about 1 week after the eggs are spawned. About 4 days posthatch, the young fry begin contacting their parents and micronip at their parents' bodies. This behavior continues until the young are about 5 weeks old. As the young grow, lesions on the parents may become apparent as mucus is continually removed. Survival of the offspring does not appear to be dependent on the provision of mucus and so this form of parental care may not necessarily occur under all circumstances. In the black-chinned tilapia, *Sarotherodon melanotheron*, the male picks up the eggs once they have been fertilized and after about 5 days of incubation in his mouth the eggs hatch and the hatched embryos remain in his mouth for just over a week. Brooding behavior lasts about 2 weeks in total and it has been hypothesized that due to the high levels of vitellogenin in the mucus of the male parent there is some provision of nutrients to the offspring during this brooding period.

The clearest example of mucus feeding by offspring is shown by the discus fish where mucus feeding appears to be obligate for offspring survival. Here, care is biparental with both parents providing epidermal mucus secretions. Eggs are laid and fertilized, attached to a hard surface, and both parents take turns in guarding and fanning the eggs (**Figure 3(a)**). Once hatched, the parents pick up the fry with their mouths and transfer them to a hard surface which the young adhere to with sticky cement glands on their head (**Figure 3(b)**). After approximately 4 days, fry become free swimming and promptly move to their parents' sides where they start to feed off mucus secretions (**Figure 3(c)**) (see **Video Clip 1**). Both parents are capable of feeding the fry and take turns by flicking all of the fry from one parent to another. In some pairs, parental care can be divided evenly between parents while in other pairs one parent may dominate offspring care. Fry will start consuming other food articles after about 1 week of feeding exclusively off their parents and by about 5 weeks posthatch are no longer consuming parental mucus.

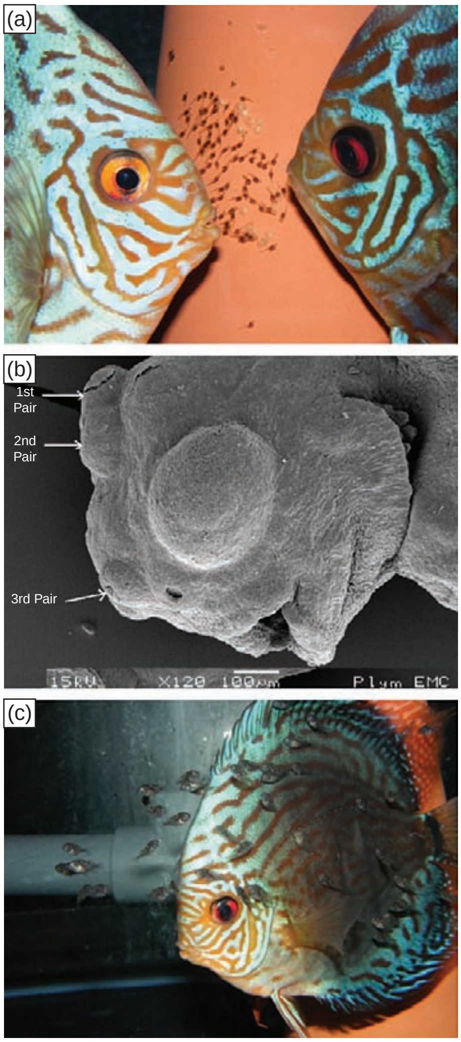

Figure 3 (a) Male and female discus parents guarding newly hatched fry. (b) Scanning electron microscope picture (120× magnification, scale bar represents 100 µm) of a discus fry showing the three pairs of cement glands used for attaching to substrates. (c) Discus fry, 1-week old, feeding from the mucus of a male discus fish. Photohraphs courtery of Dr. Richard Maunder and microscope image taken by Jonathan Buckley.

Fish mucus is known to contain many biologically active peptides and proteins and it is likely that mucus feeding may provide offspring with an array of nutritional and nonnutritional factors. Amino acids are a crucial part of the nutritional requirement of developing offspring. As many as 10 essential amino acids have been identified in the mucus of discus, including high levels of lysine and phenylalanine. It is, therefore, quite probable that the early needs of discus are met by the parental provision of basic peptides and amino acids in the mucus. Free amino acids are more easily digested by fry in comparision with complex proteins, which require energy-demanding catabolism for uptake. The early digestive system of discus larvae appears to be devoid of both an acidic environment and the digestive protease pepsin required to break down more complex proteins. Therefore, the behavior of fry feeding on parental mucus may give them access to a supply of free amino acids until their digestive system develops well enough to handle more complex proteins. By the time the fry have been feeding on parental secretions of mucus for 15–20 days, their digestive system has developed from an alkaline environment to an acidic environment containing several pepsin-like proteases. At this point, as the fry start to feed on alternative food sources, it appears that they are able to digest more complex nutritional items.

Beyond nutritional benefits

Several species of fish are known to provide some degree of passive immunity to their offspring via egg-yolk reserves and it is likely that the provision of mucus for young is an additional way of boosting offspring immunity. In the blue tilapia, *Oreochromis aureus*, it has been shown that mouth brooding, where offspring feed off mucus secretions in the mouth of the mother, increases the survival chances of the fry when the mother's immune system is enhanced through vaccination. Several studies have documented the presence of immunoglobulin (IgM) in cutaneous mucus of fish suggesting that a passive immunity could be passed on to the offspring via mucus. In mucus of the discus there is a c-type lectin uniquely expressed in parental mucus as opposed to nonbreeding adult mucus. The c-type lectins function as the preimmunity first line of defense by recognizing carbohydrate patterns found on the surface of a large number of pathogenic microorganisms. Potentially this c-type lectin could be transferred to offspring to provide them with a form of pathogenic protection.

As with immunity, there is also evidence in many fish species that transfer of maternal hormones to offspring occurs via egg reserves. It is also possible that mucus feeding may supply offspring with hormones. In the midas cichlid, prolactin, growth hormone, and thyroid hormones have been identified in parental mucus. Thyroid hormones are likely to enhance growth and survival in offspring and prolactin plays an important role in osmoregulation.

Provision of nutrients to developing offspring after hatch in these oviparous species can increase the survival chances of offspring. Some protection from predation may also be associated with these forms of nutrient provision. In particular, mouth-brooding parents can easily transport their fry away from predation threats and move the whole family to safer areas.

Parent–Offspring Conflict

There is no doubt that the provision of nutrients during parental care has an energetic cost. Extended periods of larval care in discus fish, for example, often negatively affect their subsequent reproductive performances. This energy drain can lead to conflicts between parents and offspring. For example, excessive parental investment in one brood of offspring may influence their ability to invest in future broods. An individual wishing to maximize their inclusive fitness would want to invest in current offspring up until the point where any further investment would only offer diminishing returns. Any investment past this point may squander energy that would have a greater return if invested into future offspring. Too much parental investment into current offspring will reduce the total number of an offspring that an individual could ultimately produce; this equates to a reduction in an individual's inclusive fitness. It is expected that parents should regulate the amount of care they provide to their current offspring to maximize their own fitness. Offspring, however, are also concerned with maximizing their own fitness and should seek to solicit more care than a parent wants to give.

Without a form of communication, it would be quite easy for a parent to either under- or over-provide parental care. It is possible in mucus-feeding fish that mechanical stimulation of the parental epidermis is itself a mechanism by which offspring communicate their need. Under aquarium conditions, it has been observed that adult discus fish show evidence of epidermal damage after a full term of parental care. This is due to an increase in both the size and feeding rate of discus offspring over the period of parental care, factors which serve to exacerbate the potential for mucosal feeding to cause noticeable epidermal damage. Supplementation of fry with live feed, however, reduces the impact of fry mucosal feeding. In viviparous vertebrates, there is evidence that fetal offspring can secrete compounds, most often hormones, to manipulate parental nutrient provision through placental connections. Thus, the apparently cooperative relationship between developing offspring and parent reveals itself to be more of a conflict between two different parties for survival.

Future Directions

The role of parental care in fish has been well researched (**see also Social and Reproductive Behaviors**: Parental Care in Fishes) and within mammalian systems the concepts of nutrient provision to offspring and parent–offspring conflict is well characterized. However, information on nutrient provision to offspring both before and after hatch/birth and its associated behaviors has received less attention in fish. There are inherent problems associated with studying these behaviors, for example, in observing the feeding behaviors of fry inside the mouths of their parents or developing offspring within parental reproductive organs. Many species showing oophagy or adelphophagy are large pelagic elasmobranchs where little is known about their reproductive biology in general. Research into the parent–offspring nutritional relationship in species that are more easily reared and observed in the laboratory environment, such as discus and seahorses, is now increasing with the potential to shed light on as-yet un-researched areas of parent–offspring conflict and the evolution of parental care in fish.

Glossary

Agonistic Aggressive behavioral conflicts or threat displays that include fights between individuals, territory defense, attacks, and chases.

Bioacoustic parameter The amplitude (loudness), temporal (time or duration), or frequency (spectrographic) characteristics that describe a sound signal.

Call Sound signal associated with a particular posture, display, or context, for example, courtship call produced when a male displays to a potential female mate.

Communication Patterns of energy produced by a sender, perceived and decoded by the sensory apparatus of a receiver, and used to exchange information cooperatively or manipulate.

Communication modality Signals of a particular type often classified by their sensory perception category such as electric, chemical, tactile, visual, or vocal.

Display Stereotypical behavior patterns that may consist of one or several different postures and signals for communicating in both intra- and interspecific contexts.

Disturbance Behavioral context where physical restraint by a predator may cause sound production by prey or release of sounds similar to signals elicited by human handling.

Interception Communication signal perceived by an individual receiver for whom it was not intended and whose behavior changes in response to it.

Signal Energy pattern (sound, chemical, etc.) evaluated by a receiver that can convey false or honest information about physiological condition, social status, or motivational state of a sender.

Vocal Production of a sound signal for communication that may be alternatively designated as acoustic, sonic, or soniferous.

Introduction to Vocal Fishes: Quiet versus Loud Vocalizers

We are still in an age of discovering how many vocal fish taxa there are. Estimates of sound producing fish diversity identify over 1300 species. This number is likely to be much higher because many fishes have never been monitored with close proximity audio-visual recording techniques. While fish sounds are among the least complex in pattern and diversity among vertebrates, their importance in intraspecific communication is the same as for other vocal animals, functioning in social spacing, resource defense, mate attraction, species recognition, individual recognition, female mate choice, obstacle avoidance, and predator deterrence (**Table 1**; **see also Hearing and Lateral Line**: Acoustic Behavior).

Many fishes have impressive vocal communication abilities that are readily obvious to human observers and have been the focus of active research programs. For example, the Atlantic toadfish (*Opsanus tau*; **Figure 1**) generates sound using the fastest known contracting vertebrate muscle, which is attached to its swimbladder. The domino damselfish (*Dascyllus albisella*) male produces sounds that propagate up to 12 m in coral reef habitats. The plainfin midshipman (*Porichthys notatus*) can perform 1-h-long displays of sounds that can penetrate boat hulls and regularly alarm new boaters in California! The Atlantic cod (*Gadus morhua*) can produce startle clicks with peak call pressures as high as 153B at a 1-m distance.

Table 1 Behavioral contexts for fish sound signal production and the number of families they are currently known from

Behavioral context	*# Families*	*Sound signal function*
Schooling or chorusing	35	Mate assessment? Predator confusion?
Reproductive	35	Individual and species recognition Female mate assessment and preference Mate attraction and localization Male advertisement Male–female alert? Reproductive priming
Agonistic	57	Feeding competition? Fighting opponent assessment Nest defense Social dominance Territory defense
Disturbance or distress	107	Conspecific alarm? Distress noise? Other predator attraction to disrupt attack? Predator escape stotting, startle or warning? Release of social sounds
Feeding	22	Conspecific recruitment or competition?
Swimming	20	Obstacle avoidance? Predator alert?

Question marks denote hypothesized rather than confirmed functions.

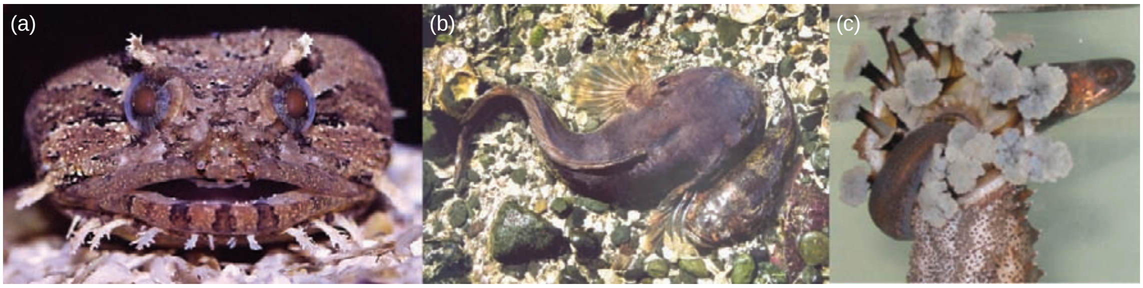

Figure 1 Examples of loud vocalizers (a) the Atlantic toadfish *Opsanus tau* and (b) the plainfin midshipman *Porichthys notatus* and a quiet vocalizer (c) the graceful pearlfish *Encheliophus gracilis*. Panel (b) shows a large type I singing male next to a smaller female fish. Courtesy of (a, b) M.A. Marchaterre, Cornell University, USA and (c) Eric Parmentier, University of Liege, Belgium.

Some fishes also produce a large repertoire of sounds, for example, the white weakfish (*Atractoscion nobilis*) has a repertoire of six statistically distinct sound types. Other fishes are considered less vocally active, and are only known to produce sounds when disturbed. However, it is possible that sounds may occur in these species in yet unmonitored behavioral contexts.

Recently discovered vocal species, once thought to be nonvocal, are simply less obvious sound communicators as they do not produce loud, year-round calls easily detected by a human observer. Such species would be better described as quiet vocalizing fishes (**Figure 2**). Quiet vocalizers include the fantail darter *Etheostoma flabellare*, the sheepshead minnow *Cyprinodon variegatus*, the pearlfish *Carapus acus*, the whitetail shiner *Cyprinella galactura*, and the cichlid *Tramitichromis intermedius*.

Quiet vocalizer calls require a hydrophone with amplifier at close proximity to a fish to be detected, usually within a few body lengths. Their sounds are characterized by sound amplitudes as low as 20 dB near the caller, short propagation distance (<1 m), occurring in lower abundance outside the breeding season or in discrete social contexts or narrow calling windows. Quiet fishes might still produce large repertoires and complex sounds and use them in the same behavioral contexts as loud vocalizing species. Many poorly studied vocal fishes are active at times or in places difficult for humans to study such as at night or in the deep sea, caves, seagrass beds, turbid waters, burrows, or buried in sand. Some fish even vocalize inside other animals. Five species of pearlfishes living inside sea cucumbers (**Figure 1**) have been discovered to produce quiet sounds either patrolling the territory around their host or once inside.

Discovery and Evolution of Vocal Fish Behavior

Vocal fishes have been known since the time of Aristotle. Even fishes producing quiet sounds were proposed as biologically significant communicators by researchers of the late 1800s, especially Leon Dufosse and William

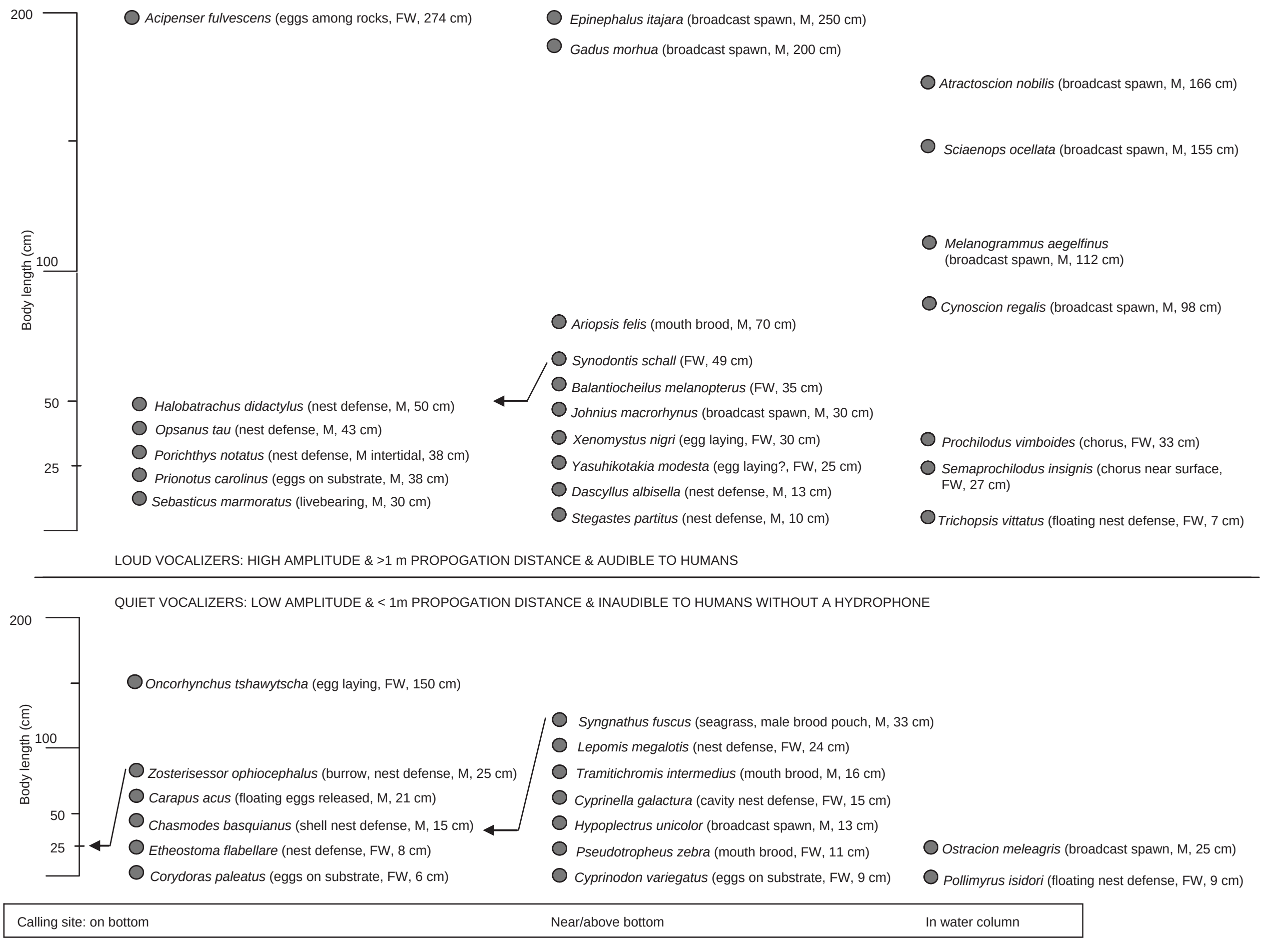

Figure 2 A sampling of vocal fish species (27 families) ranging from freshwater (FW) to marine (M) habitats, small to large body size, and varying in reproductive strategies (notes in parentheses when known). The upper panel is for loud and the bottom for quiet vocalizing fishes. Body length is for standard or total length as reported in Fishbase (http://fishbase.org/search.php).

Sorenson; both produced significant monographs on the subject. Few new fish families have been monitored with hydrophones since the extensive works of Marie Poland Fish especially in her book *Sounds of Western North Atlantic Fishes* with William Mowbray, a classic survey of marine fish sound behavior. The best-studied taxa include toadfishes, cichlids, croakers, damselfishes, cods, gobies, gouramis, elephantfishes, minnows, and catfishes. The earliest fishes evolved hearing to listen to the acoustic scene. Studies of the development of the neurological control of sound production in fishes that allows them to produce temporally patterned sounds, suggests an equally early evolutionary origin for sound communication. Modern teleost fishes have independently evolved different vocalizing mechanisms (**see also Hearing and Lateral Line**: Vocal Behavior of Fishes: Anatomy and Physiology). Absence of sound production in fishes can occur as a result of vocal mechanism loss suggesting the actions of some yet unknown evolutionary selection pressures. Several deep-sea groups have been examined for the presence of the most common vocal mechanisms. Pelagic species were found to lack the well-developed muscle and bony structures typically associated with sound production. If these groups do use sound in signaling, the mechanism involved would be novel compared to those currently known. This is not impossible; most gobies produce sound signals with a still as-yet unidentified vocal mechanism. Sharks and rays are considered nonvocal fishes. Like certain deep-sea fishes they lack key structures typically involved in sound production: bone, air-filled chambers, and flexible body parts for postural displays. However, there is some evidence for agonistic breaching behaviors that might produce hydrodynamic sounds and disturbance sounds in a few species.

Although no particular ecosystem (freshwater and marine), ecotype (benthic to pelagic), activity period (nocturnal or diurnal), life history strategy (egg laying on substrate vs. broadcast spawning into the water column), or social organization (solitary vs. closely aggregating or schooling) is exclusively associated with vocal behavior in fishes (**Figure 2**), some basic trends are emerging. Species whose social interactions are well developed have been identified as sound signalers; the greater the development of the social system, the more complex and abundant the sounds. Many vocal species are found in benthic communities where individuals defend territories and in pelagic chorusing aggregations where individuals form social dominance hierarchies. Another common theme among vocal fishes is male display while building and defending a nest with extended parental care.

Fish Call Characteristics: Simple versus Complex

The bioacoustic parameters of fish sounds are important for understanding their functions (**see also Hearing and Lateral Line**: Physiology of the Ear and Brain: How Fish Hear and Vocal Behavior of Fishes: Anatomy and Physiology). The basic sound unit or fish call (**Figure 3**) ranges in duration from 5 to 40 000 ms. An amazing exception is the plainfin midshipman whose hum call can last over 1 h. Among the simplest calls are single pulsed escape sounds with irregular temporal patterns that are produced when a fish moves away from a threatening source. Their duration ranges from <20 to 500 ms. Territorial or fighting sounds are highly variable but often of moderate duration, typically lasting from ~10 to 3000 ms. The most complex, longest (**Figure 4**), and most temporally stereotyped calls are produced during pre-reproductive activity. Prolonged courtship displays or songs may incorporate many basic sound units of different calls and can last for 55 s for the spawning chant of temperate white weakfish (>2000 purrs and 77 knocks), 143 min in a tropical marine big-snout croaker *Johnius macrorhynus* and up to several hours for the repeated male courtship boatwhistles of toadfish.

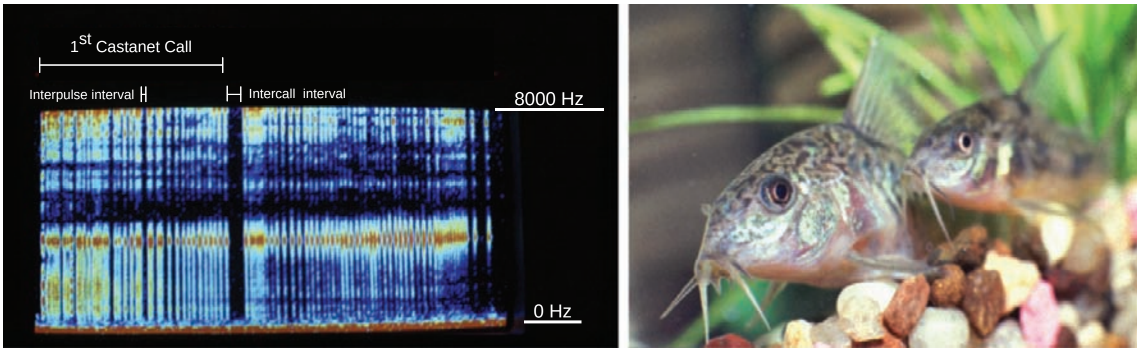

Figure 3 Spectrogram (frequency vs. time plot) of two male courtship associated sounds (basic sounds unit or call) of the diurnal quiet vocalizing miniature catfish *Corydoras paleatus*. The smaller male, at left, produces a courtship display to a silent female immediately prior to egg fertilization. These castanet calls (first call ~ 600 ms in duration) consist of a series of pulses with interpulses and cover a broad frequency range (~800–8000 Hz). Agonistic calls are simpler with fewer pulses and less regular interpulse interval durations.

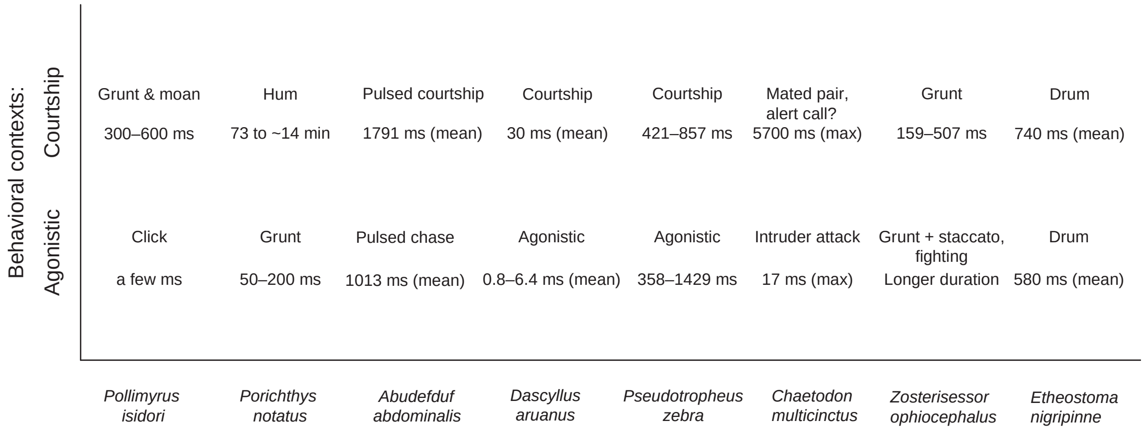

Behavioral contexts:	*Pollimyrus isidori*	*Porichthys notatus*	*Abudefduf abdominalis*	*Dascyllus aruanus*	*Pseudotropheus zebra*	*Chaetodon multicinctus*	*Zosterisessor ophiocephalus*	*Etheostoma nigripinne*
Courtship	Grunt & moan 300–600 ms	Hum 73 to ~14 min	Pulsed courtship 1791 ms (mean)	Courtship 30 ms (mean)	Courtship 421–857 ms	Mated pair, alert call? 5700 ms (max)	Grunt 159–507 ms	Drum 740 ms (mean)
Agonistic	Click a few ms	Grunt 50–200 ms	Pulsed chase 1013 ms (mean)	Agonistic 0.8–6.4 ms (mean)	Agonistic 358–1429 ms	Intruder attack 17 ms (max)	Grunt + staccato, fighting Longer duration	Drum 580 ms (mean)

Figure 4 The duration of calls (range, unless otherwise indicated) representing reproductive vs. aggressive behavioral contexts as reported in the literature. Calls are identified by either their phonetic name or context description. The longest duration calls are from reproductive contexts, and when compared within species, most but not all have longer courtship calls.

While fish call patterns are diverse, there are two distinct types that have functionally different roles. Multipulsed calls have interpulse intervals or off-times within the basic sound unit (silence between regularly timed pulses, **Figure 3**) and are broad in their frequency range. In contrast, tonal sounds consist of pure tones (narrow frequency range) without any interpulse intervals. Pulse number and repetition rate may vary among species, suggesting the signaling potential for either species or individual recognition and discrimination. Indeed, playback studies have demonstrated that damselfish neighbor versus nonresident recognition and female preference for their own species calls is based on pulse number and interpulse interval. Likewise sympatric species differ predominantly in temporal characteristics, although for some congeners these differences are in amplitude, frequency, or waveform. The most complex fish sounds are male courtship sounds that combine multipulsed sounds with highly regular interpulse intervals and tonal components. Some goby males produce tonal sounds only as an advertisement call while a female is outside the nest and only multipulsed sounds during courtship of the female inside the nest. The croaking gourami (*Trichopsis vittata*) produces the same simple pulsed sounds in all contexts.

Amplitude range of species (and, therefore, the distance over which sound can be used to communicate) falls into two broad categories: those whose sounds propagate well over 1 m and those that utilize sound over much shorter distances (**Figure 2**). In sand gobies *Pomatoschistus minutus*, intraspecific male body size relates directly to courtship call loudness and shows higher stereotypy than other acoustic parameters. In gouramis, agonistic calls are twice as loud as pre-spawning calls indicating a more private channel for mate communication.

Frequency ranges of fish sounds vary widely from 10 to 8000 Hz. The most significant behavioral aspect of frequency is the highest amplitude component in a call referred to as the dominant frequency. This correlates with male size in numerous families and is hypothesized as an element in female mate choice and as a male fitness indicator. Female damselfishes prefer larger males that produce lower dominant frequency calls. Pure tone frequency (vs. broader band) sounds are almost exclusively associated with male reproductive display. Individual recognition of male toadfish is hypothesized based on frequency differences of mating calls.

With all of these different types of sounds, fish are very selective about when, where, and how long they call suggesting energetic or interception constraints. For example, calling activity level outside the breeding season in populations of diurnal freshwater miniature catfishes in the genus *Corydoras* equals one call per hour, while >100 sounds are produced during their several hour mating activities. The vocally active noctural toadfish call all year to maintain their benthic territories and more abundantly during the breeding season.

Chorusing Behavior: Schooling, Spawning, and Feeding

In relation to sound production, schooling fishes fall into two different groups. One is considered silent or only produces hydrodynamic noises from swimming movements, where the function of the noise, if any, is undetermined. The other is where many individuals produce patterned sounds unrelated to locomotor movements in a chorus, calling at a specific time and place (e.g., groupers and croakers). In the former, hydrodynamic noises and the prevalence of the tactile sense among tightly schooling and rapidly moving individuals may place some constraint on the use of sound signaling. In the latter, there may be many advantages to sound communication. For example, large schools of marine catfishes forage on the bottom in poor visibility coastal waters and produce nocturnal choruses of short pulse burst percolator sounds that may function in short-range orientation or act as contact calls. Schooling herring produce pulsed sounds in a predictable diel pattern perhaps promoting group cohesion. Several groups of fishes form schools associated with spawning. Chorusing activity for such aggregations typically begins close to sunset and peaks nocturnally. Fewer species have diurnal or crepuscular calling peaks. Many fishes produce noises as a by-product of feeding. The teeth grinding or plankton feeding popping sounds of freshwater and marine fishes are distinctive. In minnows and puffer fishes, these sounds are intercepted by conspecifics that are attracted to potentially more abundant feeding grounds.

Reproductive Sound Signaling: Male Display and Female Mate Choice

Sound production increases during the breeding season for many vocal fishes and the characteristics of these calls potentially convey information about an individual's age, sex, size, identity, and health or fitness. In cichlids, the physiological priming and conditioning of female gonads by male calls has been demonstrated. Female toadfish and plainfin midshipman are attracted to speakers broadcasting male calls. Male advertisement calls can be used for localizing conspecifics by gobies. Sound production during the breeding season is predominantly by males on territories, between males during conflicts over resources, by males displaying to females and less frequently between females and other individuals. Male calling is clearly multifunctional serving to attract mates and repel competitors. Sound displays that propagate greater than a few body lengths in distance are least likely when a mated pair is courting. This suggests a cost to loud sounds (interception by predators or conspecifics) and a priority for a close and intimate channel of communication between sender and receiver. In the plainfin midshipman and blennies, males exist in two different phenotypes. Smaller, sneaky males intercept sounds of larger displaying males to locate females and steal egg fertilization. Sneaky males vocally mimic the simple sounds of females while larger males defend nests and produce complex sounds (**see also Reproduction**: The Diversity of Fish Reproduction: An Introduction).

Female preference for a particular male call is likely a strong component of the selection forces that shape a male's vocal display. Playback demonstrates that female cichlids choose mates on the basis of male calls. Male fitness could be conveyed by signals with lower frequency and higher amplitude occurring as a consequence of increased size of vocal mechanisms (e.g., muscles). These are inherently honest signaling features that could indicate health, vigor, or energy reserves of individual males. Choice experiments have been conducted for midshipman where females showed preference for louder and longer duration male sounds and tonal over pulsed sounds. Females of many vocal species are presumed mostly silent during reproduction, but a recent discovery of very low amplitude pre-spawning calls in gouramis suggests that cooperative communication for spawning synchronization between the sexes may be intentionally less conspicuous. An alternation of male–female calling has been observed in a few species. Mating partners of the hermaphroditic butter hamlet (*Hypoplectrus unicolor*) alternately produce a spawning sound just before gamete release. The production of such sounds specific to spawning may ensure breeding synchrony during external fertilization.

Agonistic Sound Signaling within Species

Social dominance hierarchies among conspecifics are important for defending space, mates, offspring, and food (**See also Social and Reproductive Behaviors**: Dominance Behaviors). In defending resources, communicating the age, size, or strength of an individual is highly advantageous. Unlike during reproduction, when specially patterned or multipulsed sounds are essential for identifying species and distinguishing individuals, agonistic contexts may require less specificity. Increased call loudness may correlate with escalated agonistic interactions. Contest winning cichlid males produce calls with longer durations and lower peak frequencies. Winners also exhibit increased calling to females subsequent to contests. Calls during fights may serve an appeasement function by ameliorating aggression. Both females and males produce similar agonistic sounds in many species unlike in courtship contexts. Toadfish populations exhibit alternation of calling among neighboring males where social dominance is the proposed function. Keep-out signals are produced by damselfishes to repel intruders from resting crevice territories. Gobies and catfishes compete for and defend refuges while producing abundant sounds when intruders enter, often repelling them. Feeding competition is a context widely documented for sound production among fishes and may function to repel conspecific competitors from a contested food source.

Avoiding and Repelling Predators

Predators could place very strong selection pressures on whether or not fishes are vocal as well as how, where, and when sounds are produced. Predator and prey can vocally interact with each other in several ways: (1) predator interception of prey calls; (2) prey interception of predator calls; (3) prey production of distress, alarm, escape, startle, or threat sounds when seeing or attempting to flee from a predator before attack; and (4) disturbance, prey responding to a predator once physically restrained.

Predator interception of prey fish signals has been demonstrated. Dolphins can locate and are attracted to the vocal signals of sciaenids, making them unsuspecting prey fish. Simple noise production, the swimming sounds of the Bermuda anchovy, *Anchoa choerostoma*, may attract its predator, *Caranx latus*, the yellow jack. Eavesdropping by prey of predator calls has been demonstrated in toadfish. Calling is reduced when dolphins are present, a response that appears to be a direct result of ultrasonic dolphin calls. In fact, toadfish show increased levels of stress hormones in response to dolphin sounds, suggesting that they recognize the predation threat. The specialization of ultrasonic hearing in marine schooling fishes such as herring indicates that these fishes can detect echolocating predators. Sharks are attracted to pulsed but not tonal sounds, indicating a risk element to most fish calls.

Escape sounds are commonly produced by marine fishes and occur at the start of a prey individual's escape trajectory. They occur before any contact with the predator and are produced by the movement of body musculature. Escape sounds could be merely noise. Alternatively, they could function as 'stotting sounds', a vocal equivalent of visual jumping displays in African savannah gazelles. Escape sounds could indicate to a potential predator that it has been spotted and that the prey individual is in good physical condition to get away. A predator startling function is attributed to the loud clicks of the Atlantic cod produced only in the presence of seal-like body silhouettes. Mobbing squirrelfishes have been observed to approach and attack potential predators in small groups while vocalizing. Their calls in this context are proposed as alarm or threat signals and consist of rapid pulsed sounds. Several fish families produce disturbance sounds after a predator has physically attacked them in conjunction with weaponized defense mechanisms that include chemical secretions, pinching, stabbing, and envenomating devices (**see also Behavioral Responses to the Environment**: A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food).

Sound Signals Relative to Other Communication Modalities

Sound may play an exclusive or supportive role in communication. Some gourami species lack social sounds and communicate visually while others are predominantly vocal. Calls are often directly associated with specific body postures. Cichlids vocalize quietly during body quivering, the common and often presumed nonvocal behavioral display of many fishes. In the frillfin goby *Bathygobius soporator*, females require visual stimuli in order to respond to a calling male; they will not respond to sound playback alone. Among catfishes the presence of chemical alarm signals is inversely related to the development of vocalization. Cichlid male vocal displays differ most among species where males are visually more similar indicating a communication modality trade-off. Some elephantfishes that produce a diversity of electric signals (**see also Sensory Systems, Perception, and Learning**: Shocking Comments: Electrocommunication in Teleost Fish) also produce sounds that males use to court females; however, sex discrimination depends solely on electric signals. The use of sound for male display is hypothesized as a better indicator of fitness because mechanical work is required to produce the signal. There is a significant overlap between the auditory and lateral line system in fishes (**see also Hearing and Lateral Line**: Auditory/Lateral Line CNS: Anatomy). Salmon produce sounds with inaudible and audible components during reproduction. Postural changes evaluated in butterfly fishes produce water currents that could be sensed via the lateral line while stronger movements could produce sounds detected by the inner ear. In cottids, substrate-transmitted drumming produces signals with lateral line and inner ear stimulating components. Such signal complimentarity is an exciting area for future research.

Conclusions: What Fish Sounds Can and Cannot Do

Like all other vocal animals, fishes use sounds to enhance their behavioral displays and convey information about sex, age, social status, species identity, reproductive condition, and spawning readiness. Tantalizing evidence exists for duets, call individuality and its discrimination, conspecific alarm and contact calls, and acoustic defense. Communication functions that fish sounds are not known to serve include parent–offspring signaling, sibling recognition, and mimicry. Many fish taxa remain unexplored in terms of bioacoustics. Because we now know that short propagation distance and low amplitude sounds occur more commonly than was once thought, we cannot be certain of the nonvocal status of any unmonitored fish. A developing pattern in fish bioacoustics is that simple and low-amplitude sounds can be sufficient for sound signaling. In addition, high-amplitude, interception-prone, complex calls function in species that can either avoid predation by calling from protected sites or avoid the risk of predation by other means to communicate over longer distances. New studies continue to reveal evidence of the importance of sound production in fish behavior. Current exciting studies include the influence of adult calls on juveniles indicating that sound production is innate, not learned, and the possible attraction of larval fish to nocturnal choruses on coral reefs that include fish sounds.

Glossary

Astaxanthin A naturally occurring red carotenoid pigment.

Collimating Aligning in parallel.

Cue A stimulus that may provide information to a receiver, but has not evolved in the context of communication.

Eavesdropper An individual, such as a predator or rival, other than the intended receiver, such as a potential mate, that modifies its behavior in response to a signal.

Monochromatic Having only one color.

Opsin A protein found in photoreceptor cells, covalently bound to a chromophore that changes conformation when it absorbs a photon of light.

Receiver In animal communication, an individual that modifies its behavior based on its perception, processing, or evaluation of a signal or a cue.

Signal In animal communication, a stimulus that has evolved in response to selection for a communicative function.

Signaler An individual producing a signal.

Tunaxanthin A naturally occurring red carotenoid pigment.

Introduction

Visual communication accounts for much of the popular fascination with fish. The profusion of pattern, color, and form in coral reef fish skin patterns is one of the most striking phenomena in the natural world; and many a kitchen table is graced with a male Siamese fighting fish, directing aggressive displays at passers-by. For researchers, visual signals in fishes present a powerful model for asking basic questions about the evolution of communication and about environmental effects on signaling. This is due to both the sheer diversity of communication systems, coupled with the fact that fish occupy the full gamut of possible visual environments: from lightless ocean depths and caves, to tea-stained lakes and streams, to sunny shallow reefs (**see also Vision**: Color Vision and Color Communication in Reef Fish and **Deep-Sea Fishes**).

At its most basic, communication is a two-way interaction between a signaler, who produces a sensory stimulus or signal, and a receiver, who perceives the signal and makes a behavioral decision. Signalers and receivers often exchange roles, and eavesdroppers, such as predators locating prey, often exploit communication interactions.

A basic challenge in animal communication is distinguishing between a signal – a stimulus that has evolved in an explicitly communicative context – and a cue – a stimulus whose communicative function is incidental. Signals are easy to identify if they involve postural changes, motor patterns, or skin-pattern changes performed only in the presence of an appropriate receiver, such as a ritualized courtship or aggressive display. Many of the most important visual signals in fish, however, are morphological structures such as fin extensions or constitutively expressed skin patterns that are always on. The situation is further complicated by the fact that some communication signals may have evolved in order to enhance transmission of a cue to a receiver. For example, close-range courtship motor displays may waft nonsignaling olfactory cues (e.g., metabolized steroid hormones) to the receiver (**see also Hormones in Communication**: Hormonal Pheromones).

Once a signal has been produced, it must be transmitted to the receiver, who then must detect it against background, evaluate it, and respond. An effective signal must therefore be both detectable in the environment in which it is produced and distinct from signals that would elicit a different response from the receiver.

From the receiver's point of view, a visual signal can be decomposed into spectral, spatial, and temporal components. The image that is projected onto each of a fish's two retinas consists of light varying in intensity and wavelength over space and time. Detection of visual signals is largely determined by the degree of spectral and spatiotemporal contrast between the signaler and the visual background, or among different elements of the signal.

Generating a visual signal involves multiple approaches. In rare cases, fish will directly generate light through bioluminescence (**see also The Skin**: Bioluminescence in Fishes). The vast majority of visual signals, however, involve modifying the spectral, spatial, and temporal distribution of light generated by the sun after it has been filtered through the atmosphere and the water column. This typically involves specializations in pigment cell distributions, posture, and motor patterns (**see also The Skin**: Coloration and Chromatophores in Fishes).

With the exception of a growing body of quantitative studies on the color component of communication, most work on visual communication in fishes (and in general) does not take a quantitative approach to characterizing the color, spatial, or temporal properties of stimuli, backgrounds, or ambient light conditions, whether characterizing signals themselves or evaluating receiver response. Nevertheless, the fact that visual stimuli can be readily characterized, as well as experimentally manipulated through dummies, models, videos, and computer animations, has given us substantial insight into this mode of communication in fishes.

Although relatively few studies have explicitly isolated visual components of communication signals, fishes use visual communication extensively in the context of mate choice and aggressive displays, as well as recognition of conspecifics, shoalmates, and individuals. While visual signaling has mostly been studied between conspecifics, it can play an important role in interspecific interactions. For example, the characid *Hemigrammus erythrozonus* has a visual antipredator display. Deep-sea anglerfishes use bioluminescent lures to snare prey and the monacanthid *Paraluteres prionurus* uses shape and color patterns to mimic a toxic pufferfish. Many fishes, notably the color-changing flatfishes (Pleuronectidae) use skin patterning and morphological structures for camouflage. Cooperative interactions between cleaner wrasses and their hosts involve the production of stereotypic postural and color signals by both parties.

Bioluminescent Signaling

Many marine fishes produce their own light energy, either endogenously or more commonly, by concentrating bacterial symbionts inside specialized light organs. Bioluminescence (**see also The Skin**: Bioluminescence in Fishes) is particularly useful at night and in the deep sea, where exogenous light is scarce. Bioluminescence has evolved independently many times in teleosts, exclusively in marine taxa. Bioluminescence serves a variety of functions, including prey capture and camouflage, and can play a role in shoaling and courtship.

Bioluminescence involves an enzymatic reaction whereby an oxygenase, luciferase, oxidizes a luciferin, producing oxyluciferin and emitting light. This is typically produced by symbiotic bacteria in specialized light organs, although in a few cases – midshipmen (Batrachoidae: *Porichthys* spp.), lanternfishes, and some apogonids – the luciferin–luciferase system is produced endogenously, with bioluminescence under neural control. Fishes have evolved a variety of structures to control the spectral, spatial, and temporal properties of emitted light. Both bacterial light organs and photophores can contain reflectors, filters, lenses, and light guides. Species with bacterial light organs use shutters controlled by specialized musculature to create flashes of light. Lampeyes (Anomalopidae) can use both musculature derived from the levator maxilla to draw a black pigmented curtain over the surface of the organ, or rotate the entire organ into a suborbital pocket. The fishes can cycle these movements up to 100 times per minute, creating a blinking effect that is used both for prey detection and intraspecific signaling. In the trachichthyid genus *Paratrachichthys*, bacterial organs are located around the anus, opening onto the rectum. The light is distributed anteriorly and posteriorly by translucent, collimating muscles piping light to various areas of the body in a manner analogous to fiber optics.

Three deep-sea genera of dragonfishes or loosejaws (Malacosteidae: *Malacosteus*, *Pachystomias*, and *Aristostomias*) couple a luciferin–luciferase system, emitting typical blue-green light, to red fluorescent protein and a series of filters to produce far-red light (maximum emission >700 nm) from suborbital photophores; in *Malacosteus*, the light is further modified using a superficial brown filter. Dragonfish detect these wavelengths not using a long-wavelength sensitive opsin, but with a novel, long-wavelength photosensitizer, derived from dietary chlorophyll. Accordingly, this light is invisible to most other deep-sea fishes, providing dragonfishes with a private channel with which to locate prey and signal to conspecifics. In all three of these genera, there is also an additional postorbital photophore that emits blue light, suggesting that these fish may be capable of sophisticated multicomponent signaling.

The difficulty of observing behavior in deep-sea fishes means that most inferences about bioluminescent signaling must be made from morphology. A rare exception is the leiognathids or ponyfishes, which occur in circumtropical shallow coastal waters of the Indo-Pacific. In some leiognathids, multiple shutters on the wall of the light organ mechanically control the duration and intensity of light emission. *Leiognathus elongatus* appears to be sexually dimorphic, with females lacking a light organ.

While bioluminescence allows the signaler to control the temporal characteristics of the signal, it has several limitations. Most bioluminescent signals are spatially simple and monochromatic; more important, they are fairly ineffective in brightly lit environments where vision plays a dominant role. Most visual signals, therefore, involve forms, patterns, colors, and movement that reflect available light.

Signaling with Reflected Light

Reflected-light signals are characterized by spectral reflectance as a function of space and time. Reflectance is defined as the light reflected back from a target illuminated by a uniform white light source, as a function of wavelength. Reflectance can change as a function of the angle of illumination, spatial position, and time. Many fishes express complex color patterns; over the course of a courtship or aggressive display, they vary the color and intensity of these patterns and engage in changes in position, orientation, and posture. The amount of information that can be conveyed in a display is thus considerable.

The color sensitivity of fishes ranges from around 340 nm (the near ultraviolet) to 750 nm (the near infrared), with considerable variation in visual sensitivity among species. Fishes produce colors across this spectrum. Spectral variation in signals is produced either by pigments, which absorb portions of the light visible to receivers, or by morphological structures that selectively scatter light as a function of wavelength. Pigments are typically used to generate long-wavelength colors (yellows, oranges, and reds), while morphological structures are used for shorter-wavelength colors (blues, indigos, violets, and ultraviolets) (**see also Vision**: Photoreceptors and Visual Pigments).

Pigment-Based Colors

The chemical nature of a pigment determines the wavelengths of light it can absorb (**see also The Skin**: Coloration and Chromatophores in Fishes). Many pigments in fishes are organic compounds containing long chains of conjugated double bonds, such as carotenoids and pterins. In general, small molecules absorb only high-energy (short) wavelengths, while larger molecules additionally absorb longer wavelengths of light. Carotenoids and pterins typically absorb shorter wavelengths, thereby reflecting yellows, oranges, and reds. Carotenoids bound to proteins can absorb middle wavelengths while reflecting both red and blue to produce purple. Many carotenoid-based color patches also exhibit a secondary peak in the ultraviolet, within the range of sensitivity of many fishes. Melanins are large proteins that absorb most visible and ultraviolet light to produce black. Pigments are housed in chromatophores, within small packets called chromatosomes.

Fishes cannot synthesize carotenoids; they must be obtained from dietary sources. In freshwater systems, notably threespine sticklebacks (*Gasterosteus aculeatus*) and guppies (*Poecilia reticulata*), males vary in carotenoid expression. Female sticklebacks and female guppies prefer more intense, purer carotenoid colors. The intensity of red color is determined by the concentration of astaxanthin carotenoids in the skin, while the chroma (color purity) of red is determined by the ratio of astaxanthins to tunaxanthin. Variation in astaxanthin deposition also appears to underlie the variation in the intensity and quality of orange coloration in guppies. The area of long-wavelength patches in guppies is highly heritable, while the intensity of color patches depends on carotenoid uptake from the diet and on parasite load. Intriguingly, while long-wavelength colors in freshwater fishes often appear to be limited by the availability of dietary carotenoids, this does not appear to be the case in marine fishes.

Structural Colors

Short-wavelength (green to ultraviolet) colors are often produced structurally, using small (<300 nm) particles embedded into a transparent layer backed by melanin pigment. Short wavelengths are scattered and reflected back to the receiver, while longer wavelengths are absorbed by the melanin. Adding filters to the transparent layer can further restrict the range of wavelengths being reflected.

Interference coloration is likely to account for the shimmering iridescent colors found in many freshwater fishes, notably poeciliids, cyprinodonts, and cichlids. This process involves a thin layer of transparent material, with a high index of refraction, coating the skin. Light hitting the surface at an angle is partially reflected to produce a primary reflection; much of the remaining light is refracted, reflected by the boundary at the bottom of the transparent material, then refracted again to produce a secondary reflection. The wavelengths for which these primary and secondary reflections are in phase depend on the viewing angle, the width of the transparent layer, and its refractive index. The apparent color can thus change substantially with viewing angle. Ultraviolet (UV) coloration in birds is produced by coupling multilayer interference with a scattering mechanism. Many fishes produce signals that reflect primarily in the UV (**Figure 1**).

White coloration often is produced by guanine forming microcrystalline platelets that reflect all wavelengths. If guanine platelets are packed in a dense array, they produce the specular (mirror-like) reflectance characteristic of silvery scales. These dense arrays can be concentrated in iridosomes, which intensify pigment

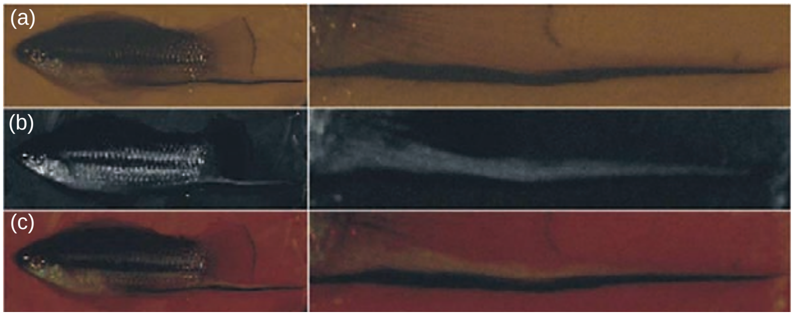

Figure 1 UV and visible spectrum imaging of male pygmy swordtail *Xiphophorus nigrensis* (Poeciliidae). (a) Color photograph in human visible (400–700 nm) range. colors by reflecting wavelengths transmitted by chromatosomes.

The spectral curves produced by fish colors can be characterized as simple (reflecting strongly in one region of the spectrum) or complex (with separate reflectance peaks in distinct portions of the spectrum). Simple colors are either step-shaped, with high reflectance of all visible wavelengths above or below a cutoff point, or peak-shaped, reflecting within a particular range of wavelengths. Long-wavelength colors tend to be step-shaped, short-wavelength colors peak-shaped. Complex spectral curves contain multiple peaks and/or steps. The purple expressed by labroids, particularly tropical wrasses and parrotfishes, is one of the most complex animal colors, with distinct peaks around 400 and 580 nm and a step around 730 nm (**Figure 2**). These color spectra might be produced by combining several interference colors together.

Spatial Patterns

A reflectance spectrum only describes a single point in space and time. Visual perception, however, depends on processing of contrast relationships among elements of a visual scene. In teleosts, notably coral reef fishes, these patterns can be intricate and highly specified. The Picasso triggerfish, *Rhinecanthus aculeatus*, for example, exhibits a black-and-white polka-dot pattern just anterior to the caudal fin; four white stripes running diagonally from the insertion of the anal fin to the midline of the body; brown and gray bands on the dorsum; a filigree of electric blue lines originating parallel at the eye and curving to meet on the gill cover; and a blue mustache above the mouth contrasting with a broad russet band that slopes down to meet the white belly.

The specification of such complex patterns has been a focus of research in evolutionary developmental biology. A diversity of repeating patterns, or textures, can be produced by subtle changes to a relatively simple molecular mechanism. The noted mathematician Alan Turing proposed the reaction–diffusion system, whereby spot and stripe patterns arise as a result of instabilities in the diffusion of two or more morphogenetic chemicals (morphogens) in the skin during early development. Differences in boundary and initial conditions, and in the number of morphogens and diffusion properties of each morphogen, can interact to produce an array of stripe and spot patterns. Such a reaction–diffusion system is consistent with the development of the body pattern of juvenile angelfishes (*Pomacanthus* spp.), in which the body pattern is not fixed on the skin over ontogeny; rather, the size of the black melanophore coloration between yellow stripes is maintained constant, by continuous rearrangement of spatial patterns.

The developmental genetics of stripe formation have been extensively studied in *Danio* spp. (Cyprinidae). In the zebrafish, *D. rerio*, blue stripes consist of a mixture of xanthophores and melanophores, and white stripes consist of xanthophores and iridophores. While there is a fairly detailed picture of the mechanisms whereby pigment cells are recruited and aggregated, the forces underlying the spatial arrangement of stripes remain unclear. The lateral line system might be involved in recruiting stripes, as it is in salamander larvae; the zebrafish mutant puma exhibits defects in both lateral line and stripe development. The zebrafish leopard gene may be acting as a component of a reaction–diffusion system. Small changes in gene structure or regulation could thus induce qualitative changes in pattern elements (**Figure 3**(**a**)), producing dramatic differences in signal structure. Such a process could account for the striking differences in pattern sometimes seen among closely related species (**Figure 3**(**b**)).

In many cases, modifications of fin rays and axial vertebrae also appear to serve primarily in a signaling context. In many freshwater fishes, caudal and/or dorsalfins are prominently enlarged in adult males. In the Montezuma swordtail (Poeciliidae: *Xiphophorus montezumae*), the lower rays of the caudal fin are longer than the standard length in

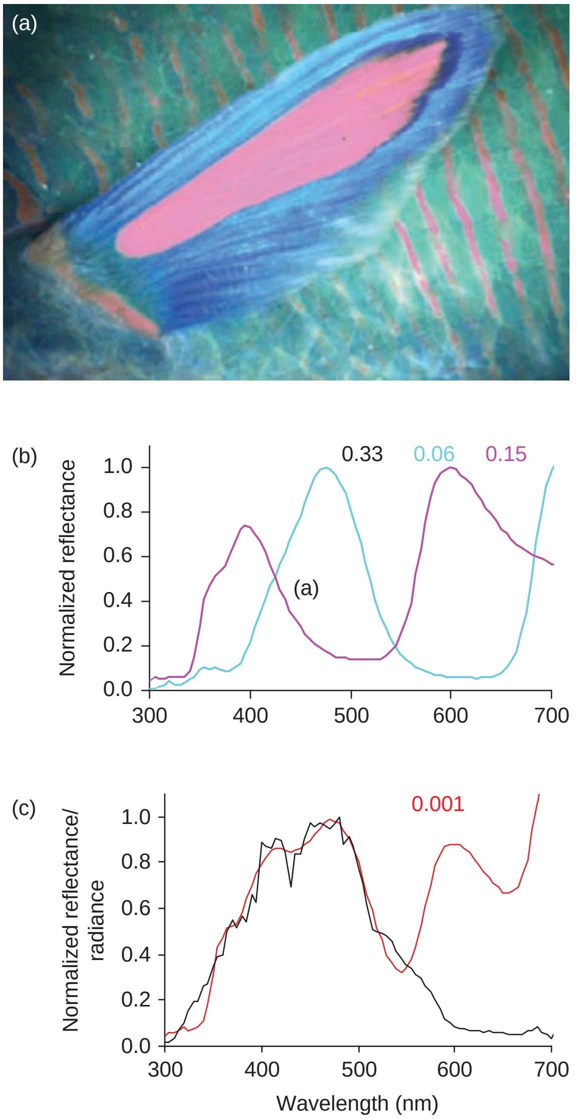

Figure 2 Communication and camouflage in an Indo-Pacific coral reef fish: (a) the purple-pink and blue pectoral fin of the wrasse *Thalassoma lunare* (Labridae) and (b) the colors of *T. lunare*'s pectoral fin. The black number 0.33 is the color distance between the two body colors. The blue number 0.06 is the color distance between blue color and background space light. The pink number 0.15 represents the color distance between purple-pink color and background space light. (c) The black curve shows background space light. The red curve indicates the purple-pink and blue reflectances of *T. lunare* added together. The red number 0.001 represents the color distance between the combined reflectances and background space light. Colors are highly conspicuous when viewed at close range, but smear into the background when viewed at a distance. Modified from Marshall NJ (2000) Communication and camouflage with the same 'bright' colors in reef fishes. *Philosophical Transactions of the Royal Society B* 355: 1243–1248.

some males. Females in several species prefer to mate with males bearing longer swords. By contrast, the highly dimorphic dorsal fin in the closely related sheepshead swordtail, *Xiphophorus birchmanni*, is unattractive to females but serves to deter rival males; accordingly, males modulate the elevation of the dorsal fin during courtship depending on whether rival males are nearby.

Temporal Properties of Visual Signals

In a signaling context, skin patterns and morphological structures are often coupled with stereotypical behaviors that maximize conspicuousness. Many fishes can change color patterns over a range of timescales, ranging from short-term flashes to ontogenetic changes over a lifetime. Male *Badis badis* (Badidae), for example, express nine distinct color patterns according to social context and dominance status. Simultaneously, hermaphroditic *Serranus subligarius* (Serranidae) alternate from a banded black and white male pattern to a solid black female pattern during a sex-changing courtship interaction. Males in several species of swordtails express conspicuous vertical bars on the flank, which they intensify over the course of courtship and agonistic interactions. Color change can operate over longer timescales as well. Male *Astatotilapia* (*Haplochromis*) *burtoni*, for example, express a drab, female-like pattern when subdominant and reproductively inactive, and a colorful, high-contrast sexually dimorphic pattern when dominant and reproductive. These shorter-term, reversible color changes are regulated via neural control of chromatophore cells, by aggregating or dispersing pigment granules within the cells.

Short-term temporal changes in reflected visual signals can also be effected by raising or lowering the fins, as in many poeciliids, or by postural changes which change the appearance of interference colors. Many signal interactions – courtship displays, aggressive displays, and cleaning solicitation displays – involve characteristic motor patterns which may also be providing information in nonvisual modalities, including olfaction and lateral-line detection of near-field vibration (**See also Social and Reproductive Behaviors**: Sexual Behavior in Fish). In some cases, fishes have evolved specialized motor control systems dedicated to communication. Male Siamese fighting fish *Betta splendens* (Osphronemidae) perform a dramatic frontal display to females and to other males, which involves a pronounced flaring of the gill covers. Both the musculoskeletal apparatus and motor control neurons appear to have been modified for this display. Female green swordtails *Xiphophorus helleri* attend specifically to the spatiotemporal visual characteristics of the male courtship display, and sticklebacks attend to variation in courtship tempo.

Color patterns also change over ontogeny (**See also Social and Reproductive Behaviors**: Socially Controlled Sex Change in Fishes). Ontogenetic color changes are also quite common. Many sex-changing reef fishes have strikingly different color patterns according to

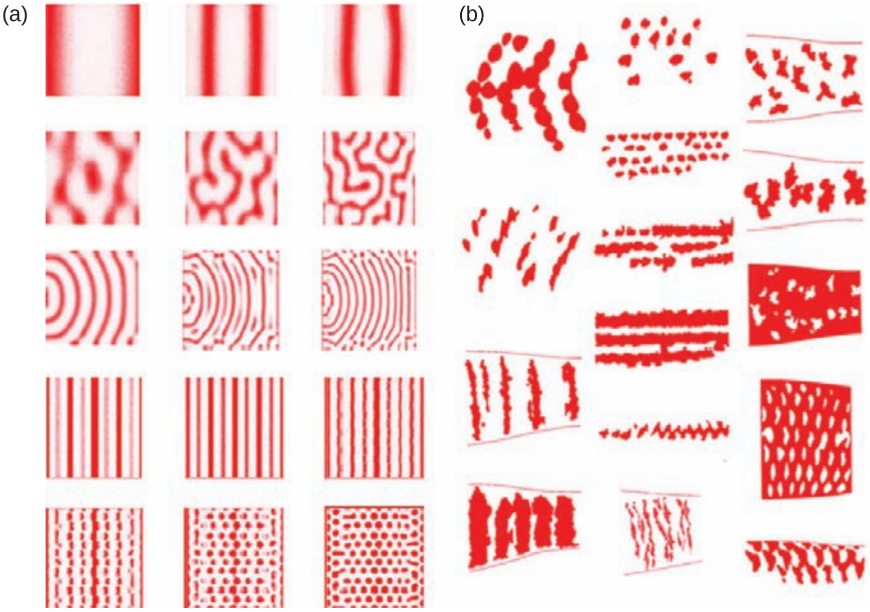

Figure 3 (a) Diversity of patterns generated by theoretical reaction–diffusion models of pattern formation. Small changes in gene structure or regulation can induce qualitative changes in pattern elements, producing dramatic differences in signal structure. (b) Such a process could account for the striking differences in pattern sometimes seen among closely related species. Distribution of red body pigmentation of 15 species of Cameroonian *Aphyosemion* killifish (Aplocheilidae). From Rosenthal GG (2007) Spatiotemporal aspects of visual signals in animal communication. *Annual Review of Ecology, Evolution, and Systematics* 38: 155–178.

sex and social status. In the bluehead wrasse *Thalassoma bifasciatum* (Labridae), both females and initial-phase males have yellow and black horizontal stripes; terminal males, which are derived from either females or initial-phase males, have completely different colors and spatial patterns: a blue head, black and white vertical bars, and a green posterior. Many pomacentrids and pomacanthids also have conspicuous juvenile color patterns strikingly different from the adult phase.

Evolution of Visual Signals

Visual signals in fishes are distinctive in the extent to which they depend on the underwater light environment. In aquatic environments, light quality and quantity varies with depth, water chemistry, and biotic factors such as plankton density. If a fish cannot make its own light, it must work with the available light environment to produce communication signals. Strong associations between transmission characteristics of the environment, visual sensitivity, and body color have been demonstrated in a variety of fish systems. Further, as on land, signal diversity is correlated with ecological complexity. The greatest profusion of fish visual signals is, accordingly, found in shallow waters on tropical coral reefs, where dozens of species coexist in a sensory environment that permits discrimination of fine spatial features and a broad range of colors (**See also Vision**: Color Vision and Color Communication in Reef Fish). In deeper or murkier water, fish tend to be drabber and spatially simpler.

Microhabitat differences can drive sensory systems and thereby speciation. Female sensitivity to red in sticklebacks correlates with the abundance of red light in the environment, and with female mating preference for red versus black males, producing divergent selection for red and black males in divergent environments. Human-induced disturbance can produce the reverse effect: in haplochromine cichlids, eutrophication of clear lake water masks the apparent color differences between two recently diverged species, promoting hybridization.

Sexual selection – both in the context of conspicuous advertisements to potential mates, and in the context of aggressive signals among sexual rivals – is a primary driver of visual exuberance in fishes. In swordtails, genus *Xiphophorus*, females exhibit an ancestral preference for the conspicuous sword elongation of the caudal fin. The preference appears to be a special case of a more general preference for large apparent size. Conspicuous signals are, however, open to exploitation by eavesdroppers. The Mexican tetra (*Astyanax mexicanus*, Characidae), a swordtail predator, shares the same broad visual biases as female swordtails, preferentially targeting males with swords. The visual spectrum is not universally shared among receivers, however. The UV (320–400 nm) is the primary area where visual sensitivity varies substantially across fish taxa, providing the opportunity for a degree of signal privacy. Only about 30% of reef-dwelling fish species are sensitive in the UV. Swordtails are sensitive to UV wavelengths, while *A. mexicanus* are not. Male swordtails in highly predated populations exhibit bright UV stripes, which females attend to in mate choice, but which are relatively inconspicuous to predators (**Figure 1**). Similarly, male guppies court at times of day and in microhabitats that minimize visual conspicuousness to long-wavelength (red) insensitive invertebrate predators, while retaining conspicuousness to females.

Sexual selection is insufficient to explain the flamboyant signals of many reef fishes, which are often highly stereotyped within a species, often identical in males and females, and in some cases, like beaugregory damselfish (*Stegastes leucostictus*) appear more conspicuous to us in juveniles than in adults. Konrad Lorenz, one of the founders of early ethology, proposed that reef-fish signals had evolved under pressure in a diverse, crowded community. By iconically encoding species identity, a distinctive pattern would minimize the incidence of aggression among heterospecifics not competing for resources. While Lorenz's idea of poster coloration remains to be thoroughly tested, some reef-fish signals are certainly targeting a broad array of receivers. For example, territorial males in many pomacentrid species express a distinct black-on-white pattern to warn off all intruders, and various species of cleaner fish have converged on a conspicuous blue-and-yellow cleaning pattern that serves to attract hosts to cleaning stations.

Spatial patterning may allow such patterns to be salient to receivers close by, while affording some degree of camouflage from larger midwater predators. High spatial frequency patterns (fine lines and small spots) provide high contrast at close range. When viewed at a distance, however, they smear together and blend into the background (**Figure 2**).

Fishes inhabit almost every conceivable visual environment, and the underwater environment poses considerable challenges for visual communication. Nevertheless, fishes have evolved a remarkable range of solutions to environmental constraints on signaling, and visual signals encode information that is critical to many fishes' social relationships, cooperative interactions, and reproductive biology. Recent advances in technology, including UV-sensitive cameras and hyperspectral imaging, will be instrumental in understanding how these sophisticated signals are detected and perceived in complex natural environments.

Glossary

Chirps Brief frequency increases in the electric organ discharge of weakly electric fish that are used as communication signals in aggression and courtship.

Electric organ discharge (EOD) Electrical discharges resulting from the summed excitation of the cells (electrocytes) of the electric organ of electric fishes that function both in communication and in locating nearby objects. Short (100 microseconds to several tens of milliseconds) electrical pulses of various voltages (a few mV to several hundred V) are generated at various rates (a few to over 1000 times per second).

Electrocytes Effector cells or syncytium specialized for generating electric fields and located primarily in the tail of electric fish. They generate and control the waveform of the electric organ discharge.

Intentional jamming An electrocommunication behavior during agonistic interactions in which a fish will adjust its electric organ discharge frequency to match that of another fish, thereby causing interference in the EOD of the other fish.

Knollenorgans Tuberous electrosensory organs used for electrocommunication among mormyrid fishes. The sensory cells are equipped with numerous microvilli and are specialized for detecting the electric organ discharge of another conspecific fish.

Melanocortins A group of peptide hormones, including adrenocorticotropic hormone and melanocyte-stimulating hormone.

Pacemaker nucleus Region in the hindbrain of electric fish that is spontaneously active and sets the discharge frequency or discharge rate.

Prepacemaker nucleus Region in the midbrain of electric fish that regulates the production of electric organ discharge modulations used in communication.

Substance P A neuropeptide particularly associated with the brain and spinal cord.

Introduction

Hundreds of species of fish swim around in the freshwaters of tropical South America and Africa chattering in a unique language: electrocommunication. Unlike their more famous cousin, the electric eel (*Electrophorus electricus*), which can produce hundreds of volts of electricity to kill prey and predators, these so-called weakly electric fish generate signals in the millivolt range for communicating with members of their own species. Over evolutionary time, these fish have modified particular sets of muscle and nerve cells to form an electric organ that produces a communication signal termed the electric organ discharge (EOD). The EOD is also used for locating objects in the environment, but the focus of this article is its use in electrocommunication (**see also Detection and Generation of Electric Signals**: Active Electrolocation). They have also evolved specialized sensory organs, electroreceptors, that detect the signals produced by themselves and by other fish (**see also Detection and Generation of Electric Signals**: Morphology of Electroreceptive Sensory Organs). Fish emit the EOD continuously, and the EOD waveform and/or discharge rate conveys information about the species and gender identity of a fish. Fish can also briefly modulate this continuous discharge to send discrete signals that function in aggression and courtship. Electric signaling is a highly specialized form of communication, but, in a remarkable case of convergent evolution, it arose independently in two orders of the teleost fish: the Gymnotiformes in South America and the Mormyriformes in Africa.

Why communicate using electricity? Most of these fish are nocturnal and live in dark or muddy waters where visual communication would be impossible. Moreover, these fish often inhabit areas that are dense in aquatic vegetation, which would distort many acoustic communication signals. In such environments, electric signals are advantageous because they are neither influenced by light levels nor susceptible to environmental distortion. However, one disadvantage of electric signals is that they degrade in strength (amplitude) over a short distance. Consequently, electrocommunication is only effective for most species when fish are within about 1 m of each other.

Discovery of Electrocommunication

Ancient Egyptians and Greeks were well aware of the capacity of fish to generate electricity since they had experienced the powerful electric discharges of strong electric fish. However, it was not until the 1950s, largely through the work of zoologist Hans Lissmann, that scientists learned about the role of weak electric discharges in communication. Lissman collected weakly electric fish, mainly *Gymnarchus*, from the Upper Volta River in West Africa, and transported them to his laboratory at Cambridge University in England. First, he observed that whenever an electrical current was sent through a copper loop placed in the fish's tank, the fish would react aggressively. Then he recorded the continuous EOD of these fish and played it back through one of six sets of electrodes placed in the aquarium. The electric fish only attacked the electrodes that delivered the EOD, indicating that EOD was both detectable and behaviorally meaningful to the fish.

Generating Electrocommunication Signals in Two forms: Wave versus Pulse EODs

Most electric fish generate their electric field through modified muscle cells termed electrocytes. Like muscle cells, electrocytes fire action potentials, but unlike muscle cells, they fire nearly synchronously and have no contractile elements. The timing of electrocyte firing – the tempo and rhythm of electrocommunication – is controlled by a particular region of the hindbrain, the pacemaker nucleus. Neurons in the pacemaker travel down the spinal cord and synapse on to electromotor neurons that, in turn, synapse with electrocytes. The shape of the waveform – the timbre of the communication signal – is largely determined by the structure of the electrocyte membranes and the rate at which ions flow into the electrocyte (**see also Detection and Generation of Electric Signals**: Electric Organs and Generation of Electric Signals).

The timing and shape of EODs are extraordinarily diverse among species. Nevertheless, electric fish can be placed in one of two general categories based on their EOD form. In fish with a wave-type EOD, the EOD takes the shape of a continuous, quasi-sinusoidal wave that, when the fish is at rest, is remarkably constant in waveform and frequency (**Figure 1**). Indeed, the EODs of these fish are among the most precise biological oscillators

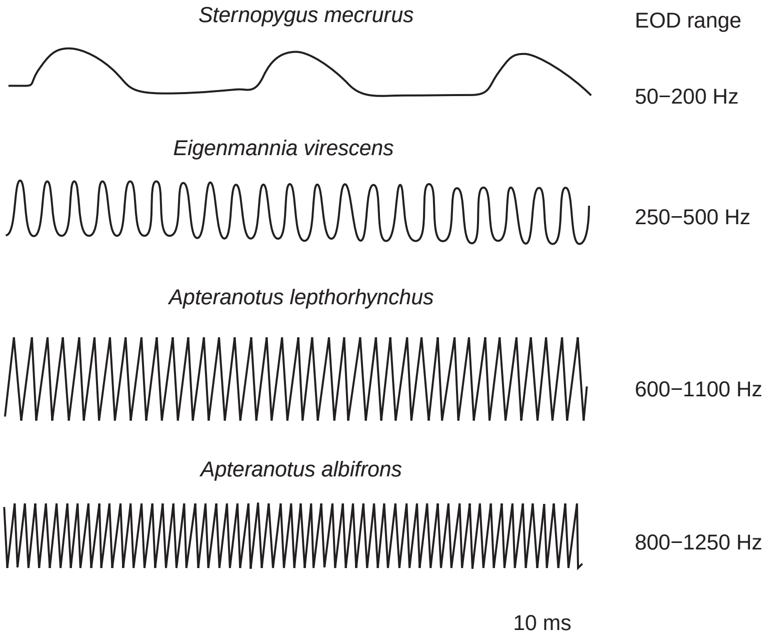

Figure 1 Wave-type electric organ discharges (EODs) of four Latin American weakly electric fish species. The EODs differ primarily in frequency, and these differences are used in species recognition. Reproduced from Smith GT (1999) Ionic currents that contribute to a sexually dimorphic communication signal in weakly electric fish. *Journal of Comparative Physiology A* 185: 379–387 and Zakon HH and Smith GT (2009) Weakly electric fish: Behavior, neurobiology, and neuroendocrinology. In: Pfaff D, Arnold A, Etgen A, Fahrbach S, Moss R, and Rubin R (eds.) *Hormones, Brain and Behavior*, vol. 2, ch. 17, pp. 611–638. New York: Academic Press, with permission from Elsevier.

known. When these signals are transduced into an audio signal, they sound like a constant ring at a single pitch that reflects the EOD frequency of the fish. Because EOD contains mostly a narrow range of frequencies, the electroreceptors are narrowly sensitive to this frequency range. Only one African species emits a wave-type discharge; about two-thirds of South American electric fish species have wave-type discharges.

Other fish generate pulse-type EODs, in which the time between pulses is longer than the duration of the pulse (**Figure 2**). The discharge rate within an individual is highly variable. When these signals are transduced into an audio signal, they sound like a rapid popping that frequently speeds up and slows down. Some species can even completely turn off their discharge for periods as long as 10 s. In pulse-type fish, the EOD contains a broad spectrum of frequencies, and their electroreceptors, compared to those of wave-type fish, are more broadly tuned. Mormyriform electric fish have a unique electroreceptor type, the Knollenorgan, that is specialized for electrocommunication. Through higher brain processing, the activity in Knollenorgan pathway is silenced when a fish produces its EOD, and thus the Knollenorgan activates only in response to the EOD of another fish. All but one African electric fish species and about one-third of gymnotiform electric fish in Latin America emit pulse-type EODs.

Communication through the Continuous EOD: Function in Species and Sexual Identification

Electric fish emit EODs continuously beginning from a few days after hatching (**see also Detection and Generation of Electric Signals**: Development of Electroreceptors and Electric Organs). The waveform and frequency of the continuous EOD conveys information to other fish about individual and/or species identity. At maturity, these parameters of the EOD commonly

Hopkins, with permission from Elsevier.

diverge between males and females and thus can be used to convey sexual identity as well.

Pulse-Type EODs

Among fish with pulse-type EODs, many species have their own characteristic waveform. For example, a few species have a single phase (monophasic); most have two (biphasic) or three phases while some have as many as four phases (**Figure 2**). Across species, the pulse duration ranges from less than 0.1 ms (e.g., *Polliyrus isidori*) to nearly 10 ms (e.g., *Paramormyrops gabonensis*). The ability of fish to discriminate variation in waveform was demonstrated by Heiligenberg and Altes, who measured the response of a pulse-type fish, *Hypopomus artedi*, to playback EODs that varied in waveform, but not in frequency content. Fish responded at highest rates to natural waveforms from their own species and considerably less to synthesized waveforms, in which the phases of the waveform were shifted. Other scientists demonstrated that, in another pulse-type fish *Gymnotus carapo*, each individual has its own stable and characteristic waveform. These fish are very territorial, and they can use these waveform signatures to distinguish familiar neighbors from potentially threatening intruders.

In the breeding season, the EOD waveform of pulse-type fish differentiates sexually (**Figure 2**). Most commonly, the pulse duration of males increases. In the mormyrid *Brienomyrus brachyistius*, mature males have an EOD pulse that is twice the duration of the female EOD. When males were presented with playbacks of another male, they tended to ignore the signal. But when presented with female EODs, males briefly accelerated their discharge rate to form a courtship signal termed a 'rasp'. Males also rasped to a synthetic square pulse, but only if it was the same duration as a natural female EOD, indicating that duration is the key component of the female EOD that males attend to.

In the gymnotiform pulse fish*, Brachyhypopomus gauderio*, males broaden their EOD pulses and increase their height (amplitude) during the night, and females are attracted to the males with the broadest, tallest discharge. However, broadening the pulse incurs at least two costs. First, males spend a great deal energy to generate this sex-typical signal. They expend over 20% of their daily energy use on electric signaling, compared to only 4% for females. Second, broadening the pulse adds low-frequency energy to their EOD and makes them more susceptible to predators that are sensitive only to such low frequency (see below).

Wave-Type EODs

Among wave-type fish, species identity is largely conferred through EOD frequency rather than waveform. Species vary in EOD frequency from 50 to 2000 waves per second or hertz (Hz), with each species commonly emitting their own characteristic pitch (**Figure 1**). When fish are presented with playbacks of different frequencies, they are much more likely to make attacks and electrical displays toward frequencies in their own species specific range than toward frequencies typical of other species.

In many wave-type species, EOD frequency is sexually dimorphic. The most common pattern is for males to have lower EOD frequency than females, though in some species, such as the well-studied *Apteronotus leptorhynchus*, that pattern is reversed. Male-typical frequencies usually provoke an aggressive response from males while female-typical frequencies commonly elicit a courtship response. Within a sex, EOD frequency also apparently signals social status. For example, in *A. leptorhynchus* living in a large social group, males with the highest (most masculine) EOD frequency tended to dominate the best retreat sites. Females with the highest EOD frequency outcompete low-frequency females for retreat sites as well.

Communication through EOD Modulations: Function in Aggression and Courtship

In addition to conveying information through the continuous EOD, fish communicate more context-specific information through transient modulations of the EOD. These modulations vary in duration from 10 ms to as long as 10 s, and fish produce them at different rates and proportions depending on whether they are engaged in aggression or courtship. For example, many pulse-type fish simply turn off their EOD for about 0.1 to 2 s during either same sex or opposite sex interactions. These signals, termed interruptions, are generated when neurons in the mid-brain send signals to the hindbrain pacemaker nucleus and inhibit its firing.

Some wave-type species that have particularly high EOD frequencies, such as those in the genus *Apteronotus*, cannot interrupt their EOD. Instead, they briefly accelerate their EOD frequency. These electrocommunication signals are termed chirps, based on the sound they make in an audio recording. Generation of chirps also originates in the mid-brain when a specific nucleus, the prepacemaker, stimulates cells in the pacemaker to transiently increase their firing frequency. During a chirp, the EOD frequency rises (50–400 Hz) for a brief period (10–200 ms) (**Figure 3**). Fish can distinguish between their own EOD chirps and those of other fish by comparing the timing or pattern of signals received by the electroreceptors on different parts of its body. When a fish chirps, it will experience the signal uniformly over its whole body. When a fish is detecting a chirp from another fish, it will feel the chirp

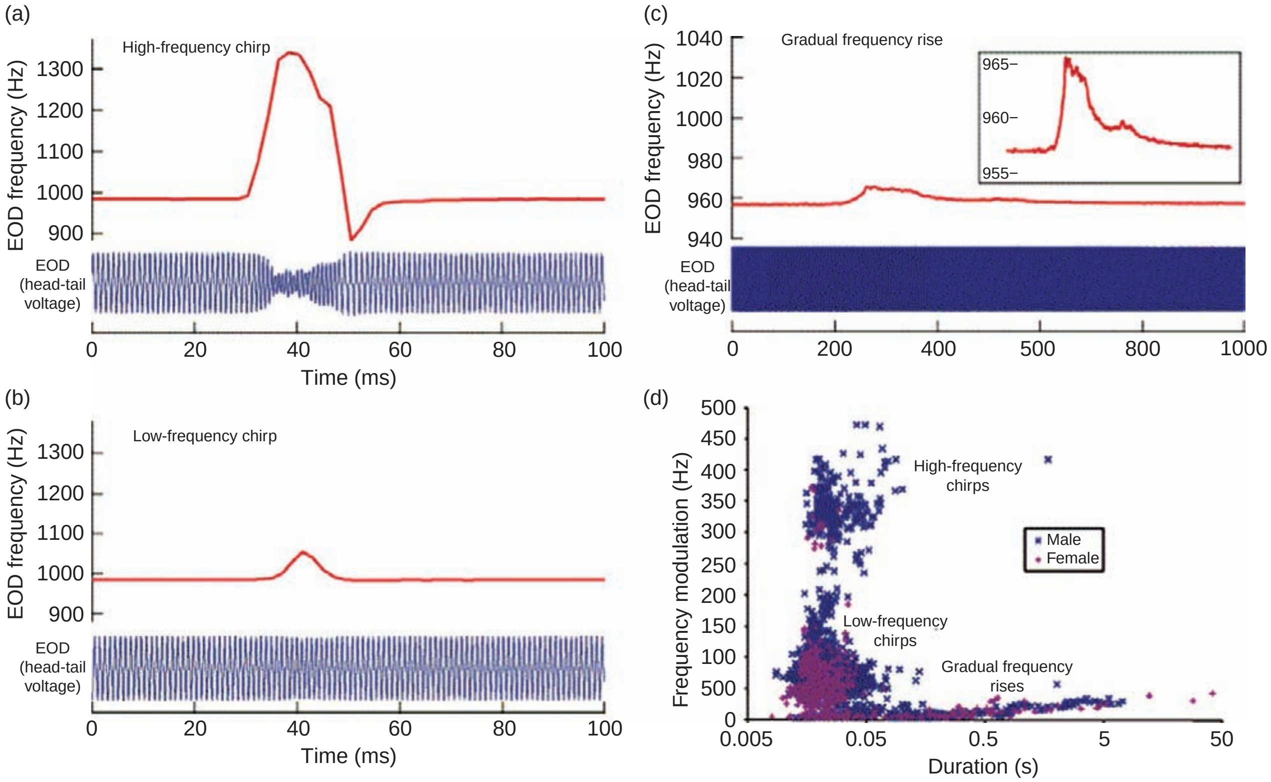

Figure 3 Electric organ discharge modulations – chirps and rises – used in electrocommunication in *Apteronotus leptorhynchus*. (a) High-frequency chirp type used primarily in courtship interactions. (b) Low-frequency chirp type used primarily in aggression. (c) Gradual frequency rise. (d) Scatter plot showing the three classes of EOD modulations and their differential production by sex. Compared to males, females rarely produce high-frequency chirps and are more apt to produce gradual rises. Reproduced from Zakon HH and Smith GT (2009) Weakly electric fish: Behavior, neurobiology, and neuroendocrinology. In: Pfaff D, Arnold A, Etgen A, Fahrbach S, Moss R, and Rubin R (eds.) *Hormones, Brain and Behavior*, vol. 2, ch. 17, pp. 611–638. New York: Academic Press, with permission from Elsevier.

asymmetrically on either side of its body, and its own EOD will be modified by the other fish's chirp.

Aggression

In nature, electric fish often live in rather dense aggregations and compete for food, mates, and retreat sites, so aggression between individuals of the same species is common. Fish chase and attack each other while modulating their EOD through frequency increases or interruptions. In the pulse-type mormyrid species *Gnathonemus petersii*, fish change their discharge rate at different phases of an aggressive encounter. Aggression often begins with a head butt, which is accompanied by an increased discharge rate. The aggressive fish frequently takes an antiparallel position next to the fish it is attacking, positioning its electric organ (located in the tail) next to the second fish's head, where the electroreceptors are at greatest density. In this position, fish increase their discharge rate from about 10 to 140 Hz. During a chase, the aggressor commonly signals through short (300–1000 ms) or long (<1 s) interruptions.

Some pulse-type gymnotiformes, such as *Brachyhypopomus* and *Gymnotus*, interrupt their EODs during aggression as a sign of submission. In fights between males, the defeated fish makes a sequence of interruptions once the outcome has been established. After these interruptions, the fighting subsides. In male–female pairings, the female often interrupts her discharge when she is persistently pursued by a male, as if she is electrically hiding.

Chirps are the most prominent aggressive electrocommunication signal in wave-type gymnotiforms such as *Apteronotus*. In *Apteronotus* agonistic chirps, EOD frequency rises about 50 Hz for about 20 ms (**Figure 3**). During male–male interaction, the largest males with the highest EOD frequency chirp at the highest rates, indicating that chirping signals dominance. Two males interacting at a close distance commonly trade chirps at the rate of about once per second in a regular back and forth rally – an echo response. Fish chirp most vigorously during the nonviolent period between attacks, suggesting that chirps may serve as a warning signal to deter aggression rather than a threat of impending attack.

Female *Apteronotus* are far less likely than males to produce chirps in agonistic interactions, but much more commonly produce longer duration EOD modulations termed rises. During a rise, the EOD frequency only increases by ~5–20 Hz, but the duration is much longer (1–200 s) than in chirps (**Figure 3**). When interacting with males, rises are usually long in duration (~30 s) and are commonly considered submissive or courtship signals. However, when females interact with each other, the meaning of rises appears to change. Females with a high EOD frequency make short-duration (~1 s) rises toward females with lower EOD frequencies. Because high-frequency females are usually dominant to low-frequency females, these rises appear to function in aggression, thereby establishing hierarchy among females.

Sometimes two interacting fish have very similar EOD frequencies, and their EODs interfere with each other. This phenomenon, referred to as jamming, disrupts a fish's ability to use its EOD frequency for electrolocation, and many fish adjust their EOD frequency up or down to avoid such interference. Despite the impairment caused by jamming, sometimes fish exhibit intentional jamming as an apparent aggressive signal (**Figure 4**). For example, when *Apteronotus* fight over a shelter, the fish with the lower EOD sometimes elevates its signal into the jamming range of the second fish, presumably as a means of threatening the second fish. In a study using EOD playbacks, fish elevated their EOD frequencies to match the frequency of the EOD playback while biting the electrodes immediately before and during the modulations, indicating that intentional jamming is an aggressive response.

Courtship

Electric signaling is equally important in courtship as it is in aggression. In the pulse-type mormyrid, *B. brachyistius*, males are very territorial and commonly lunge at and chase nearby females, while making quick bursts of ~100 pulses in a second. In this phase, females often make short interruptions of their discharge. During courtship, males circle around and follow the female while

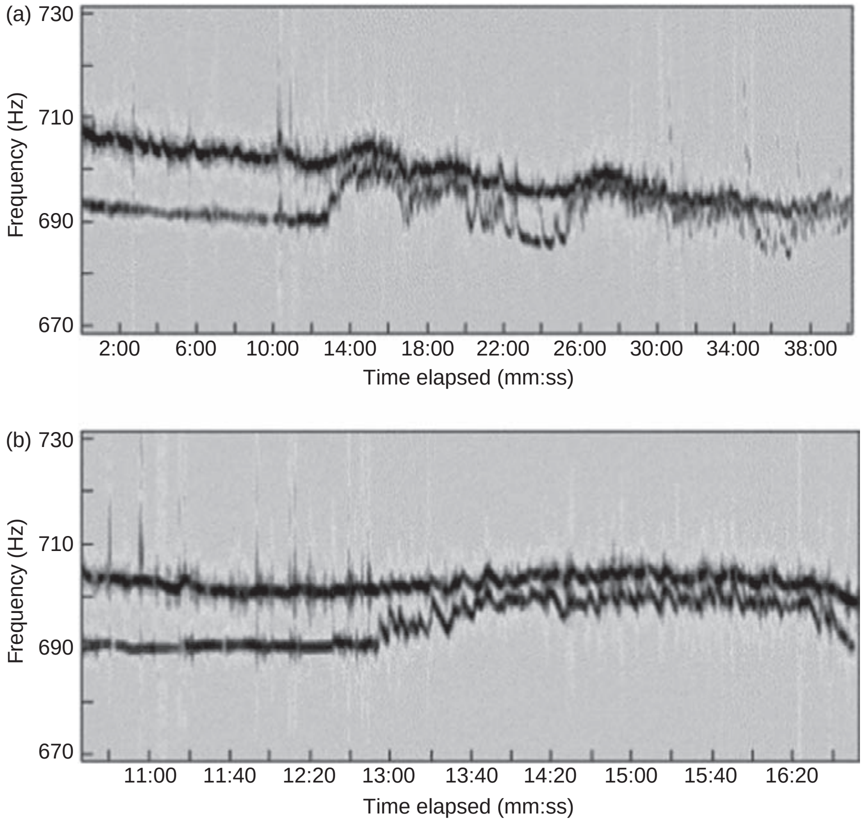

Figure 4 Intentional jamming during agonistic interactions between two female weakly electric fish, *Apteronotus leptorhynchus*. (a) Two fish began the interaction with electric organ discharge (EOD) frequencies at about 693 and 708 Hz. After 12 min, the fish discharging at 692 Hz increased its EOD frequency by about 10 Hz to match the EOD of the other fish and thereby causing interference. (b) Enlargment of (a) showing one detailed phase of intentional jamming. In both panels, chirps are visible as brief upward spikes emitted most commonly by the fish in the upper trace. Reproduced from Tallarovic SK and Zakon HH (2005) Electric organ discharge frequency jamming during social interactions in brown ghost knifefish, *Apteronotus leptorhynchus*. *Animal Behaviour* 70*:* 1355–1365, with permission from Elsevier.

producing rasps (a quick series of 4–10 pulses followed by a slow decrease in pulse rate). The female stops making interruptions and instead makes bursts of about 20 pulses in 1 s. They continue in a duet of rasps and bursts until spawning when the male begins to creak (a sequence of slow discharges and bursts, bracketed by interruptions) while the female continues to burst.

In wave-type gymnotiforms, courtship consists of a series of complex movements accompanied by bouts of chirping. These chirps are much different than those produced during aggression: EOD frequency increases are larger (200–300 Hz) and last longer (50–200 ms) than those of aggressive chirps (**Figure 3**). In *Eigenmannia,* the dominant male, who usually has the lowest EOD frequency among the males, increases his agonistic displays on the day before spawning, emitting regular chirps while patrolling a large area. After nightfall, the dominant female, who usually has the highest EOD frequency among the females, stops feeding and seeks shelter within floating plants. Meanwhile the male searches for the female while increasing aggression toward the lower-ranking males. After finding the female, the male swims back and forth underneath her while she remains in the plants. Right before spawning, the female raises her EOD frequency by tens of hertz, and the male responds with a series of courtship chirps. They then release their gametes and swim away from the plants.

Hormonal Influences on Electrocommunication Systems

Many sex differences in electrocommunication behaviors are exhibited only during the breeding period and, therefore, vary seasonally. Accordingly, the same physiological signals – sex steroid hormones such as androgens and estrogens – that control reproductive physiology also regulate electrocommunication behaviors. In many pulse fish, mature males have an EOD that is larger in amplitude and longer in pulse duration than that of females, and experimental treatment with androgens masculinizes the EOD. Androgens achieve this effect in mormyrids by acting on the morphology of the electrocytes; they increase the size of the electrocytes and the thickness of the electrocyte membranes. In gymnotiforms, androgens alter the physiology of electrocytes by changing the activity of ion channels in the electrocyte membrane. For example, in *Sternopygus,* androgen treatment causes a fish's electrocytes to produce longer, male-like discharges by slowing the rate at which sodium flows into the cell and potassium flows out of the cell. In some species, estrogens can also feminize the EOD. In *Sternopygus,* estrogen treatment speeds up the electrocyte discharge by causing changes in the sodium current that are opposite from those caused by androgens. In addition to acting on waveform and pulse duration, hormones influence EOD frequency and its modulations. Androgens decrease EOD frequency in species in which EOD frequency is lower in males than females. When sexual dimorphism in EOD frequency is reversed, such as in *A. leptorhynchus,* androgens have the opposite effect.

Steroids can directly affect the electrocommunication system by binding to receptors both in electrocytes and in neurons that control the EOD. However, steroids can also influence electrocommunication behavior indirectly by modifying other regulatory pathways. For example, androgens appear to promote chirping behavior in *Apteronotus* by acting through the serotonin and substance P systems in the brain. Androgens modify daily changes in male EOD waveform of *Brachyhypopomus* by altering the response of electrocytes to the peptide hormones in the melanocortin family.

An electric fish's electroreceptors are particularly sensitive to its own EOD, but their sensitivity also changes seasonally. If its electroreceptors did not adjust to seasonal changes in the EOD, they would decrease their ability to detect the fish's own discharge, compromising the fish's ability to electrolocate. Fortunately, electroreceptors are also steroid sensitive. When *Sternopygus* is implanted with androgens, masculinizing its EOD frequency, the electroreceptors simultaneously shift their tuning to keep them matched with their new EOD frequency.

Evolution of Electrocommunication

Electroreception, the ability to detect electric fields, arose in the earliest vertebrates over 500 million years ago and was retained in most cartilaginous fish. However, it was lost evolutionarily in the teleost fish, only to re-emerge independently twice during teleost evolution. In two orders (Gymnotiformes and Moryriformes), electroreception was coupled to the ability to generate EODs, and this opened the possibility for electrocommunication. The ancestral weakly electric fish likely had a monophasic, pulse-type EOD. However, these electric fish were likely detectable by predators, such as certain catfish, that could detect low-frequency electric components in this EOD. In subsequent evolution, species arose that had more complex multiphasic EODs, which eliminated the low-frequency components of the EOD, and thereby made them undetectable to electropredators. Although predation is commonly considered a force that simplifies communication signals, electric fish provide an example for which predation likely enhanced signal complexity.

In wave-type gymnotiforms, EOD frequency appears to have increased during evolution. The evolutionary relationships among electric fish are still the subject of debate, but many phylogenies show that the Apteronotidae, which discharge at the highest frequency, is the most recently evolved group of gymnotiforms. These fish abandoned their muscle-derived electric organ and instead evolved an electric organ that consists completely of neural tissue. Neurons in this system are connected only by electrical synapses, which enable them to discharge unusually rapidly (700–2000 Hz). This high-frequency EOD likely enhanced their ability to electrolocate in fast-moving streams and colonize waters that were unoccupied by other electric fish species. However, this full-throttle electrogenesis system is apparently unable to decrease firing rate or change EOD waveform, and this restricts the kinds of electrocommunication signals they can use. For example, apteronotids can only communicate through frequency elevations while pulse fish and low-frequency wave fish can communicate through changes in waveform, complex bursts, and decreases in pulse rate or complete interruptions.

Yet even within Apteronotidae, evolution has produced a spectacular diversity of EOD modulations in just the past ~5–10 million years. Across these closely related species, frequency elevations during a chirp can vary from 50 to almost 500 Hz, and the duration of chirps can range from 20 to 600 ms. Therefore, even though evolving a completely neural electric organ limited the production of certain classes of electrocommunication signals, these fish diversified their electrocommuncation signals through elaboration of one particular class of EOD modulations.

Electrocommunication as a Model in Neuroethology

Electric fish have become one of the most fruitful animal models in the field of neuroethology (the study for the neural basis of naturalistic behaviors). Indeed, certain electrocommunication behaviors, such as the jamming avoidance response, are understood at the cellular and circuit level more completely than almost any other vertebrate behavior. The utility of electric fish as a neuroethological model comes largely from the fact that the neural circuits underlying electrocommunication are relatively simple and electrocommunication signals are relatively easy to elicit and playback in the laboratory.

Electricity is the language of the nervous system in all animals. In most animals, the brain's electrical signals get translated into communication signals by activating a complex motor apparatus (such as the vocal apparatus). In electric fish, communication is far more direct; there is almost no translation between signal production by the nervous system of one fish and signal reception by another fish. The activity of specific cell types is very directly tied to the generation of the communication signal. Consequently, it is relatively easy to investigate how modification of cellular processes leads to changes in electrocommunication behavior. Moreover, because electric signaling varies so much among species, one can explore how electric circuits underlying behavior have evolved to generate diversity of communication systems.

Glossary

Amygdala A small area of the mammalian brain that processes emotional information.

Cerebellum The small hindbrain found in vertebrates.

Cognition The process of sensing, learning, and remembering information.

Hippocampus A small discrete area of the mammalian brain that processes information connected with spatial learning or timing and also plays a role in consolidating memories.

Lateral pallium A defined area within the fish telencephalon that functions like a mammalian hippocampus.

Medial pallium A defined area within the fish telencephalon that functions like a mammalian amygdala.

Telencephalon The forebrain area in a vertebrate brain.

Introduction

Animals that can learn and remember information can alter their behavior in response to changes in their environment; such abilities help promote survival and success. Multiple experiments and observations across a broad range of fish species have shown that fish have impressive, sometimes even sophisticated, learning and memory abilities. Some species of fish are able to navigate long-distance migrations using memories of places they have previously been to guide their chosen routes. Other species that spend much of their time living within a territory learn and remember key facts about neighboring rivals. If a rival male invades your territory, knowing how strong or committed he is will enable you to modulate your own level of aggression and will help you to decide whether to escalate to a fight or not. Thus, learning and memory allow fish to vary and fine-tune their responses on a daily basis.

To integrate and consolidate information and to turn this into memories demands a certain degree of brain specialization. Fish have several distinct brain areas that are devoted to processing different forms of learning and memory. This article explains our current understanding of fish cognition, and it will consider the function of learning and memory and the kinds of complex behavior that it promotes. A few examples will explore the kinds of mechanism that underlie certain cognitive processes.

Different Forms of Learning and Memory

Even on a day-to-day basis, fish need to learn and remember different kinds of information. On a very basic level they can form simple associations. For example, they might learn that less aggressive opponents have lighter pigmentation in their skin and so lighter colored fish will be less of a threat. However, fish can also learn more complex associations. For instance, they can learn lists of landmarks to help them navigate to a specific place and they can learn elaborate escape routes when threatened. Some species learn to combine different kinds of information and then integrate these to make decisions about how to behave. For example, fish learn to integrate time information with spatial information – learning different events occur in certain parts of the environment at different time points in the day. Thus, fish show a range of learning abilities from simple to complex.

As fish learn new information, they build memories that can be recalled and used in the future. Studies with birds and mammals have found that they can store different types of memory – for instance, sometimes individuals recall single facts over a short period of time (e.g., short-term memory), but other forms of memory combine several pieces of information such as what kind of event occurred as well as where and when it happened (known as episodic memory). In contrast to the many studies in birds and mammals, we know less about memory processes in fish. Some work has shown that fish can remember and recognize the identity of specific individuals. Small groups of guppies, *Poecilia reticulata*, for example, can learn to recognize one another. Being able to recognize individuals also has been found to promote cooperation and even decreases competition in foraging situations in threespine sticklebacks, *Gasterosteus aculeatus*.

Areas of the Fish Brain Involved in Learning and Memory

The fish brain has clear similarities to other vertebrate brains – as we move from the front of the fish toward the back of the head, there is a distinctive forebrain, followed by a cluster of structures in the mid-brain and then to the hindbrain before reaching the spinal cord (**see also Brain and Nervous System**: Functional Morphology of the Brains of Ray-Finned Fishes). Many of the neural connections between different brain regions, including those seen in fish, are similar across different vertebrate taxa. Yet, as you look at a fish brain, it looks different to the brains of birds and mammals (**Figure 1**).

This is because fish lack a well-developed cortex; instead they have a much thinner pallial layer associated with the paired hemispheres that make up their forebrain – also known as the telencephalon. Our brains have a particularly thick cortex formed from six layers that make up the gray matter known as the neocortex. The convoluted neocortex is the material that gives our own brains their distinctive crinkled appearance.

Several distinct regions within the fish brain contribute to learning and memory processes. The small hindbrain, or cerebellum, helps to control various aspects of movement and motor coordination, but it is also involved in certain forms of simple learning. For instance, the cerebellum has been shown to affect some categories of associative learning such as classical conditioning – where fish learn about the predictive relationship between stimuli. Simple associative learning is the same process that made Pavlov's dogs salivate when they heard the sound of a bell. Over a series of trials Pavlov would ring a bell a few seconds before food was made available. Very quickly, a dog learns that the bell predicts food. Once the dog has learned the association, the sound of the bell is sufficient to start the dog salivating in anticipation of receiving food. For over 100 years (the earliest by Mobius in 1873), researchers have used classical conditioning experiments with fishes in thousands of experiments. Some have used appetitive conditioning (e.g., conditioning that a light or sound signals food and results in eating behavior) and others have used aversive conditioning (e.g., conditioning that a light or sound signals a shock and results in escape behavior).

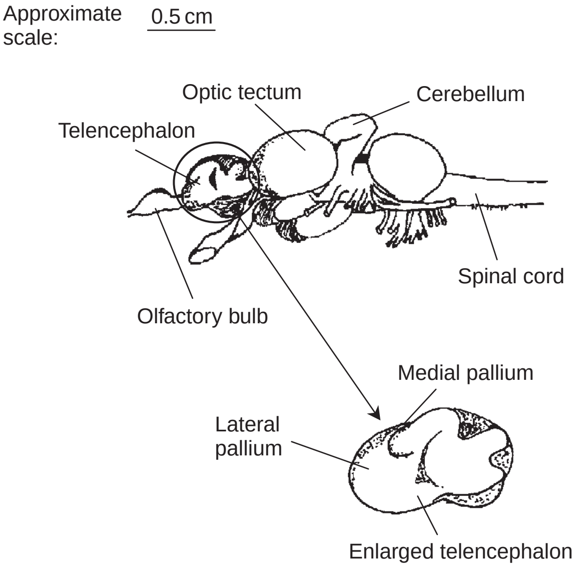

Figure 1 Schematic drawing of a goldfish brain. The telencephalon, or forebrain, has been enlarged to show more detail of this structure.

Many other kinds of stimuli and responses are used in associative learning. One commonly used technique in mammals pairs a light switching on followed by a puff of air blown at the eye resulting in a blink. Fish do not blink, but instead perform an eye retraction response, where their eyes briefly move a little way back into their sockets in response to a brief, mild electric shock close to the eye that induces a sensation similar to tingling in the skin. Goldfish (*Carassius auratus*) trained in this way quickly learn to retract their eye as soon the light switches on.

This kind of learning process is very widespread across the animal kingdom – even jellyfish and sea slugs learn to make connections if one stimulus predicts the onset of another. As learning associations between pairs of stimuli can be achieved by forming just a few connections within a small circuit of neurons, it is often considered to be a simple form of learning.

We know that the fish hindbrain, or cerebellum, plays a role in simple learning because damage to this area disrupts the fish's ability to learn the association between the light coming on and the delivery of the mild shock. Control experiments demonstrate that spontaneous delivery of the shock alone still generates the eye retraction response – so surgically lesioning the cerebellum does not prevent the fish from showing the eye retraction response. Rather, the lesioning affects the ability to learn the predictive link between the light coming on and the shock (**Figure 2**). More recently, experiments have shown that the metabolic activity of the cerebellum is increased when intact, normal goldfish are learning the association between the light followed by the delivery of the electric shock. Cytochrome oxidase (COX), a key component of metabolism, levels were significantly higher in fish trained with paired, predictive stimuli. This was not the case for

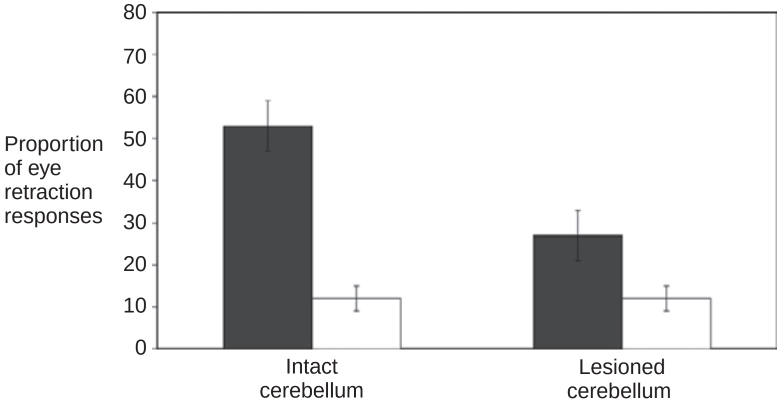

Figure 2 Mean proportion of eye retraction responses (±standard error) in fish with either an intact cerebellum or where it has been lesioned. Filled bars show the responses of fish that are given a light cue shortly before the onset of a mild electric shock. Fish with an intact cerebellum learn to respond to the light coming on, but learning this association is impaired in fish with a damaged cerebellum. The white bars are spontaneous responses to the shock delivered without a predictive light cue – both groups of fish responded in a similar manner to this kind of stimulation. Reproduced from Rodríguez F, Durán E, Gómez A, *et al.* (2005) Cognitive and emotional functions of the teleost fish cerebellum. *Brain Research Bulletin* 66: 365–370.

goldfish that were given the same two stimuli but where these were presented in a random fashion – so the light no longer reliably predicted when a shock would happen.

Toward the front of the fish brain the paired spheres of the telencephalon contain areas that are connected with different kinds of learning and memory. One area, known as the medial pallial region, has been linked with emotional learning. Emotions such as fear and aggression are an important component of cognition because they help the animal learn about potentially dangerous events to avoid similar situations in the future. The role played by different brain areas within the telencephalon has been studied using surgery to make very precise brain lesions to prevent defined areas of the brain from working. After fish recover from the surgery they are given a number of different tasks to perform and their solution is compared with control fish with no lesion.

Damage to the medial pallial area of the forebrain impairs tasks that involve some form of emotional learning. In one study, goldfish were trained to avoid a mild electric shock. How the fish learn to avoid electric shocks can be measured using a shuttle-box tank – this is a tank divided into two ends with a shallow channel connecting the ends (**Figure 3**). The fish learn that when a light is switched on, they must swim to the opposite end of the tank – if the fish fail to leave the side they receive an electric shock, but if they swim to the opposite end no shock is given. Normal goldfish have no difficulty in learning that the light cue means that they should quickly escape from the area they are currently in. After surgery, fish with a lesioned medial pallial area are slower in this shuttle-box task. It is believed that damage to the medial pallial region of the fish forebrain prevents the fish from recognizing the fear associated with the delivery of a shock and this impairs the formation of the memory.

Responses strikingly similar to those seen in the goldfish have been shown in mammals when a particular area called the amygdala is lesioned. Next to the amygdala in the mammalian brain is another important region called the hippocampus; this structure in both birds and mammals is known to play a vital role in two different kinds of learning and memory process. The first is associated with

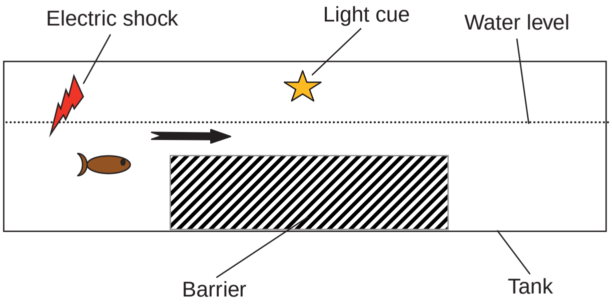

Figure 3 Schematic drawing of a shuttle-box tank. A light signal is shortly followed by the delivery of a mild electric shock. Fish learn to avoid the shock by swimming through a narrow area to the opposite end of the tank when the light cue is switched on.

spatial learning – being able to recognize where we are in an environment relative to key features such as a safe place to hide or a good place to find food. The second involves the timing or sequence of events or processes. To see if fish showed similar impairments, researchers began to look at the area next to the medial pallial region – the lateral pallial area. When this region was surgically lesioned, goldfish had deficits in learning and remembering spatial and timing tasks. Thus, the lateral pallial area functions in a very similar way to the hippocampus found in birds and mammals.

The results of these lesioning experiments are intriguing at several levels and clearly point toward a remarkable degree of anatomical conservation of brain function across the vertebrates from fish to birds and mammals. By carefully observing the early development of the fish brain and comparing this to the development of a mammalian brain, it has now been shown that the lateral and medial pallial regions of the fish brain have the same developmental origins as brain tissue that goes on to become the specialized hippocampus and amygdala (respectively) in the mammalian brain.

Factors That Affect Learning and Memory

The environment a fish lives in can influence many aspects of fish cognition. For fish that school or live in groups, the social environment can influence both what is learned and how it is learned. For example, social learning can be an effective way to learn new skills. Fish watching other fish perform a task can learn to copy the behavior. All kinds of information relevant to survival in nature can be learned by watching others, for example, the location of profitable feeding patches, the nest site of an attractive mate, a novel route that leads to a safe area with shelter, how to capture and handle a new kind of prey, or how to recognize species that are dangerous predators.

However, the process of learning about predators can be dangerous – if you make a mistake it may be your last (**see also Behavioral Responses to the Environment**: A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food). Detecting predator presence or categorizing different types of predator is possible in several fish species. In some species, such as guppies and minnows (*Phoxinus phoxinus*), pairs or small groups of fish will move closer to a predator to inspect it. This apparently intrepid behavior is used to determine how likely the predator is to seek out prey at that point in time. Once the group has gauged the predator's motivation to hunt, they return to their school.

Fish that lead a more solitary existence, or those that only school from time-to-time, typically rely on trial and error learning – learning new skills and recognizing what works or does not work for themselves. Even for these fish, the environment can shape the kinds of information that they learn and use. Different populations of threespine sticklebacks, for example, learn and use very different forms of spatial information. Fish sampled from ponds use visual landmarks to guide them to a particular location, whereas fish from river habitats use direction of water flow(rheotaxis). To explore these different preferences, researchers tested pond and river fish in a long channel down which there was a uniform flow of water and a series of visual landmarks of rocks or plants. At one end of the channel a small amount of food was hidden among gravel and the fish had to learn how to locate it. Sticklebacks from river environments almost always relied on the direction of water flow to help them locate the hidden food, whereas sticklebacks from pond environments relied on visual landmarks (**see also Sensory Systems, Perception, and Learning**: Spatial Orientation: How do Fish Find their Way Around?; **Figure 4**).

A series of control trials proved that the sticklebacks did not rely on the smell of the food, but rather they learned how to find the food using concepts such as 'swim upstream', 'swim downstream' or 'the food is by the rock'.

In certain cases memory duration appears to be directly affected by how changeable different experiences are. For instance, fish from stable and unchanging environments develop longer-lasting memories than fish from places where things change on a regular basis. Examples of this can be seen in how different prey capture and handling skills are remembered. If fish consistently experience one or two forms of prey, they remember the specific techniques that enable them to effectively forage on those prey. However, fish that face changes in availability of different prey species appear to forget how to handle certain kinds of prey if they do not encounter them for a few days.

Sensitive Phases for Learning or Imprinting

Some forms of learning take place only during a particular phase in an animal's life. Learning that occurs during a particular sensitive time or phase is often referred to as imprinting. Not all fish undergo phases of imprinting, but one well-studied example is the Atlantic salmon, *Salmo salar*. During the first year or so of their life, juvenile Atlantic salmon live in freshwater streams and rivers. In late spring juvenile salmon start to change their behavior and physiology as they prepare for the migration that will take them out to sea (**see also Fish Migrations**: The Biology of Fish Migration and Pacific Salmon Migration: Completing the Cycle). As their bodies begin to prepare for life in saltwater, there are surges in hormones such as thyroxine that are believed to promote reorganization in specific parts of the brain associated with processing olfactory information. These areas change because the fish

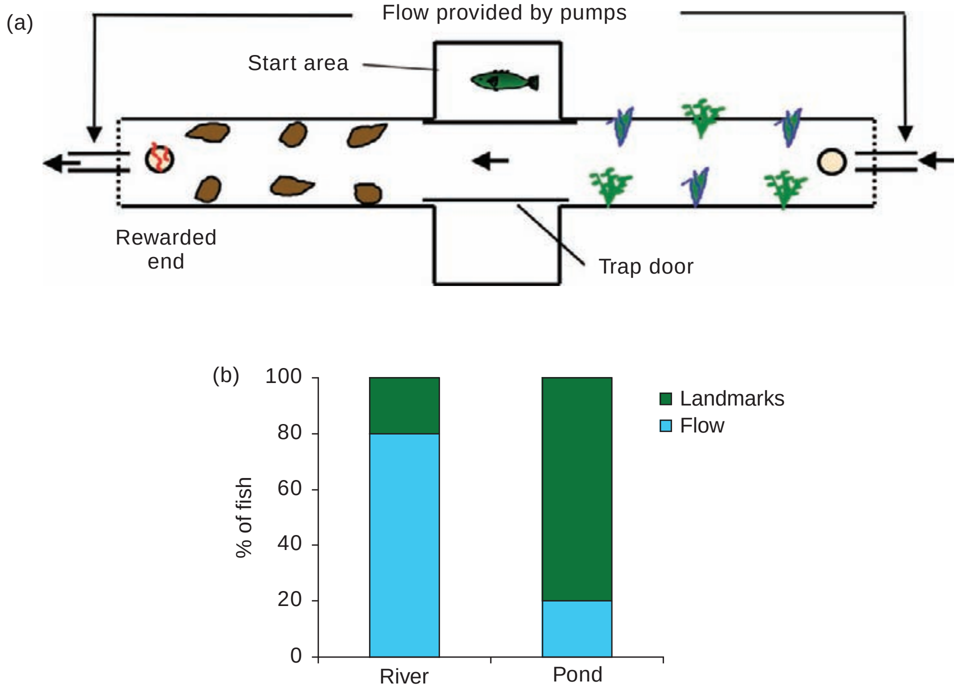

Figure 4 (a) Schematic diagram of the channel with two spatial cues: water flow direction or different visual landmarks. Threespine sticklebacks sampled from rivers and ponds are tested to determine which type of cue they prefer to use to help them locate the food reward (three worms) hidden at one end of the channel. The fish can be released from one of two possible start chambers and the order in which these are used is randomized to prevent the fish from learning a simple turn direction to solve the task. Using both start chambers during training prevents the fish from learning rules such as 'turn right on entering the channel'. Once fish have learned to locate the food reward, the spatial cue they use (water flow or visual landmark) can be tested by putting the two cues into conflict with each other. For example, the flow direction can be reversed within the channel, or the plant and rock landmarks could be switched between ends. (b) Results from a cue conflict trial. Fish sampled from rivers were shown to follow the flow direction to try and find the food reward. However, fish sampled from ponds preferred to remember which visual landmarks they should swim past.

need to learn and remember the signature odors of their river system. As the fish begin to swim downstream toward the sea they imprint, or learn, river-specific smells released by the plants and animals living within the river. These smells form a sequence, or list, of learned odor landmarks that can be remembered and reversed years later to help the fish find their way home when they are sexually mature.

Learning and Memory in Applied Contexts

Knowing that fish are capable of different forms of learning and memory and how this affects their behavior is used to help manage populations of fish. For species that are farmed, it is increasingly common for farmers to train the fish to feed themselves. Special feeders allow fish to obtain only a small meal of a few food pellets at a time as opposed to large numbers of pellets being sprayed across a sea cage or pen at random times of day. This method of self-feeding has a number of advantages; it means the fish are able to feed when they are hungry and motivated to feed; it results in better growth. Furthermore, this technique uses less food overall which leads to less waste which has both positive economic and environmental implications.

There are several different types of self-feeder now commercially available. Some require the fish to swim toward the feeder and this breaks a light beam signaling the feeder to release a small number of pellets. Other designs require the fish to push a paddle with their snout or pull on a string to release the food pellets (**Figure 5**).

In situations where populations of fish are threatened, various conservation programs try to restock captive-reared fish in attempts to increase the biomass of the fish population. Many reintroduction programs have failed because the majority of released fish perish shortly after release. The problem appears to be that once the fish are released into the wild, they need to learn how to forage on live prey and how to respond to predators. The hatchery environment does little to promote learning and memory in this regard – during early development all the fish experience is the constant, safe routine environment where pellet food is plentiful and predators are excluded. Various attempts have now been made to train the fish as to how to feed on live prey, how to recognize predators, and how to respond to change and novelty by learning and remembering previous experiences.

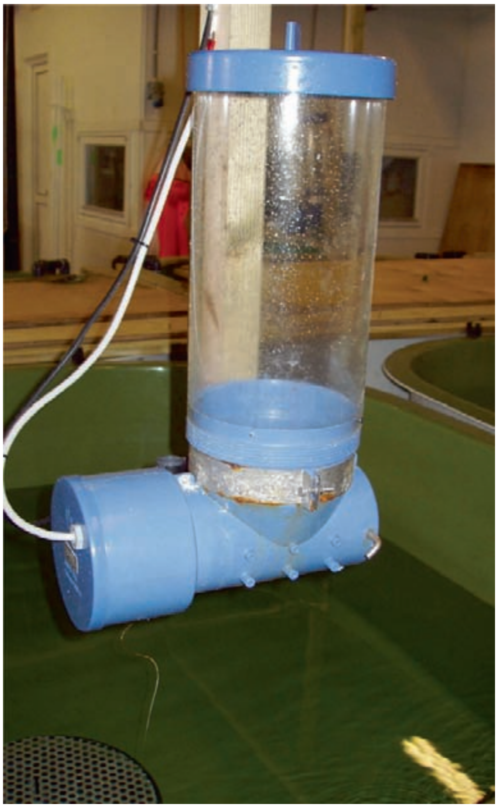

Figure 5 Photograph of an ArvoTec TD2000 self-feeder. The wire underneath the feeder can be pulled to deliver a small number of pellets into the water below the feeder. Fish learn to manipulate the wire using their mouths.

Summary

In this article the fundamental role played by learning and memory processes has been explored. These skills give fish the ability to adapt and shape behavior, allowing fish to out-smart predators and helping them find and relocate profitable feeding sites. Although fish were once portrayed as simple stimulus–response automata with limited memory capacity, we now recognize many fish as having impressive cognitive abilities, with some fish even rivaling other land-based vertebrates such as the birds and mammals.

Glossary

Analgesia The absence of the sense of pain without loss of consciousness usually provided by an analgesic drug or endogenous opioids.

Analgesic A medication or drug (painkiller) that reduces or eliminates pain.

Classical conditioning A learning process in which an organism′s behavior becomes dependent on the occurrence of a stimulus in its environment by pairing a neutral stimulus with a stimulus that evokes a behavioral response; the stimulus that evokes the behavioral response is given whether or not the conditioned response occurs until eventually the neutral stimulus comes to evoke the behavioral response.

Habituation The gradual decline of a response to a stimulus resulting from repeated exposure to that stimulus.

Negative reinforcement A particular behavior is strengthened by the consequence of the stopping or avoiding (e.g., escape) of a negative condition (e.g., electric shock). Negative reinforcement strengthens a behavior because a negative condition is stopped or avoided as a consequence of the behavior.

Nociception The neural process of encoding and processing noxious stimuli that may damage tissue and be potentially painful. It is the afferent activity produced in the peripheral nociceptors that is transmitted to the central nervous system.

Nociceptors Sensory cells that preferentially detect mechanical, thermal, or chemical stimuli, above the noxious threshold. Nociception is usually accompanied by a reflex withdrawal response and may also result in the sensation of pain.

Noxious stimulus An agent that can potentially cause injury to tissue. Agents such as high mechanical pressure, extremes of temperature (usually above 40 °C for mammals and 30 °C for temperate fish or below 4 °C), and chemicals that excite the free nerve endings of nociceptors (e.g., acids or irritants), are noxious.

Pain An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.

Stress-induced analgesia A physiological mechanism where increased stress reduces sensitivity to noxious stimulation or pain. Moderate stress provides an analgesia effect via the release of endogenous opioids from the central nervous system.

What Are Nociception and Pain?

The detection of a noxious stimulus that may produce or actually produces tissue trauma is termed ‘nociception’. This important sensory mechanism is typically followed by an instantaneous reflex withdrawal response away from the noxious stimuli. Nociception can be considered as an alarm system that alerts an animal to potential damage and enables it to take appropriate action to minimize or avoid injury. All vertebrates, including fish, and some invertebrates have nociceptors, receptors which preferentially detect noxious stimuli.

Tissue damage gives rise to the sensation of pain in humans but whether animals experience an internal emotional state and have feelings is subject to debate. Human pain is described by the International Association for the Study of Pain as “An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” For pain assessment to occur we rely on self-report between humans – we can tell each other about the pain we feel. However, this is impossible when trying to detect pain in other animals. Nociceptors, of course, do not detect pain *per se.* Instead, like all other sensory receptors, they simply detect an environmental change, which in this case is a noxious and potentially damaging stimulus (**see also Toxicology:** The Effects of Toxicants on Olfaction in Fishes). The sensation is produced by the nociceptive system and the brain.

To explore the possibility of pain perception in nonhumans we use indirect measures similar to those used for human infants who cannot convey whether they are in pain. We measure physiological responses (e.g., cardiovascular) and behavioral changes (e.g., withdrawal) to assess whether a tissue-damaging event is painful to an animal. If these responses are comparable to those of humans and are protracted negative changes, this may signify some degree of discomfort. In addition, if the administration of a painkiller or analgesic reduces any adverse reactions in animals, then it can be hypothesized that these responses are a direct result of a noxious, potentially painful, experience.

Definitions of animal pain are based upon behavioral and physiological changes rather than subjective states that cannot be measured. In addition to the detection of noxious stimuli and the accompaniment of an immediate reflex withdrawal, vegetative responses may also occur that signal pain (e.g., inflammation and fight-or-flight responses). Of the key behavioral changes, this article focuses on learning to avoid a noxious stimulus, nonreflexive changes in behavior, and suspension of normal behavior. Many behaviors shown by injured animals (including humans) aim to reduce additional damage, and also drive the individual to learn to avoid future damage and to allow healing. Other neurobiological criteria have been suggested to verify the capacity for pain in animals.

Why Is Fish Pain Controversial?

Fish have a nociceptive system, the simple detection and reflex withdrawal response to noxious stimuli – this is an accepted fact. The debate centers on the idea that fish may experience the suffering or discomfort necessary for pain perception. In part, the debate considers the lack of an enlarged neocortex identical to the human cortex (**see also Brain and Nervous System:** Functional Morphology of the Brains of Ray-Finned Fishes). Without an enlarged neocortex, it is suggested that fish are incapable of having an emotional state similar to human feelings and that any response to pain is reflexive and limited to the hindbrain and spinal cord. However, studies have now shown that the forebrain and midbrain of several fish species are activated in a specific way to tissue damage.

If the argument that fish do not possess the brain structures to experience pain is accepted, then only primates and humans can suffer from a painful experience; hence, fish, amphibians, and reptiles, including birds and nonprimate mammals, cannot suffer and are merely reflex in nature by making only automatic responses to external stimuli without any thought process. This opinion suggests that a function suddenly arises in evolution with no primitive ancestor and, as such, is contrary to the established knowledge of the mechanisms of evolution of other motivational drivers or emotions. Rather than suggesting that animal pain has to be indistinguishable from pain as experienced by humans, perhaps animal pain should be considered on a phylogenetic sliding scale with fish having a primitive, rudimentary type of pain and humans having an advanced pain sensation.

Recent research has demonstrated that fish fulfill the criteria for animal perception of pain as defined by authors such as Bateson, Molony, Sneddon, and Zimmerman. Fish possess a similar nociceptive apparatus compared with mammals; a potentially painful stimulus results in negative changes in physiological responses and detrimental changes in behavior (although some of these may aid recovery from pain); and administration of analgesia ameliorates these reactions.

The remainder of this article now leaves the issue of perception of pain and focuses on responses to noxious, potentially painful stimuli. Specific attention is given to the capacity of fish to learn to avoid noxious stimuli, behavioral responses to a potentially painful event, species-specific responses, and finally whether such stimuli are important to a fish.

Learning to Avoid Noxious Stimuli

Fish learn to avoid noxious stimuli and often exhibit learning after just one trial in experiments using classical conditioning with negative reinforcement. These experiments involve fish learning to associate a predictive or conditioned stimulus (CS) with an unconditioned stimulus (US) to perform a conditioned response or behavior (**see also Sensory Systems, Perception, and Learning:** Fish Learning and Memory). Negative reinforcement uses a punishment to train the fish and typically this is an electric shock that is painful to animals (including humans). Fish are, therefore, trained to associate an innocuous CS (e.g., a light or sound) with the US (e.g., an electric shock) which is given rapidly after the CS to produce an escape response. Eventually, the fish learns to perform the escape response to the CS even before the electric shock is given. In this way, the fish is successfully conditioned to exhibit the escape response prior to the shock in order to avoid what should follow the CS.

Goldfish (*Carassius auratus*) and rainbow trout (*Oncorhynchus mykiss*) will avoid an area where they are given an electric shock for some time afterward. However, if this area is also the feeding area, starved goldfish will re-enter the area after 3 days to seek food (**Figure 1**) and trade off obtaining food with experiencing the electric

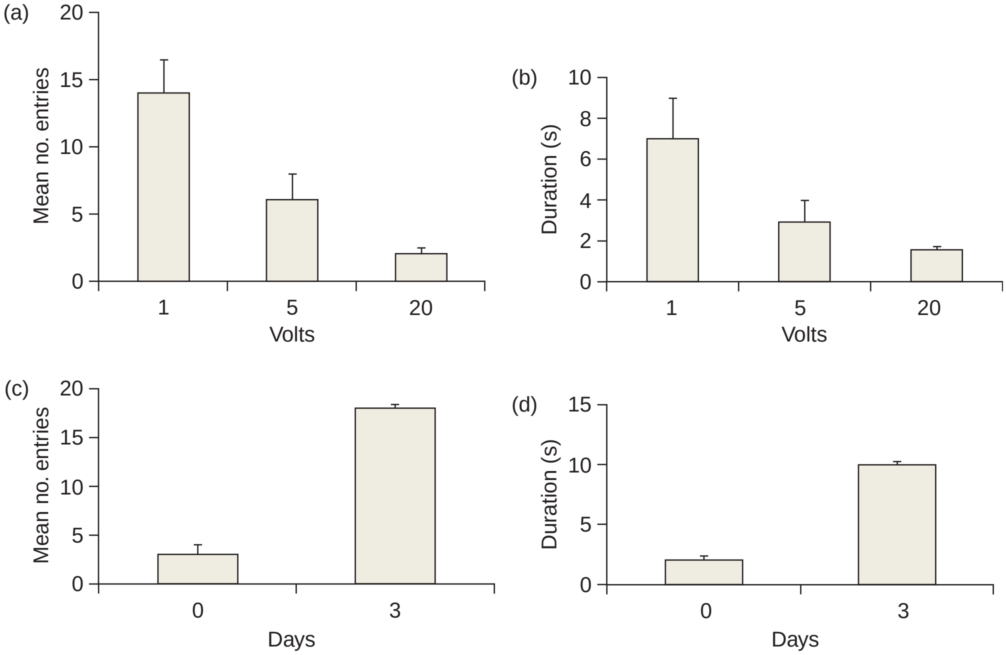

Figure 1 (a) Mean number (+SE) of entries and (b) duration (+SE) of time spent in a feeding/electric shock zone in goldfish after the application of an electric shock at 1, 5, and 20 V. (c) Mean number (+SE) of entries and (d) duration (+SE) of time spent in the feeding/electric zone in goldfish after 0 and 3 days food deprivation. Reproduced from Millsopp S and Laming P (2008) Trade-offs between feeding and shock avoidance in goldfish (*Carassius auratus*). *Applied Animal Behaviour Science* 113: 247–254, with permission from Elsevier.

shock. However, as the intensity of the electric shock increases, the number of entries and time spent in this shock/food zone decrease remarkably (**Figures 1**(**a**) and **1**(**b**)). Food deprivation for 3 days results in goldfish increasing the number of entries and time spent in this shock area (**Figures 1**(**c**) and **1**(**d**)), but the fish perform more tail flips and escape responses when in this zone, possibly due to the previous experience of being shocked. This would suggest some form of fear or anticipation of the shock. Other experimental studies using classical conditioning with an electric shock show that when using morphine, a painkiller, goldfish do not respond to the shock. Therefore, teleost fish can learn to avoid a noxious, potentially painful stimulus.

Behavioral Responses to Pain or Nociception in Fish

Relatively few studies have explored the responses to a potentially painful event in fish. However, evidence is growing that fish exhibit detrimental changes in behavior while experiencing a potentially painful stimulus, although some of these changes may aid recovery. Noxiously stimulated rainbow trout, common carp (*Cyprinus carpio*), goldfish, and zebrafish (*Danio rerio*) display abnormal behaviors after subcutaneous injection of dilute acetic acid (0.1–5%) into the frontal lips. These include (1) rocking where the fish rocks from either pectoral fin on the substrate, which is a similar behavior to a fish struggling to maintain equilibrium and (2) rubbing the injection site typically against the side of the tank and/or into the substrate. These behaviors are mainly seen immediately after the injection of the noxious stimulus (**Figure 2**) when the stimulus is likely to be the greatest.

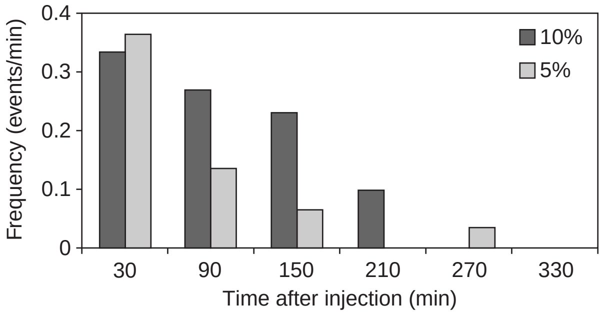

Figure 2 The frequency of anomalous behavioral events performed by common carp after subcutaneous injection of 5% or 10% acetic acid at 30-min intervals after the treatment. Reproduced from Reilly SC, Quinn JP, Cossins AR, and Sneddon LU (2008) Behavioural analysis of a nociceptive event in fish: Comparisons between three species demonstrate specific responses. *Applied Animal Behaviour Science* 114: 248–249, with permission from Elsevier

Rocking, as seen in primates and other animals, has been interpreted as an indicator of poor welfare, and the act of rubbing a painful area is seen in mammals (including humans). However, in fish these behaviors appear to be context specific. In barren conditions of rectangular or cylindrical tanks, the frequency of rubbing is reduced in rainbow trout relative to tanks that contain a gravel substrate. Increased stress also reduces the performance of these behaviors perhaps due to stress-induced analgesia. High stress results in the release of endorphins that can act as natural painkillers within the mammalian nervous system, thereby reducing the perception and performance of pain-related responses.

Decreased activity levels and frequency of swimming are also observed in zebrafish and rainbow trout (**Figure 3**), although this response appears to be species specific (see below). While the acute response to a noxious stimulus is a rapid escape response, it is typically followed by a reduction in frequency and duration of behaviors, which is believed to conserve energy for the healing process as well as having a protective role over further injury to the wounded area.

In addition to these behavioral changes, injection of acetic acid dramatically increases ventilation rate or opercular beat rate, suggesting increased metabolic rate. However, the ventilation rates observed during pain tests (90–100 beats/min) are much higher than those typically recorded for rainbow trout during other forms of stress such as handling (~69 beats/min) and are more comparable with rates recorded when trout are swimming at maximum speed. Given that activity is reduced in these fish, it would appear as if they are ventilating rapidly with no obvious extra energy demands except recovery from the painful event (**Figure 4**). This rise in ventilation rate subsides along with the reduced performance of anomalous behaviors and the return to normal activity.

One of the key factors for an animal to be considered experiencing pain is the suspension of normal behaviors. Acid-treated rainbow trout did not resume feeding for 180 min (**Figure 5**) unlike those injected with saline, which resumed feeding after 80 min. Acid-treated rainbow trout administered with morphine do not show this increased latency to feed and resume feeding at the same time as control fish. Indeed, morphine also ameliorated both the reduction in activity and the increase in ventilation rate, suggesting its efficacy as an analgesic in rainbow trout. However, another study conducted quite differently recorded rainbow trout feeding immediately after a similar noxious stimulus; the explanation for the differences between studies is unknown.

Species-Specific Responses

Pain-related responses differ between species. For example, rabbits are more likely to respond to pain by remaining motionless (freezing) for long periods unlike

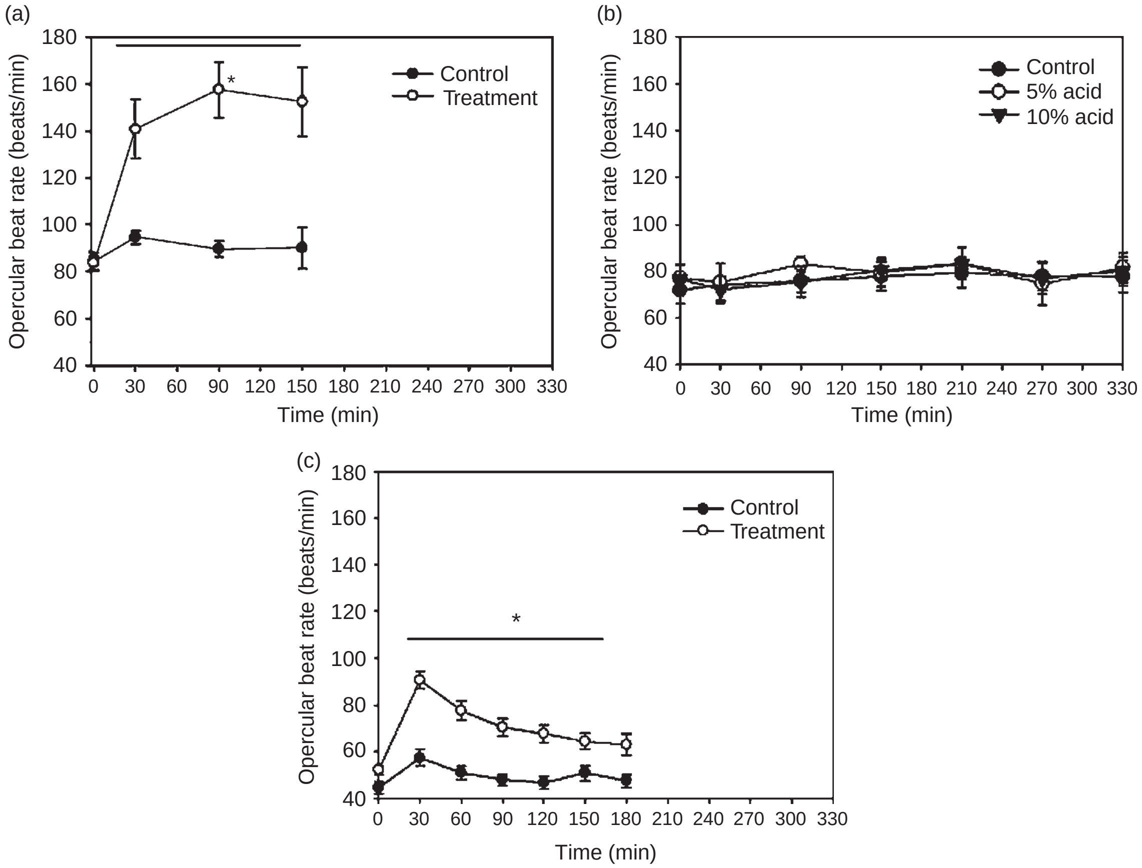

Figure 4 The mean frequency of opercular beats (±SE) before (0 min) and at subsequent intervals after the subcutaneous injection of saline as a control and acetic acid (treatment) in (a) zebrafish, (b) common carp, and (c) rainbow trout. rodents, which perform a variety of behaviors such as writhing and flinching. Common carp, rainbow trout, and zebrafish show different responses to noxious stimuli (**Figures 3** and **4**). Although all the three species express rocking behaviors, only rainbow trout and common carp rub the affected area. Zebrafish and rainbow trout decreased activity (**Figure 3**) and enhanced ventilation rate (**Figure 4**) but common carp did not (**Table 1**). This species variability has an impact on developing universal and robust indicators for assessing the perception of pain in fish. Putative pain indicators may be needed for each fish species since even within the cyprinid group, common carp and zebrafish display significant diversity in their response.

Intraspecific variation has also been recorded. Rainbow trout responses vary according to the degree of boldness (or stress coping style). Some rainbow trout are classified as bold due to their relatively high propensity for taking risks in the face of novel circumstances in contrast to shy fish that exhibit a cautious strategy and are less willing to take risks. Bold fish are much more active, aggressive, and perform high-risk behaviors when under predation risk compared with shy fish. These individual phenotypes influence many behaviors, including responses to a

Table 1 Behavioral changes seen in common carp, rainbow trout, and zebrafish after the administration of a noxious stimulus

Response to pain	*Common carp*	*Rainbow trout*	*Zebrafish*

potentially painful event. Under predation risk, noxiously stimulated bold rainbow trout actually reduce their use of a refuge area in response to a predator cue in contrast with both bold and shy controls which increase their refuge use. Bold trout are also more willing to perform rubbing behavior at a higher rate than shy fish. Dominance status also affects the response to noxious stimuli because subordinate trout exhibit no physiological or behavioral changes during noxious stimulation (see details below). Therefore, boldness and dominance status should be accounted for when assessing pain-related responses.

How Important Would Pain Be to a Fish?

Much of the controversy surrounding fish experiencing pain revolves around the question of whether or not the fish has a conscious awareness of pain. However, it is impossible to get into the mind of a fish and know what it truly experiences. Rather than tackling this impossible-to-measure concept, researchers have explored how significant the experience of noxious stimuli or pain is by providing competing stimuli. If pain is important, the animal should be unable or show impaired responses to other stimuli. However, if responses to competing stimuli take priority, then perhaps the perception of noxious stimuli is less significant to fish.

Rainbow trout normally avoid novel objects, but when given a noxious stimulus their fear response diminishes. Acid-injected fish spent approximately 33% of their time in close proximity to the object compared with <5% in control fish injected with saline. When given morphine, acid-injected fish avoid the object, demonstrating that analgesia resulted in a normal fear response. Similarly, noxiously treated rainbow trout do not perform anti-predator behaviors when a predator cue is introduced into their tank (**Figure 6**(**a**)). Control fish increase escape attempts and increase refuge use, whereas acid-injected fish do not and actually reduce cover use in response to a predator cue. These experiments demonstrate that pain may take priority in the context of fear and predation.

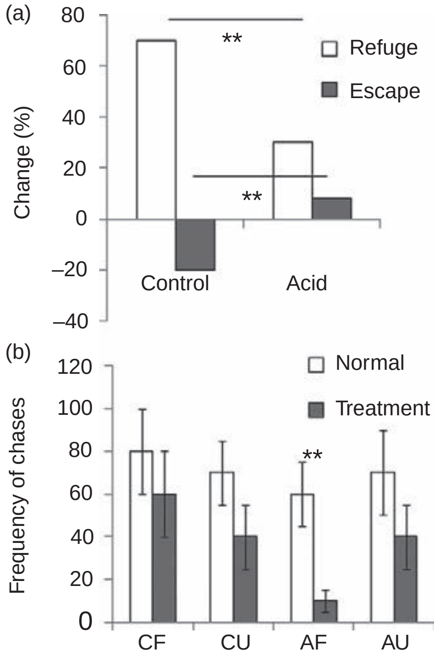

Figure 6 (a) The mean percentage change in refuse use and escape behavior in rainbow trout that were injected subcutaneously with saline as a control or acetic acid. (b) The mean frequency of aggressive chases performed by dominant rainbow trout before (normal) and after (treatment) injection with saline and placed into a familiar (CF) or unfamiliar (CU) social group or injected with acid ($^{**}P < 0.001$). AF, familiar; AU, unfamiliar (upper line indicates significant difference between control and acid fish in refuge use; lower line indicates significant difference between control and acid fish in escape behavior; $^{*}P < 0.05$). Reproduced from Ashley PJ, Ringrose S, Edwards KL, *et al*. (2009) Which is more important in fish: Pain, anti-predator responses or dominance status? *Animal Behaviour* 77: 403–410, with permission from Elsevier.

Most experiments have been conducted on individual fish and few have accounted for fish being held in social groups. Animals will readily exhibit pain-related changes in behavior in isolation, but not in the presence of conspecifics. This altered behavior may serve to protect the individual's social status. Alternatively, the external stimuli may produce opioids that would reduce pain-related changes.

Rainbow trout readily form dominance hierarchies (**see also Social and Reproductive Behaviors:** Dominance Behaviors). Acid-injected dominant trout do not exhibit any physiological changes seen in individually housed fish, such as increased plasma cortisol or elevated ventilation rate, but they do show a suspension in their normal rate of chasing the lower-ranked fish. However, when acid-injected dominants are placed in a tank with unfamiliar fish, the reduction in aggressive chases is not seen and it would appear that maintaining dominance status is the imperative in this context (**Figure 6**(**b**)). This behavior correlated with high plasma cortisol in the unfamiliar treatment, possibly resulting in stress-induced analgesia. Social status in rainbow trout and other salmonids is particularly crucial in obtaining the best resources with dominants monopolizing food and preferable habitats, whereas being subordinate comes at a high cost with increased stress levels. This may explain why status took priority over exhibiting signs of pain.

Future Research Perspectives

Research on nociception and its relationship to pain perception in fish is in its infancy. Even among the few fish species studied, profound species differences exist for the responses to noxious stimuli; therefore, many more species need to be tested to develop behavioral criteria for species-specific pain assessment. In addition, only electric shock, temperature, and subcutaneous injection of noxious stimuli to the lips have been used to evoke responses. Other tests such as application of noxious stimuli to fins may be more relevant given the prevalence of fin erosion, especially in spawning salmon in aquaculture. Confounding factors such as intraspecific variation in behavioral phenotype and environmental and/or social context also warrant further exploration. Fish may be less willing to perform pain-related behaviors in a certain context but this does not mean they are not experiencing the negative affective component of pain. Given the debate surrounding catch-and-release angling, there is little evidence to date that hooking a fish results in pain even though the tissue damage is likely to be nociceptive. Studies are needed to thoroughly examine this important area.

Glossary

Allocentric cues Features of the environment that are stored in an animal's memory and used to navigate.
Beacon A landmark that directly signals the position of a goal.
Compass A cue that imparts directional information.
Egocentric cues Body-centered movements related to direction traveled.
Ethmoid tissue Tissue around the nasal cavity.
Migration A regular directed movement of a group of animals.
Pilotage Orienting by chaining landmarks or locations together in sequence.
Rheotaxis A directional preference to flowing water.
Route integration An ability to gauge position in relation to a starting point, which would allow an animal to take a winding path outward and then travel directly back home. This is also known as dead reckoning.
Spatial map An internal representation of space based on surrounding objects.

Introduction

Fish are the most diverse vertebrate group, living in every aquatic niche from the open sea to small freshwater ponds, and differences in the behavior between species reflect this diversity. Some fish remain in a similar location for their entire lives and others migrate over vast distances to reach suitable feeding or breeding sites (**see also Fish Migrations:** The Biology of Fish Migration). These behaviors present a variety of navigational challenges to fish during their lifetimes. For example, Pacific salmon spawn in freshwater lakes or streams, and after a period of time, the offspring migrate to sea (**see also Fish Migrations:** Pacific Salmon Migration: Completing the Cycle). Once mature, the fish are able to home precisely to their natal stream to spawn, and so the cycle is repeated. These long-range migrations are one end of the navigational scale. At the other end, fish are challenged within their local home range to find mates, avoid predators, and find their way home. To achieve all of these fish must be able to orient efficiently, and in the aquatic environment this has to be in all three dimensions rather than the two with which we as terrestrial animals are familiar. Of course, fish need to obtain information about their surroundings to be able to navigate over both large and small distances. The sensory systems of fish have evolved to cope with the unique difficulties that they face in their aquatic environments. The different sensory systems that fish have also affect the way that they navigate.

This article deals with the way that fish navigate between locations. First, the mechanisms of long-range migration are discussed, before considering how fish orient over local areas using memory-based systems. Second, the senses that fish use to obtain information from their surroundings are examined. Together, this gives an overview of how this diverse group of vertebrates perceive and learn information about their spatial world, and how they act on this information to orient efficiently from place to place.

Orientation Mechanisms

Long-Range Migration

Some of the most famous examples of fish navigation are the incredible feats of salmon migration (Salmonidae). These fish spawn in freshwater systems where they reside for an amount of time that varies from days to years depending on the species, before migrating to the sea (**see also Fish Migrations:** Pacific Salmon Migration: Completing the Cycle). Migration is a costly process and many fish do not survive. There must, then, be overriding benefits to the fish for this behavior to have evolved. It is thought that migrating salmon take advantage of the high productivity of the marine environment. This increase in food quantity and/or quality allows the fish to grow fast, and to reach a larger overall size. Over evolutionary time, this would lead migrating fish to have a higher level of fitness (more surviving offspring), than fish that did not migrate. After a period of time in the open sea the salmon home back to their natal stream with an impressive level of spatial and temporal accuracy.

There are still many mysteries about the way that fish migrate in the open ocean. This is partly due to the difficulty of studying fish in marine environments and consequently, most of what we know about navigational mechanisms has been gleaned from controlled laboratory experiments. Salmon need two pieces of information to successfully return home. The first is the location of their current position with respect to home, and the second is the heading that they must take. In other words, they need a map and compass. It is not known how salmon ascertain their own position in the open ocean, but it is thought that they may use magnetic cues in a bicoordinate system, as some turtles do. More research has considered the cues that salmon may use as a compass, but the evidence is still scant.

A number of different sources of information could play a role in compass guidance including celestial and magnetic cues, both of which are used by terrestrial animals to navigate over large distances. By using polarizing filters, it was found that juvenile rainbow trout (*Oncorhynchus mykiss*) can use polarized light patterns in the sky to obtain directional information, but surprisingly they lose this ability as they reach adulthood, so polarized light cannot be used as a compass to guide adult salmon home. Other fish have been shown to use the sun as a time-compensated compass and this remains a candidate cue for migrating salmon. However, the problems with celestial cues are that they are unavailable when the sky is overcast, and their use is restricted to close to the water surface.

More recently, it has been suggested that salmon might orient to the Earth's magnetic field. Rainbow trout are able to detect changes in the intensity of an experimentally imposed magnetic field, and the mechanism behind detection appears to rest with the presence of biogenic magnetite particles in the snout of these fish (**see also Sensory Systems, Perception, and Learning:** Magnetic Sense in Fishes). In electrophysiological experiments, it was shown that the trigeminal nerve, near the snout of the trout, responded to changes in magnetic field intensity. Behavioral studies showed that the trout could discriminate between magnetic field intensities – the fish could be trained to swim to and strike a target to obtain food when only one of two intensities was presented. So together, the evidence shows that fish can respond to changes in the magnetic field in experimental situations. The challenge now is to determine whether they do use magnetic cues in their natural environment, when they are navigating across the open ocean.

Once they have orientated themselves in the direction of home, the salmon must locate their natal stream. Experiments have shown that they are able to do this by using site-specific olfactory cues, which the young salmon imprint on while swimming seaward. This sensitive phase in learning in the smolts coincides with an increase in the level of the hormone thyroxine, which is thought to trigger neural changes in the olfactory system. During their homing journey, the mature salmon use these learned olfactory signals to enable them to reach the precise location where their journey originated. The fish orient themselves against the direction that the signal is traveling (positive rheotaxis – i.e., facing into the current), allowing them to home to the olfactory source over long distances (**see also Fish Migrations:** Pacific Salmon Migration: Completing the Cycle and Eel Migrations).

Short-Range Orientation

Fish that do not migrate, but remain in the same area over their lifetimes, also face navigational challenges. Tracking current position in relation to important locations, such as a home site or shelter, would enable a fish to find a mate, escape predation, or find its way home. One way of achieving this is to remember body-centered movements about directions traveled (e.g., turn left, then right). This is termed egocentric orientation.

A second way to orient efficiently is to encode allocentric cues from the surrounding environment into memory. This requires an individual to learn and remember certain aspects of its surroundings, which are then used to orient. The process can be very simple, for example, a fish could learn to associate a single landmark with a food reward, but it can also be complex – some fish can even learn and remember information from different sources and integrate these together. The next section examines the experimental evidence for these processes in more detail.

Learning egocentric cues

Fish can be trained to swim through mazes to obtain a food reward. If they are not given any landmarks (either inside, or outside the maze) to help them solve the task, they can learn a sequence of body-centered movements. For example, turn left, then right, then right again. Fish could use this type of information in their natural environment – chaining a sequence of commands together to move from place to place.

So, fish can learn egocentric cues to find a goal, but what happens if the fish makes an incorrect turn in the sequence, would it then be lost? One possibility is that fish could route-integrate in a similar way that early transatlantic navigators navigated across sea. To do this they would need to gauge their position in relation to a starting point and would need information about both distance and direction. They could then take a winding path outward from a starting point, and could then travel directly back home by calculating the most direct route. However, we do not yet know whether fish are capable of storing distance and direction and route-integrating by this method.

Learning allocentric spatial cues

Another way of orienting would be to learn spatial information about the surrounding environment. One of the first experiments that tested whether fish can do this was carried out in the early 1970s. It had been noticed that tide-pool dwelling gobies (*Bathygobius soperator*) could jump from one rock pool to another when threatened by a predator. Impressively, they could do this even when they could not see the landing pool from takeoff. This suggested that the fish were remembering something about their surroundings, but how? A number of interconnecting artificial pools leading to a large pool simulating the sea were set up (**Figure 1**). Half of the fish in the experiment were allowed to experience simulated high tide; all of the pools were covered in water so that they could swim over the entire area. Half of the fish were denied this experience. The fish were prodded with a stick, and it was found that they could only jump accurately from pool to pool and eventually to the sea when they had previously experienced high tide. This suggested that the fish were learning their surroundings at high tide, and they were using this spatial knowledge at low tide when they could no longer see each pool. So fish do seem to have an ability to form a map of their surroundings, but what type of information is included?

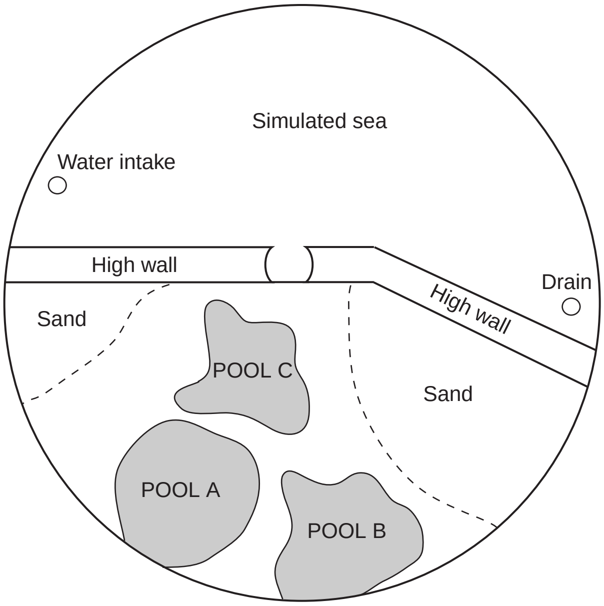

Figure 1 A plan view of the simulated tidepools used to test spatial memory in intertidal fish. At simulated high tide the fish were able to swim over the three pools and learn the general topography. At simulated low tide the fish were restricted to the pools, and could not swim over the area. Only the fish that had experienced high tide were able to jump from pool to pool and into the sea when threatened with a simulated predator. Modified from Aronson LR (1971) Further studies on orientation and jumping behavior in the Gobiid fish, *Bathygobius soperator*. *Annals of the New York Academy of Science* 188: 378–392.

Fish can use simple landmark cues to guide them. For example, goldfish (*Carrasius auratus*) were trained to use a plastic block as a beacon to label the location of a patch of food that was hidden under the substrate in a tank. However, what happens when the fish move out of range of such a landmark?

One possibility is that fish can learn a sequence of landmarks in order. We have already seen an example of this is salmon, which memorize a sequence of smells during their outward journey to the sea, and return by reversing this sequence. This ability to orient along sequences is also called pilotage and implies that fish can learn and remember the order of cues that they have previously encountered. Coral reef butterfly fish (*Chaetodon* spp.) swim backward and forward along a route to forage. When a coral reef head along this route was removed the fish got lost, suggesting that they were chaining features of the reef together in order in a similar way to the homing salmon.

This idea was tested further in blind Mexican cavefish (*Astyanax fasciatus*), which have no eyes and which orient using their mechanosensory lateral line organ. As the cavefish swim, they create a flow field in the water around them. When the fish pass an object, this field is distorted; cells in the lateral line detect these distortions and relay the information to the brain where an image of the fish's immediate surroundings is built (**see also Bony Fishes:** Blind Cavefish, **Hearing and Lateral Line:** Lateral Line Neuroethology, and Lateral Line Structure). Usefully from an experimental point of view, the cavefish swim faster when they encounter something that they do not recognize. This behavior enables a test of what the fish can learn and remember. By allowing the fish to learn an environment, changing a feature, and testing whether they speed up, one can test whether they have recognized the manipulated change, and therefore see whether they encoded that information during training. This was done in an experiment where the fish first learned a sequence of landmarks (which was shown by their speed decreasing). The landmark order was then switched. As the fish swam faster, it was concluded that they had recognized the change, and that they could learn and remember order. The perceptual range of the cavefish lateral line is less than two body lengths, but in the wild they would range across much larger areas. The experiments showed that they might be able to orient outside of their perceptual range by chaining landmarks together in order.

So, fish can use single landmarks to orient and can pilot along sequences in order. But what happens if the fish loses its way along a sequence, or if one of the landmarks moves? Fish may be able to learn and remember a spatial map that includes distances and directions between a number of landmarks. One of the first indications that fish can encode geometry came from work on goodeids. These fish appear to be able to use the angles and distances between the walls of an arena to find a reward. If placed in a rectangular arena (where the corners diagonal from one another are indistinguishable geometrically), the fish made errors as they could not tell the opposite corners apart. However, if the experimenters painted each wall a different color, the fish were able to find the reward with very few mistakes. It was concluded that they were able to learn and remember information about features and could combine this with the information about the geometry of the area to solve the task. However, recent work has revealed that instead of fish learning the complete geometry of an arena, they might just learn a snapshot-like view of one corner. This may have been enough to learn the task. Further work is being undertaken to work out how fish, and other animals, encode these kinds of spaces.

A further complication that fish face is that their environment is intrinsically three-dimensional. Aquatic systems, unlike terrestrial, are volumes through which fish can swim in all directions – up and down, side to side, and back to front. This potentially increases the difficulty of the orientation task. Aquatic environments have a unique extra cue that may aid this process, hydrostatic pressure, which fish might use to give them information about movement in the vertical axis. There has been very little work on three-dimensional orientation, and we are only just beginning to work out how fish cope with this problem.

Sensory Systems Used to Obtain Spatial Information

Fish have a number of different ways of sensing their surroundings and, not surprisingly given the difference in environments that fish and humans inhabit, these are very different from our own. Humans are highly visual animals – we tend to rely on our eyes to find our way around our local surroundings. Fish can also use visual cues, but their eye structures are different to terrestrial animals to cope with the demands of life underwater (**see also Vision:** Behavioral Assessment of the Visual Capabilities of Fish). There are two main problems for an animal that senses information using its eyes in aquatic systems. The first is the high refractive index of water, and the second is the high level of light absorption. The first is dealt with by the shape of the cornea, which is spherical with a high refractive index. The second problem is more difficult to solve. Light is absorbed by water, and scattered by suspended particles. In extremely clear water, objects cannot be seen for more than a few hundred meters, but in most cases, a fish's visual perceptive range is far shorter than this, sometimes only a few centimeters. Hence, vision may not always be the most appropriate sensory system to rely on.

Some senses impart general information about direction, or objects. For example, as seen above, fish have sensitive olfactory organs, which can be used to orient along chains of smells. Recently, sound cues have also been revealed to play an important role in orientation of coral reef larval fish. These fish return to reefs following a pelagic larval phase, and it appears that they may be attracted to reef sounds at settlement. Similar course-scale information is gained from the magnetic sense, which gives salmon long-range directional information during migration. Aquatic systems have a unique cue that is not present on terrestrial environments – hydrostatic pressure. Fish can use their gas-filled swimbladder to sense changes in pressure, and they can use this to ascertain their depth. Dogfish (*Scyliorhinus canicula*), which do not have a swimbladder, can use vestibular hair cells in their inner ear to sense changes in hydrostatic pressure. This allows fish to determine whether they are swimming up or down, which is essential in the three-dimensional aquatic environment.

Other senses impart fine-scale information. Vision is one, but as seen above, fish can sometimes be precluded from obtaining information in this way. The mechanosensory lateral line is a sensory system that is unique to aquatic animals, and that has specifically adapted to cope with the demands of a watery existence. Using this sense, fish can get extremely fine-scale information on their immediate surroundings. Some fish have also evolved an electrosense, which can operate passively, allowing a fish to respond to electric cues emanating from prey, or actively. The weakly electric elephantnose fish (*Gnathonemus petersii*) is in the latter category; they emit electric signals using a specialized organ in the tail. When these signals hit an object, they are bounced back and projected onto receptors on the surface of the skin. This is analogous to vision where images are projected onto the retina of the eye. Surprisingly, electric fish can make out object depth using electrolocation, which means that they can even perceive landmarks in three dimensions (**see also Detection and Generation of Electric Signals:** Active Electrolocation).

A fish's sensory systems can sometimes be integrated together during navigation, or they can be used in parallel systems, where one sense takes priority over another at certain times. For example, weakly electric fish use electrolocation to locate prey, but can switch to other sensory cues if the electric sense is impeded. Interestingly however, while schooling, these fish integrate both vision and electrolocation together – they need both for the behavior to persist.

Flexibility in Learning and Remembering Spatial Information

As seen above, there are a large number of ways that fish can orient efficiently from place to place. Recent work has aimed at working out when fish will use particular mechanisms. Two important factors influence what and when spatial information is learned: the first is the environment that the fish live in, and the second is the sensory system that the fish use to gain information.

Experiments have shown that fish that originate in ponds and rivers differ in whether they are likely to use landmarks or egocentric cues. Three-spined sticklebacks (*Gasterosteus aculeatus*) were trained to find food at the end of an arm of a maze-shaped like a 'T'. They could either learn to turn in one direction (e.g., left), or they could use a landmark, that was placed at the decision point, to guide them. Fish that were from ponds tended to use landmarks to orient through the maze, but fish from rivers were more likely to use body-centered cues. This seems to be due to the increased stability of ponds compared to rivers, where landmarks are more likely to be displaced by currents (**see also Sensory Systems, Perception, and Learning:** Fish Learning and Memory).

The sensory system that a fish has is also likely to influence the spatial mechanisms that it uses to orient. As described above, blind Mexican cavefish orient using their lateral line organs. These blind fish evolved from sighted ancestors that invaded caves in Northeastern Mexico about 100 000 years ago. Some of the eyed ancestors remained above ground; hence, there are two clear morphs of the same species – an eyed, surface and a blind, cave morph (**Figure 2**). The eyed fish are highly visual and can use their eyes to orient, whereas the blind fish must reply on their lateral line to gain fine-scale information about their surroundings.

Recent work has suggested that these different sensory systems affect the way that the fish orient. The eyed fish use landmarks, whereas the blind are less likely to. Presumably, this is because the perceptual range of the lateral line is smaller, so they cannot perceive landmarks from as far away as a visual animal is able.

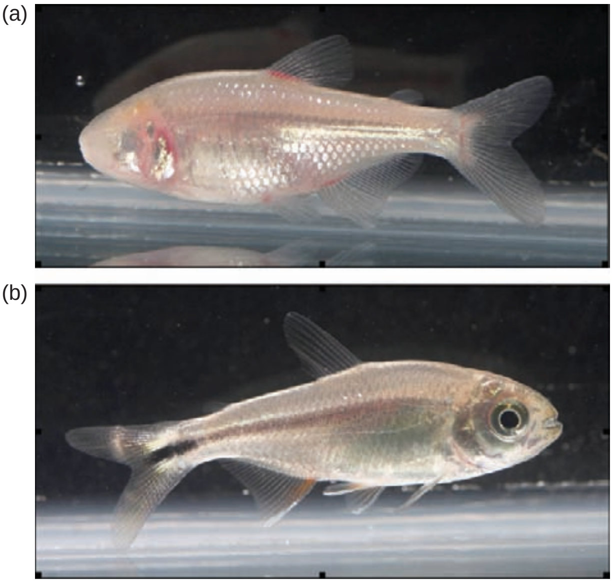

Figure 2 The two morphs of the species *Astyanax fasciatus*. (a) Blind cave morph, which relies on its lateral line to obtain fine-scale information of its surroundings. (b) Highly visual surface morph.

Conclusion

Fish are able to orient through their environments in a myriad of ways. They can migrate vast distances through relatively featureless oceans, and they can orient precisely within a short range. They use a huge variety of different senses to obtain information about their environment, ranging from senses that we are familiar with, such as vision, olfaction, and audition, to senses that are completely beyond our perceptual abilities. These include a magnetic sense which allow salmon to determine compass direction, and electrolocation, which enable weakly electric fish to perceive objects in three dimensions. The lateral line is a sense that is only found in aquatic animals, and has been exquisitely shaped to an aquatic existence. These sensory systems themselves appear to shape the way that fish orient through their surroundings, as does the environment that the fish live in. Fish can learn and remember an array of sophisticated information, which matches most terrestrial animals. They can learn simple pieces of body-centered information about whether to turn left or right to reach a goal. They can also encode spatial information from the surroundings into their memory. This process might be simple, telling a fish which landmark signals a goal, or it could be complex, including a memory of distances and directions between landmarks. In addition, fish must cope with the complexity of their volumetric world. Our challenge now lies in discovering how fish manage this, given that it is difficult for artificial intelligence systems and also for us humans.

Glossary

Magnetic moment The torque exerted on a magnet or dipole placed in a magnetic field.

Vector A quantity, such as a magnetic field, that has a magnitude (intensity) and a direction.

Introduction

Both teleost and elasmobranch fishes have been shown in behavioral experiments to possess a magnetic sense. Like birds, fish respond to both the direction and the intensity (the strength of the field or the force it exerts on, e.g., a compass needle) of the Earth's magnetic field. In compass reactions, fish orient their bodies or swim in particular directions in response to the direction of the Earth's magnetic field. Behavioral responses to the intensity of the Earth's magnetic field may be involved in position determination during navigation, in a manner similarly used by humans to determine position from geographic latitude and longitude. Taken together, these responses to magnetic intensity and direction, respectively, are consistent with the hypothesis that fish can navigate using a map to determine their current location and a compass to set a course toward a goal such as a feeding site, a migratory destination, or a home range.

How fish detect magnetic fields, however, remains unresolved. It seems likely that teleost fishes use chains of small crystals of magnetite found in the nose that act like very small compass needles in response to the external magnetic field. In contrast, the elasmobranch fishes might use either magnetite or the highly sensitive electroreceptors in the ampullae of Lorenzini, which are exposed to induced electric fields as the fish, the saltwater medium, or both the fish and medium move through the Earth's magnetic field. Neural responses to magnetic field stimuli have been demonstrated in the trigeminal and octavolateralis nerves, respectively, of teleost and elasmobranch fishes. These results are consistent with the use of both these mechanisms, but the issue of just how magnetic fields are detected in the fishes is still being debated by researchers.

Our knowledge of and ability to study the magnetic sense have grown in recent decades, but whether or not fish can use the Earth's magnetic field for navigation remains unclear. We now have reliable techniques to investigate the behavioral and neurophysiological properties of the magnetic sense. New techniques are also being developed to detect and characterize cells that contain magnetite, which may be the cells that detect magnetic fields in teleosts and perhaps also in the elasmobranch fishes. Although experimental designs for investigation of the potential use of the magnetic sense in navigation are yet to be developed, recent developments in equipment for tracking experiments suggest that studies of navigation by fishes will advance rapidly in the near future.

Magnetic Fields in Nature and the Laboratory

The Earth's magnetic field is like the field that would be produced by a very large bar magnet embedded in the core of the Earth (**Figure 1**). The north and south magnetic poles constitute a magnetic dipole that dominates (generally >90%) the field observed at the surface of the Earth. The magnetic field observed at a point on the Earth is a vector that has an intensity and a direction as indicated by a compass needle that is free to rotate in three dimensions. The declination of the Earth's magnetic field (the angle between the directions of geographic and magnetic north) arises from the displacement of the magnetic

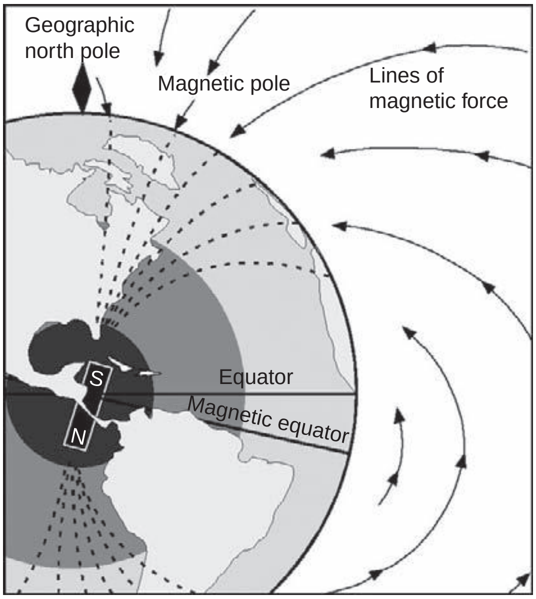

Figure 1 The main magnetic field of the Earth. The main magnetic field is a dipole (represented by the bar magnet in the core of the Earth) but contains some non-dipole components (not shown). The field due to the magnetic dipole in the core is represented by field lines, which show how the intensity (through increasing concentration of field lines) and inclination (through increasing angles of intersection of field lines with the surface of the Earth) of the field increase systematically between the magnetic equator and the magnetic poles. Adapted from Walker MM, Dennis TE, and Kirschvink JL (2002) The magnetic sense and its use in long-distance navigation by animals. *Current Opinion in Neurobiology* 12: 735–744.

poles relative to the geographic poles, and means that a magnetic compass needle seldom points directly toward geographic north.

The dipole field causes the intensity and inclination (the angle at which magnetic field lines intersect the surface of the Earth) of the vector to vary systematically from 25 to $65-70\,\mu$T and from 0° to 90° between the magnetic equator and poles, or 2–5 nanotesla per kilometer (nT km^{-1}) and about 1° per 100 km between the magnetic equator and poles. Local magnetic anomalies cause nonsystematic variations in intensity that can range from tens to thousands of nT km^{-1}, whereas the solar wind (a flow of charged particles from the sun that causes electric currents to flow in the upper atmosphere) can cause rapid variations in intensity over short periods (seconds to hours). These nonsystematic variations appear to overwhelm the systematic variation in the field and make it difficult to understand how animals such as fish might navigate using the Earth's magnetic field.

Laboratory study of the magnetic sense requires careful consideration of the magnetic fields present in the laboratory together with the use of magnetic fields produced by either magnets or, more usually, electromagnetic coils. As magnetic fields from different sources interact, an experimental situation, such as an orientation arena, should ideally be located in a purpose-built structure that is free of magnetic materials and, failing that, as close as possible to the center (in three dimensions) of a room. Electromagnetic coils provide greater control over stimulation because they permit experiments in which only magnetic field direction or intensity changes, and permit easy variation in the size of changes in field parameters.

Behavioral Responses to Magnetic Fields

Fishes from at least two teleost orders have been shown to respond to magnetic field direction in orientation experiments, whereas both teleost and elasmobranch fishes have been successfully conditioned to magnetic fields. The following sections examine key results from these experiments.

Orientation to Magnetic Direction

The critical assumption of orientation experiments is that the spontaneous directional choices made by animals placed in featureless orientation arenas match the directions they would choose in their normal environment. The directions chosen by the fry and smolts of sockeye salmon (*Oncorhynchus nerka*) in orientation arenas were consistent with the hypothesis that they were orienting to the axis of the lake in which they would live until they reached the smolt stage and began their migration to the sea. Similarly, when placed in a featureless arena where there was a radial current flow after experience with a current flowing from west to east in their home tank, juvenile chinook salmon (*O. tshawytscha*) oriented preferentially in the east–west axis despite being able to choose any orientation direction. The orientation directions of the fish in the arenas used in both sets of experiments could be changed by varying the direction of the magnetic field in the tanks using electromagnetic coils.

Laboratory Conditioning

Freely moving fish, including yellowfin tuna (*Thunnus albacares*), rainbow trout (*Oncorhynchus mykiss*), zebrafish (*Danio rerio*), sharks, and short-tailed stingrays (*Dasyatis brevicaudata*), have been trained to discriminate the presence and absence of a magnetic intensity anomaly in experimental tanks. Responses produced by the fish in different experiments included swimming through a hoop, pressing a lever, and swimming through a defined area in anticipation of food reward given at the end of experimental trials depending on whether the anomaly was present or absent. Although the tuna learned to discriminate the presence and absence of the anomaly field

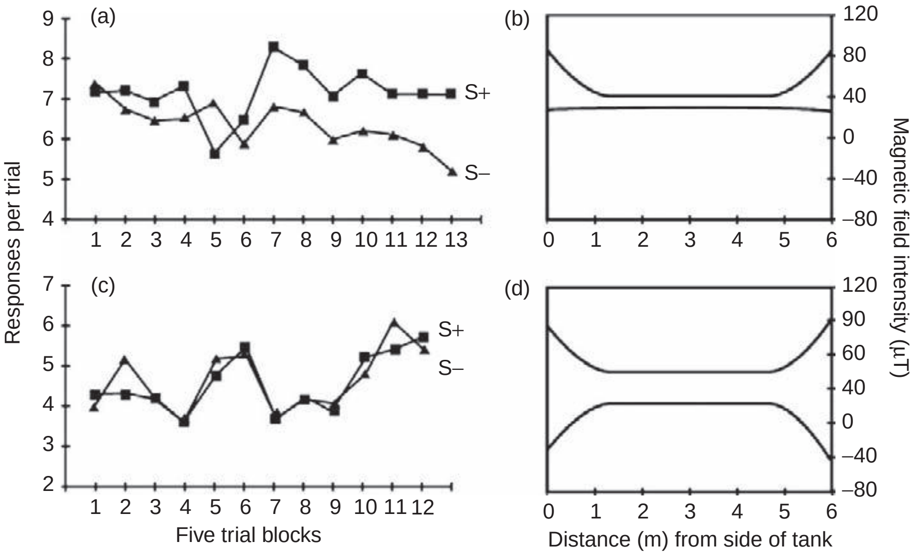

Figure 2 Behavioral responses to magnetic fields by teleost fish. (a, b) Magnetic discrimination learning in individually trained yellowfin tuna. In the training procedure, individual fish swam through a hoop during 30-s trials. Depending on the magnetic field presented, response by the fish was reinforced with food (S+, squares) given at the end of each trial or unreinforced (S–; triangles) no matter how often the fish responded. Each point is the mean of five S+ (squares) or S– (triangles) trials. Fish (*n* = 7) were required to discriminate the presence and absence (indicated by varying and constant intensity values across the tank in (b) of a localized magnetic-field anomaly projected into the experimental tank by a coil through which direct current could be passed. To control for possible generalized effects of the experimental field on behavior, some of the fish were trained with the magnetic field of the Earth as S+ and the localized anomaly as S–, whereas for the remaining fish the anomaly was S+ and the Earth's field was S–. (c) and (d) Fish (*n* = 2) were required to discriminate between two magnetic anomalies (indicated by the mirror-image curves of varying intensity values across the tank in (d) produced by reversing the polarity of the current passed through the coil. Adapted from Walker MM (1984) Learned magnetic field discrimination in the yellown tuna, *Thunnus albacares*. *Journal of Comparative Physiology A* 155: 673–679.

(**Figures 2**(**a**) and **2**(**b**)), they could not discriminate between the fields (**Figures 2**(**c**) and **2**(**d**)) that resulted from the addition and subtraction of the anomaly from the Earth's magnetic field in the tank. That is, the fish failed to distinguish between the mirror-image patterns of variation in intensity that occurred when the anomaly was added to or subtracted from the uniform Earth's field as the fish swam in the tank during trials. Finally, round stingrays (*Urobatus halleri*) have also been trained to respond to magnetic field direction by entering one of two enclosures at opposite ends of their tank depending on the direction of the magnetic field in the tank.

In cardiac conditioning, an animal that is not moving is presented with a stimulus that is followed by a brief electric shock. If the animal can detect the stimulus, the presentation of the stimulus alone will come to be followed by a decrease in heart rate. Nishi and his colleagues reported cardiac conditioning of Japanese eels (*Anguilla japonica*) to magnetic fields that differed in both magnetic field direction and intensity. Stimuli presented included changes in magnetic field intensity and direction ranging from 12 663 to 192 473 nT and from 21° to 80° easterly shift in the direction of the horizontal component of the magnetic field in the experimental tank (**Figure 3**(**a**)). Significant reductions in heartbeat rates (**Figure 3**(**b**)) occurred in 17 of 19 eels in both the marine and freshwater phases of the life cycle. Further experiments showed that these responses did not occur when the eels had been made anosmic and argued that magnetoreception takes place in or around the nares of the eel. Taken together, these experimental results demonstrate that the magnetic sense can be analyzed using conditioning approaches in the same manner as better-known sensory systems.

Neural Responses

Behavioral responses depend on information about an external stimulus, such as a magnetic field, that must be collected by specialized sensory cells and converted into streams of action potentials moving along a sensory nerve. As they travel along the sensory nerve, these action potentials can be detected by electrodes, permitting researchers to record and analyze the information transmitted to the brain from the sensory cell.

Responses in the Trigeminal Nerve of Teleost Fish

Neural recordings in response to changes in magnetic field intensity and direction, separately and together, have been made from individual nerve fibers (single

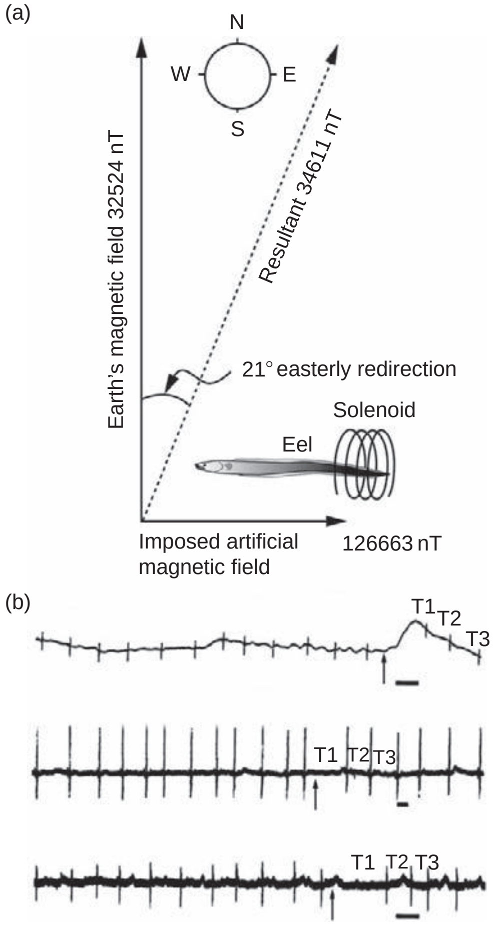

Figure 3 Cardiac conditioning responses to magnetic fields in eels. (a) The eel's head lay at the center of a solenoid (35-cm diameter) wrapped around a polyvinyl chloride (PVC) aquarium and oriented in the east–west axis. The solenoid in the apparatus produced a field that added to the geomagnetic field. The imposed field ranged between 12 663 and 192 473 nT with the resultant intensity ranging from 35 611 to 187 298 nT. These intensity changes produced resultant fields whose directions ranged from 21° to 80° to the east of magnetic north. (b) Electrocardiograms showing changes in heartbeat rate in response to magnetic-field changes in Japanese eels (scale = ~1 s). Arrows indicate the onset of the conditioning stimulus (magnetic field); T1–T3 indicate beats used to compare response to the magnetic field change with heartbeat rate during control tests in the absence of the experimental magnetic field. Adapted from Nishi T, Kawamura G, and Matsumoto K (2004) Magnetic sense in the Japanese eel, *Anguilla japonica*, as determined by conditioning and electrocardiography. *Journal of Experimental Biology* 207: 2965–2970, with permission from the Company of Biologists.

units) in the superficial ophthalmic (SO) branch of the trigeminal nerve (TN) of rainbow trout. The responsive units in the trout showed regular firing patterns except during phasic (transient) responses to a trebling of magnetic intensity presented as square waves at frequencies of 0.5 and 1 Hz (**Figures 4**(**a**)–**4**(**c**)). Both excitatory and inhibitory responses were observed, but each unit responded only to either the onset or the offset of a stimulus and responded more or less strongly to the stimulus when it was presented at different frequencies. For the units shown in **Figure 4**(**b**), post-stimulus time histograms (PSTHs) showed that the latency (10–15 ms; the first point after the stimulus step and the period during which the firing rate was more than two standard deviations above the mean for each unit) and time course (~100 ms) of the responses by the two units exposed to both stimulation frequencies were similar. The peak amplitudes of the responses in the units in the upper and lower panels of **Figure 4**(**b**) decreased and increased, respectively, when the presentation rate of the step change in intensity increased from 0.5 (left panels) to 1 Hz (right panels). **Figure 4**(**c**) (the same unit as in the upper panels of **Figure 4**(**b**)) shows the response to the onset but not to the offset of a change in magnetic intensity (upper panels) but shows no response to either the onset or the offset of a reversal in magnetic field direction. As with the unit shown, no unit responded when magnetic field direction was reversed without a simultaneous change in intensity. This finding could result from there being only a small proportion of units that respond to magnetic direction, by detection of magnetic field direction through another detection mechanism, or by integration in the brain of the signals from many different detector cells with different orientations and that each detect the field in a primary axis.

Induced Electrical Signals in Ampullary Electroreceptors

Evidence consistent with the hypothesis that elasmobranch fishes could use their ampullary electroreceptors to detect electric-current flows, induced by their own or the water's movement through the Earth's magnetic field, has been obtained by recording responses to electrical and magnetic field stimuli in the Black Sea skate (*Raja clavata*). Afferent nerves from ampullary electroreceptors in the wings, and primary area acoustico-lateralis in the dorsolateral region of the medulla oblongata of the brain, responded to both electrical and magnetic field stimuli in the skate. Excitatory and inhibitory responses were recorded in the afferent nerves so long as the magnetic field was varying continuously when the fish was not moving or when either the fish or the water were moving but the field was static. That is, responses occurred when electrical fields were likely to be induced. These results clearly confirmed that the electroreceptors do detect the electric current flows induced by magnetic field variations and by the movement of either the fish or the saltwater through a static magnetic field. Subsequent demonstration that elasmobranch fishes detect magnetic fields, in behavioral experiments, now present an

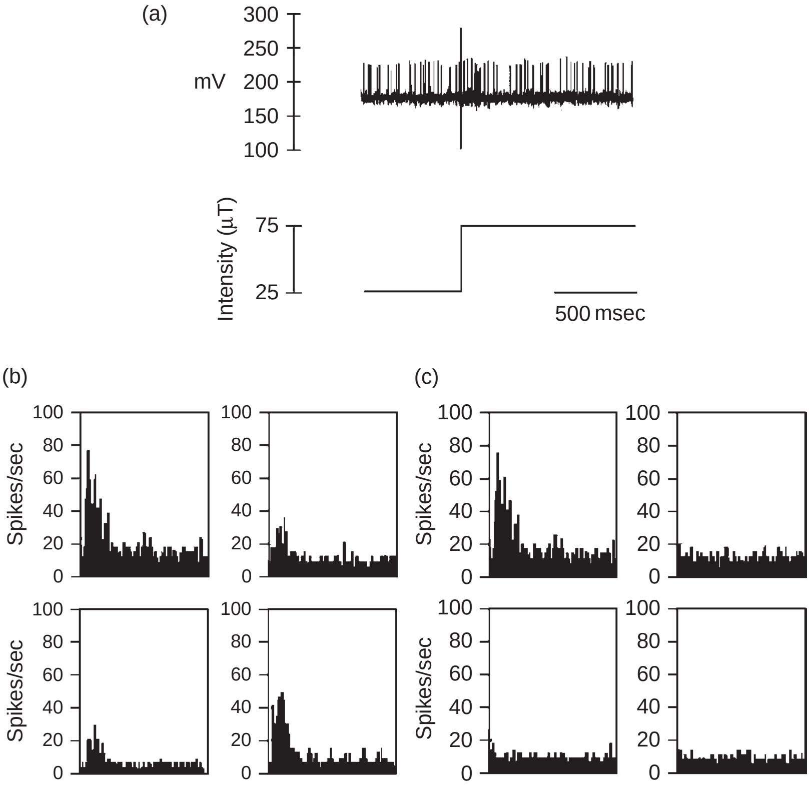

Figure 4 Neural responses to magnetic-field stimuli. (a) Spontaneous activity of a single unit (upper trace) in the TN of the rainbow trout in the background magnetic field followed by the activity for 1 s following the onset of a stimulus (lower trace) that produced a step change in magnetic field intensity from 25 to 75 μT within the experimental tank. (b) Post-stimulus time histograms (PSTHs) of responses by two spontaneously active units (unit 1 in top panels, unit 2 in bottom panels) to the same stimulus presented 128 times each at 0.5 (left panels) and 1 Hz (right panels). The magnetic stimulus trebled the magnetic field intensity but did not change field polarity. Each plot begins at stimulus onset and is of 500-ms duration with the magnetic field remaining constant throughout the period shown in each panel. Sampling bin width is 2 ms. Note that the top left panel in (b) is the same record as the top left panel in (c). (c) PSTHs of responses by one spontaneously active unit to the onset (left panels) and offset (right panels) of a trebling of magnetic field intensity (upper two panels) or a reversal of magnetic-field polarity in the experimental tank but with no change in field intensity (lower two panels). The presentation rate together with the number and duration of stimulations were as for the left-hand side panels in (b). Adapted from Walker MM, Diebel CE, Haugh CV, *et al*. (1997) Structure and function of the vertebrate magnetic sense. *Nature* 390: 371–376.

opportunity to explore further the potential role of ampullary electroreceptors in magnetic field detection by elasmobranchs.

Magnetite-Based Magnetoreceptor Cells?

Following the discovery of magnetotactic bacteria and their use of chains of magnetite crystals for orientation, a search for magnetic material suitable for use in magnetoreception in animals identified magnetite in a variety of animals. Crystals of magnetite are divided into three categories based on their size, shape, and magnetic properties. Superparamagnetic (SPM) particles are typically less than about 35 nm in size with a magnetic moment that will rotate without movement of the crystal. Single-domain (SD) crystals are typically between 35 and 100 nm in size, are permanently magnetized, and have the maximum magnetic moments for magnetite; they will physically rotate in response to an external field if they are free to move. Multidomain (MD) particles of magnetite are typically >100 nm in size and only weakly magnetized. Of these, single domains have the strongest possible interaction with the relatively weak magnetic field of the Earth.

The simplest hypothesis for transduction of the magnetic field of the Earth into a signal that can be detected by the nervous system involves the use of chains of SD magnetite such as those that are observed in the magnetotactic bacteria and fish. The motion of these chains in response to the external magnetic field will then convert the magnetic field stimulus into a mechanical stimulus that could readily be detected using mechanically gated ion channels linked to the magnetite chain.

The crystal and magnetic properties of SD magnetite have been used to identify chains of SD crystals (**Figure 5**(**a**)) within cells in the nose of the rainbow

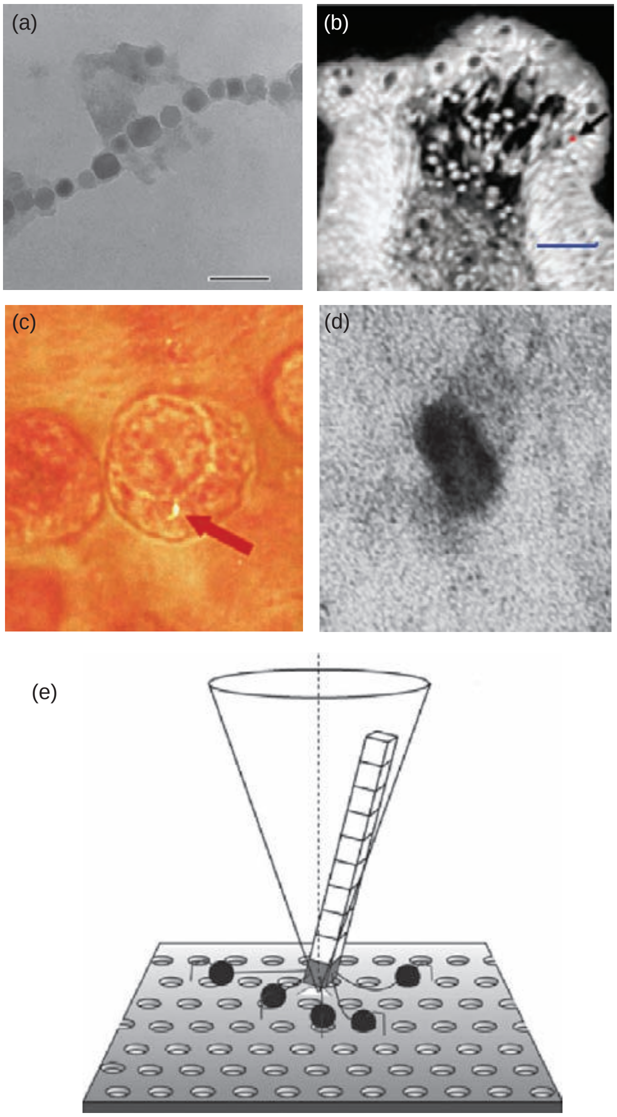

Figure 5 Detection of intracellular magnetite. (a) A chain of single-domain magnetite crystals extracted from sockeye salmon (*Oncorhynchus nerka*). Scale = 100 nm. (b) Autofluorescence image of a magnetite-containing cell within an olfactory lamella of rainbow trout viewed using a confocal laser scanning microscope (CLSM) in transmission mode. The red spot indicates where the reflection of the laser light by the magnetite was detected. Scale = 25 μm. (c) CLSM 30 − μm wide overlay in reflected and transmitted light modes of a candidate magnetoreceptor cell isolated from a trypsin digest of an olfactory lamella. The arrow indicates a chain of reflecting crystals. (d) Transmission electron micrograph of a crystal associated with a reflectance in the trout olfactory lamellae. The crystal is 50 nm long, iron rich, and was distinguished as a crystal from other dark particles in the thin section by its bright reflection in dark field. (e) Conceptual model showing how a magnetosome chain might be connected at one end to the cell membrane (surface) and linked by cytoskeletal filaments (lines attached to spheres) to an array of mechanically gated ion channels (holes) located in the cell membrane and centered on the end of the chain. The filaments will restrict the range of movement of the chain to a cone aligned perpendicular to the membrane. Movement of the chain to one side of the array under thermal agitation will cause the cytoskeletal filaments to pull open channels on the opposite side of the array (illustrated by the spheres that normally block the channels being pulled out of the channels as the chain rotates away from them). When the chain moves back toward the axis of cone, relaxation of the tension on the filaments allows gating springs (short lines connecting the spheres to the membrane) to close the channels. Within the cone, the variance of motion of the chain will depend on the intensity of the external field.

trout despite the small size (~50 nm) and extreme rarity (<5 ppb by volume) of the crystals. Reflections of laser light off crystal surfaces permitted detection of the chains of magnetite crystals in reflection mode confocal laser scanning microscopy (CLSM) (**Figures** 5(**b**) and 5(**c**)). Mapping the reflections in three dimensions, then permitted imaging of single crystals in thin sections in the transmission electron microscope (**Figure** 5(**d**)) and unique identification of the crystals as magnetite using atomic and magnetic force microscopy.

The cells containing the magnetite particles are $10 - 12\,\mu\text{m}$ in length, have a distinctive multilobed shape, and are consistently located near the basal lamina of the olfactory epithelium (**Figures** 5(**b**), (**c**)). The cells are relatively rare and were found only near the tips of the olfactory lamellae (distal to the cells of the olfactory sensory epithelium). The chain of magnetite crystals in each cell is about $1\,\mu\text{m}$ long and the chains interact strongly enough with the Earth's magnetic field to permit detection of the field by the cell. The location of the chain of magnetite crystals within each cell suggests that a mechanical linkage of the chain to the cell could transduce the movement of the chain, in response to the external magnetic field, into changes in the membrane potential of the cell. **Figure** 5(**e**) illustrates how a chain of magnetite particles might be linked by filaments to mechanically gated ion channels to convert the signal from the magnetic field of the Earth into a mechanical signal that changes the receptor potential of the detector cell to cause release of neurotransmitter to a sensory neuron. If, indeed, the cells work in the manner suggested, the magnetoreceptor system might be able to measure both the intensity and the direction of the Earth's magnetic field.

Neuroanatomy

Although the mechanism of magnetic field detection in the teleost fishes may be different from the elasmobranchs, this section focuses on the teleost fishes, as the elasmobranch electroreceptor system is already well described. Detection of neural responses to magnetic stimuli in the trout led to use of a fluorescent dye (Di-I) to trace the nerve from the recording site in the SO branch of the TN to both the endings of the individual nerve cells and to the brain (**Figure 6**). Posterior to the orbit (the eye socket), the SO branch joined other branches of the TN and ended in cell bodies that make up part of the anterior ganglion (**Figure** 6(**c**)). Anterior to the orbit, the SO branch has branches that innervate the skin, surround the olfactory nerve and olfactory capsule (processes 1–3 in **Figure 6** (**c**)), and also penetrate the olfactory lamellae within the olfactory capsule itself (**Figure** 6(**c**)). Fine branches of the SO penetrate the olfactory lamellae from both the top and the base before terminating in finer processes within the olfactory lamellae, where the magnetite-containing cells are most often found (**Figures** 6(**a**), 6(**d**), and 6(**e**)). The proximity of the fine branches of the TN to the cells that contain the magnetite in the trout invites the hypothesis that the magnetite-containing cells transduce magnetic field information for transmission through the TN to the brain. Testing this hypothesis will require the ability to demonstrate that the magnetite-containing cells make synaptic contacts that permit encoding and transmission of magnetic field information by the TN.

Do Fish Use the Earth's Magnetic Field to Navigate?

Navigation can be defined as the processes by which an animal first estimates its current position relative to some goal that it cannot detect directly, and then sets a course to reach that goal (e.g., using a map and a compass). Evidence that fish use the Earth's magnetic field for navigation is currently limited to one study in which scalloped hammerhead sharks were tracked around seamounts in Baja, California. The tracked fish made repeated round-trip journeys each night, traveling away from El Bajo Espiritu Santu seamount to spend the night in deep water and returning each morning. Monte Carlo simulations demonstrated that the paths of the fish were associated with magnetic field features but not with bathymetric features associated with the seamount. Consistent with the above definition, **Figure** 7(**a**) shows a broadbill swordfish that clearly traveled independently of the flow directions of either local or major currents, including the Gulf Stream, and maintained the same course for some days.

The discovery that juvenile lemon sharks will home rapidly after being experimentally displaced (**Figure** 7(**b**)) opens the way for more detailed studies of the role of the magnetic sense in navigation. The likely motivation for the lemon sharks to home as rapidly as they did was to escape predation because numerous large sharks that feed on smaller sharks inhabit the water around the Bimini Islands. There are very likely to be other fish species in which juvenile animals inhabit nurseries to which they return after experimental displacement. Thus, the opportunity exists to begin experimental study of the navigation behavior of different fish species.

Outlook

Fishes have played a central role in studies of the structure and function of the magnetic sense. More is known about the crystal properties of biogenic magnetite, the candidate magnetite-based magnetoreceptor cells, and the magnetic-field detection pathway in the fishes than in any other metazoan group. We are, however, only just beginning the systematic study of the magnetic sense in

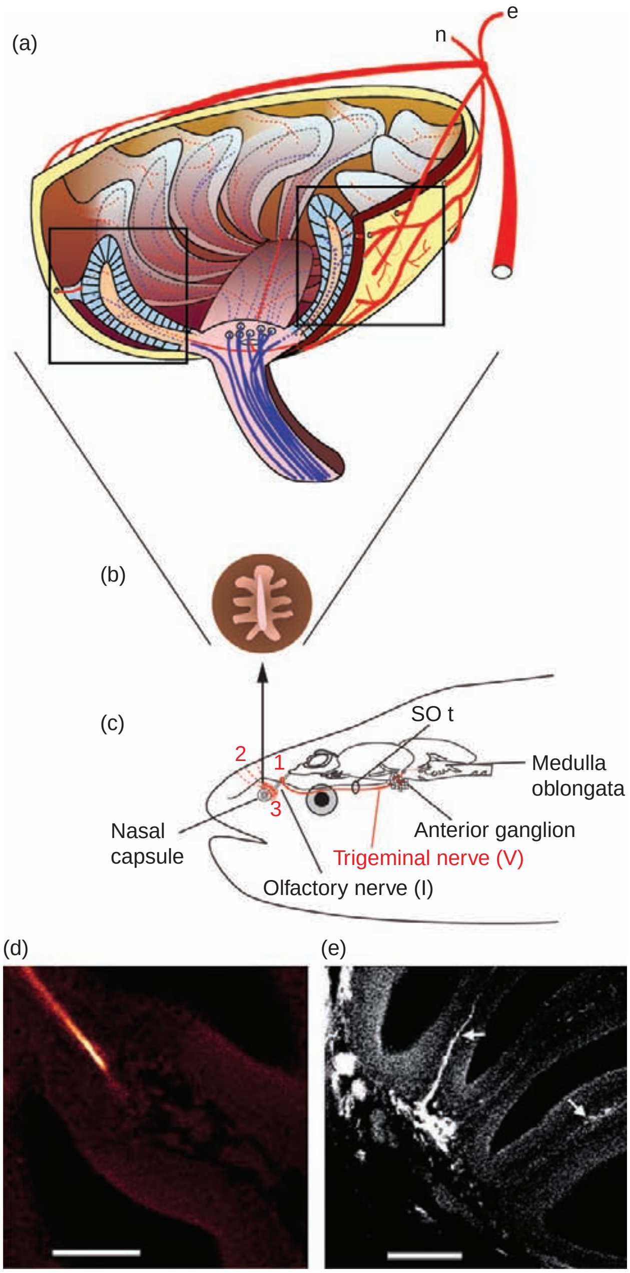

Figure 6 Relationship between the superficial ophthalmic branch of the trigeminal nerve and magnetite-containing cells in rainbow trout. (a) Schematic diagram of the innervation of the head region and nasal capsule of the trout by the superficial ophthalmic (SO; shown in red in (a)–(c)) branch of the trigeminal nerve (TN). One process innervates the nasal membrane and flap (n), and the other (right (e)) is process 2 in (c). Others form a network of nerves that surround the nasal capsule (right box). Within this network, the smaller branches have fine processes that pass through the nasal membrane, lining the nasal capsule, and innervate, both at the top and the base, individual olfactory lamellae that form the olfactory rosette. The olfactory nerve (blue) is the combination of all axons of the olfactory sensory cells which are situated in the mucosa and send their axons to the olfactory bulb. The network of nerves surrounding the capsule generally lies in a fatty layer (light shading on outside surface of capsule; right box in (a)), which is typically found between the neurocranium (not shown) and the outer membrane (brown) that lines the nasal capsule. The pale area in the front two lamellae represents the folded layers of the olfactory epithelium that are separated internally by the lamina propria. New lamellae are formed in the area of the nasal capsule (not shown). The left box outlines the area shown in (d). (b) Olfactory rosette within the trout nasal capsule (top view). The nasal flap that lies over the top of the olfactory rosette has been removed for clarity. (c) Innervation of the SO in the head region of the trout. The label SOt identifies the SO trunk where the SO branches of the trigeminal (cranial nerve V) and anterior lateral line (cranial nerve VIII) nerves pass together across the top of the eye before diverging to innervate the front of the head. (d) Optical slice through a single olfactory lamella (Scale = 100 μm). A labeled fine process from a branch of the SO branch can be seen entering the lamella through the top. (e) Fine processes can also be seen entering the lamina propria of several lamellae (arrows) from their bases (Scale = 100 μm). These processes originate from a different branch of the SO than the one that innervates the area in (d). Adapted from Walker MM, Diebel CE, Haugh CV, *et al*. fish and other animals, and there is far more yet to be discovered than has been learned to date. Thus, for a magnetite-based magnetoreceptor system, descriptions of the internal structure of candidate magnetoreceptor cells, their synaptic links to afferent nerves and central projections in the brain, are priorities for structural study of the magnetic sense in all animals, including the fishes, which are well suited for such work. Similarly, functional studies of these magnetoreceptor cells, the coding of magnetic field information for transmission to the brain, analysis of the psychophysical properties, and demonstration of dependence of sensory capacity on the structure of the sense are all required if we are to understand the magnetic sense in detail. Finally, the opportunity exists to begin comparative study of the navigation behavior of fish and homing pigeons, in which navigation has been studied intensively for many decades. Although powerful experimental evidence for the use of the Earth's magnetic field in navigation exists only for homing pigeons, there will be much to learn from such comparative studies just as there will be from comparative studies of the magnetic sense itself in fish and birds. We look forward to exciting advances in our understanding of the properties and use of this most enigmatic of animal senses in the years to come.

Glossary

Circadian Internally generated with a periodicity of about 24 h. From the Latin *circa* (about) and *dies* (day).

Circadian clock Cellular mechanism or multicellular structure that spontaneously expresses a rhythm with a periodicity of about 24 h. Also called circadian oscillator or, in the case of a master clock that drives others, circadian pacemaker.

Circatidal Internally generated with a periodicity of about one cycle of the tide, that is, about 12.4 h.

Daily With a periodicity of exactly 24 h. Synonymous with 'diel' or 'nycthemeral'. Used for environmental cycles. Should also be used for physiological and behavioral rhythms whose endogenous nature is not certain and whose observed periodicity is 24 h.

Entrainment Forced synchronization of an endogenous rhythm to the periodicity of an external factor, called a zeitgeber. Opposite of freerun.

Freerun State of an endogenous rhythm that follows its own natural periodicity, called the 'freerunning period'. Usually expressed under constant conditions. Opposite of entrainment.

Hourglass A mechanism that triggers an output after a certain amount of time has elapsed from a resetting event (which can be the output itself). It is a conceptual alternative to circadian clocks in some phenomena, although there is little evidence for it.

Masking Effect of an external factor on a circadian variable, resulting in the variable expressing a different state than that prescribed by the internal clock. For example, light can mask the wake–sleep cycle by rendering an animal active at a time when it would normally be asleep.

Phase A particular reference point or segment during an oscillation.

Phase shift A resetting of the internal clock or its zeitgeber. In a phase advance, the rhythm is temporarily shortened and its expression occurs earlier than expected. In a phase delay, the rhythm is temporarily lengthened and its expression occurs later than expected. Advance values (usually in hours) are assigned a positive sign and delay values are assigned a negative sign.

Subjective day or night Under constant light or constant darkness, the time segment during which the internal clock would expect to see day or night.

Transients Cycles that are temporarily shortened or lengthened during a phase shift. They reflect a gradual readjustment of the clock to a new steady state.

Zeitgeber An environmental factor that varies cyclically (e.g., light intensity) and that synchronizes (entrains) an endogenous clock to its own periodicity.

Introduction

The rotation of the Earth on its axis imposes a daily cycle of light and darkness on almost all organisms. Depending on the habitat, temperature and humidity can also vary on a 24-h basis. Such environmental cycles have led to the evolution of internal clocks in almost all living things. These clocks are cellular or multicellular structures that generate an output with a periodicity of about 24 h. The daily approximation defines the clock and its output rhythm as being circadian (from the Latin *circa* (about) and *dies* (day)). Other biological clocks exist with different periodicities, such as the duration of the tide cycle (12.4 h, circatidal clock) or the year (circannual clock), but the circadian variety is by far the most common and the most studied.

Circadian clocks have adaptive value for animals. With them, animals can keep track of time and anticipate significant events, such as dawn, dusk, and food arrival. Physiological systems can thus be revved up in advance of activity and food intake. Circadian clocks can also be involved in daylength measurement and thus in photoperiodic responses. Finally, circadian clocks can synchronize sleep with that portion of the day to which the animal's sensory abilities are less well adapted. If slumber were only a blind response to darkness, for example, any animal venturing into a permanently dark place would be transformed into a sleeping beauty, a serene but not very profitable state of affairs.

The basic procedure to demonstrate the existence of a circadian clock is to continuously measure a physiological or behavioral variable under constant laboratory conditions (constant light (LL) or darkness, stable temperature and oxygen content, and food available *ad libitum* or given at random intervals), and observe cycles that persist for at least a few days. The rhythm always exhibits a periodicity (called the 'freerunning period') slightly different from 24 h. This deviation from 24 h is a fundamental feature of circadian rhythms. It illustrates the fact that biological clocks (like most manufactured watches) need not keep exact time. Some clock drift is allowed as long as there is a mechanism that resets the clock every day to the environmental cycle being tracked. This synchronization of the biological clock by an external cycle is called 'entrainment'.

The deviation from 24 h is also providential, for it proves the endogenous nature of the rhythm. If the freerunning period was exactly 24 h, it could be argued that the animals were responding directly to an environmental cycle which the laboratory conditions failed to control (e.g., noise in the building, or some hard-to-detect geophysical phenomenon). However, no such environmental cycles could explain circadian rhythms of, say, 23 h. Moreover, there is often considerable variation between individuals in the exact value of their freerunning periods, another indication that the rhythms are generated internally and not driven by an exogenous factor.

Circadian physiology has been extensively studied in mammals, most notably in humans, rats, mice, and hamsters. Comparatively little work has been done with fishes. This is due, in part, to the fact that we are yet to find a fish species that is easy to keep, obtainable in great numbers, and that gives precise rhythms which last for a long time in constant conditions. As compared to laboratory rodents (the workhorses of circadian rhythms research), whose clocks remain self-sustained for months, fishes in constant conditions exhibit circadian rhythms that usually damp out within several days, or several weeks at most. We do not know the reason why these endogenous cycles seem to persist longer in mammals than they do in fishes.

Expressions of Circadian Rhythmicity

As is the case for other animal groups, locomotion is the most commonly measured circadian variable in fishes, probably because it is relatively easy to automate the continuous recording of swimming movements. Usually, an infrared light beam is set up across the aquarium and beam interruptions are recorded by computer. Other less-common methods include automated video-image analysis and recorded disruptions of a standing ultrasound wave. Freerunning rhythms of locomotion have been observed in more than 40 different fish species, including hagfish, lamprey, sharks, cyprinids, ictalurids, gymnotids, salmonids, and labrids. Freerunning periods generally vary between 20 and 29 h. The activity rhythms are often represented in the form of an actogram, as in **Figure 1**.

Another variable that can freerun is 'demand feeding'. Fishes can be taught to push an object in order to obtain

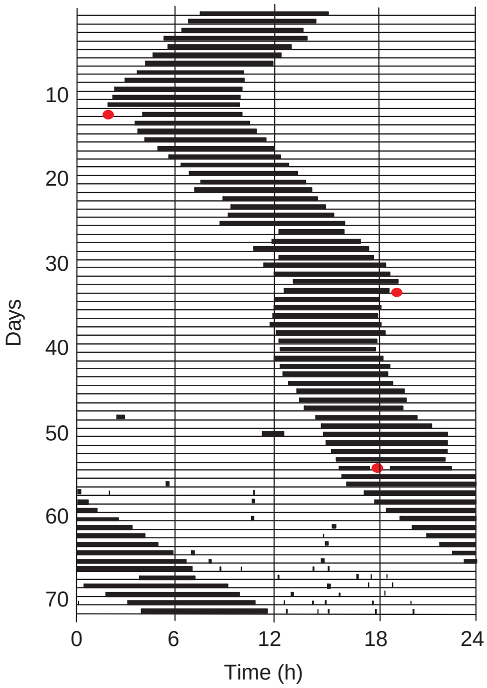

Figure 1 Actogram of the freerunning activity rhythm of an inshore hagfish in constant darkness. Lines represent successive days, with the thick parts showing the times when the fish was active. The fish was active for about 7.5 h each day. On the first day, the fish was active from 7.22 a.m. to 3.05 p.m.; these times gradually changed so that on day 10 the fish was active from 2.14 a.m. to 9.46 a.m. Thus, the biological clock in this fish, using activity onsets as reference points, had a freerunning period of 23.43 h during the first 10 days. The three circles represent 15-min pulses of light shown to the fish to phase-shift its rhythm. Adapted from figure 3 in Ooka-Souda S and Kabasawa H (1995) Circadian rhythms in locomotor activity of the hagfish, *Eptatretus burgeri* V. The effect of light pulses on the freerunning rhythm. *Zoological Science* 12: 337–342.

food. The hits are recorded by a computer. Freerunning rhythms of demand feeding with periodicities of 20–30 h have been obtained from the European sea bass (*Dicentrarchus labrax*), the rainbow trout (*Oncorhynchus mykiss*), the wels catfish (*Silurus glanis*), and the goldfish (*Carassius auratus*).

Freerunning rhythms have also been reported for the electric discharges of gymnotid fishes, air gulping of the river loach *Indoreonectes evezardi*, body color change in mummichogs (*Fundulus heteroclitus*), as well as oxygen consumption, retinal cell proliferation, and hormone levels in several species.

The freerunning rhythms of fishes are usually noisy (there is a fair amount of activity during the supposed rest phase, or inactivity during the supposed activity phase). Moreover, as already mentioned, seldom are the rhythms self-sustained for more than several weeks. The most precise and long-lasting fish rhythms to date have come from the electric discharges of *Gymnorhamphichthys hypostomus*, and the locomotor activity of the inshore hagfish (*Eptatretus burgeri*), the white sucker (*Catostomus commersoni*), the lake chub (*Couesius plumbeus*), the burbot (*Lota lota*), and various wrasses, with the inshore hagfish leading the pack with maximum reported durations of 75 days (**Figure 1**). It is noteworthy that *G. hypostomus*, the inshore hagfish, the burbot, and the wrasses prefer to sleep hidden, either buried in sand or underneath rocks. The search for a model subject in fish circadian research might benefit from a focus on species that sleep deeply and out of sight.

The value of the freerunning period (symbolized by τ, the Greek letter tau) is calculated by fitting a regression line through predefined reference points (e.g., daily activity onset), or, more commonly in the case of the noisy rhythms of fishes, with the help of a special technique called 'periodogram analysis'. This mathematical tool assesses the most likely period of a rhythm and assigns a statistical probability value to it.

The freerunning period of fishes can be influenced by the seasonal timing of the animals' capture. Lake chubs express longer freerunning periods of activity immediately after a winter capture than after a summer capture. Burbot and longnose dace (*Rhinichthys cataractae*) also show a summer–winter difference, but reversed: their freerunning period is longer after a summer capture. The causes of such seasonal variation and interspecific differences remain unknown.

Freerunning periods can also vary depending on whether the fish are single or in shoals. In both the white sucker and the mummichog, groups of 25 fish have yielded longer freerunning periods than fish kept separately. The reasons for this are not understood.

Finally, freerunning periods depend on whether the rhythm is measured in LL or in constant darkness (DD). Early work on the circadian physiology of animals led to the formulation of what is known as Aschoff's rule: increased light intensity lengthens the period in nocturnal animals but shortens it in diurnal ones. It is difficult to say whether fishes follow this rule; first because many species are hard to categorize as diurnal or nocturnal (see below), and second because fish rhythms are not always expressed in LL. However, a few studies have managed to document some influence of light intensity on the freerunning period of fishes. Zebrafish (*Danio rerio*) and mummichogs are diurnal in the laboratory and show longer freerunning periods in DD than in LL, as predicted by Aschoff's rule. Conversely, goldfish go against Aschoff's rule: they are mostly diurnal, and their period is longer in LL than in DD. In the nocturnal gymnotids, the period is lengthened as light intensity is increased from 0 to 100 lux, congruent with Aschoff's rule. However, in the nocturnal Amur catfish (*Silurus asotus*), the period decreases as light intensity increases from 0 to 10 lux. It has been suggested that Aschoff's rule should be altered to state that the periods are lengthened with increasing light intensity in animals whose freerunning period in DD is less than 24 h, with the opposite being true for animals with a freerunning period in DD over 24 h. The validity of this new formulation remains to be established for fishes. Whatever the most correct formulation turns out to be, the physiology behind these effects of light intensity on freerunning periodicity is still unknown.

Some fishes have failed to show freerunning rhythms in the laboratory, be it under LL or under DD. Most interesting among them are cave populations. The Mexican tetra (*Astyanax mexicanus*) includes both a blind cave form and a sighted surface form; the cave form is arrhythmic in the laboratory, while the sighted one freeruns in both LL and DD. Lack of rhythmicity in cave dwellers is a likely case of regressive evolution in an environment devoid of daily cycles. However, not all cavernicolous fishes are arrhythmic. There is need for further research to determine how widespread the loss of internal clocks is in cavefishes.

Another expression of circadian rhythmicity, besides freeruns, is the anticipation of daily recurring events. When fishes are fed at the same time every day, they commonly become more active and pay more visits to the feeding site a few hours before mealtime. This so-called food-anticipatory activity is not an expression of hunger because activity dips down to its normal level past the usual mealtime even when food is withheld. Even though the fish are still hungry, their internal time sense tells them that foraging past the regular mealtime would be unprofitable. This time sense could be based on an hourglass mechanism reset by dawn or dusk rather than on a circadian clock; however, this hypothesis has been refuted by a few observations of freeruns of food-anticipatory activity when scheduled feeding was interrupted and constant conditions were put in place, and also by cases of anticipation that began before dawn or dusk when the food arrived soon after dawn or dusk (an hourglass set by a light signal would trigger anticipation after the light signal, and not before).

More than one feeding time can be anticipated. Shoals of golden shiners (*Notemigonus crysoleucas*) and individual rainbow trout are capable of anticipating two daily feeding times, even when one is at night and the other during the day. In the same vein, golden shiners and inangas (*Galaxias maculatus*, ex-*Galaxias attenuatus*) can anticipate the arrival of food in one part of their aquarium in the morning and in another part in the afternoon, a phenomenon called 'time–place learning', which is commonly thought to be based on a circadian mechanism. Golden shiners can also learn to feed in one-half of their aquarium in the morning, the other half at midday, and back to the first half in the afternoon.

Fish can anticipate events unrelated to food, such as dawn and dusk. Activity often increases or decreases a few hours before dawn or dusk even in the absence of changes in sunlight intensity. For example, nocturnal American eels (*Anguilla rostrata*) in the wild have been seen moving up toward the entrance of their dark cave shelter several hours before dusk. In addition, parental convict cichlids (*Argocentrus nigrofasciatus*) can retrieve their young a few minutes before nighttime, even in a laboratory setting where no light attenuation announces the end of the day.

A somewhat indirect way to demonstrate the existence of a circadian clock is to phase-shift the light–dark cycle, advancing or delaying it by a few hours, and to observe transient cycles of activity in the next few days. Rather than start right away at the new time of lights-on or lights-off (depending on whether the fish is diurnal or nocturnal) following the phase shift, activity onset occurs at first at the old time of lights-on or lights-off and slowly drifts across clock times from day to day until it is resynchronized with the new phase of the light–dark cycle. This reflects the gradual readjustment of the clock. As a rule, fishes seldom provide such evidence, as they usually resynchronize very quickly to phase shifts of the light–dark cycle. They show no, or at most one, transient cycle. However, two cases of prolonged transits have been documented: in one, golden shiners exhibited 2–3 days of transients after a 6-h shift; in the other, inshore hagfish showed 7–13 days of transients after a 12-h shift (**Figure 2**). It is unclear whether cases with no or very few transients reflect an easily shifted clock or a masking effect of light and darkness on activity levels.

Circadian clocks are also likely to be involved in sun-compass orientation, the ability to use time of day and the position of the sun to find cardinal points. At least a dozen fish species are known to orient by sun compass. For example, when bluegill sunfish (*Lepomis macrochirus*) are displaced from shore to open waters, they swim in a fairly consistent direction (the one that would take them to shore) on sunny days, but they set off in random directions on overcast days; moreover, their orientation is shifted by 90° when sunrise is artificially made to appear 6 h ahead of time (6 h is a quarter of the full day, just as 90° is a quarter of a full circle).

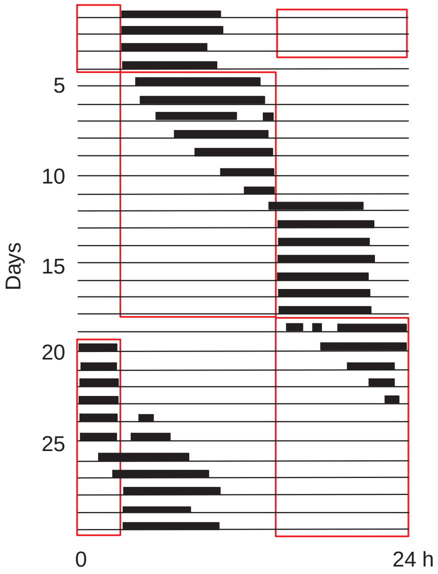

Figure 2 Transient cycles in the activity rhythm of an inshore hagfish following 12-h phase shifts of the light–dark cycle. Boxes show light times. Adapted from figure 6 in Ooka-Souda S, Kabasawa H, and Kinoshita S (1985) Circadian rhythms in locomotor activity in the hagfish *Eptatretus burgeri*, and the effect of reversal of light–dark cycle. *Zoological Science* 2: 749–754.

Entrainment of the Circadian Clock

As a rule, circadian clocks do not freerun in nature. (There are a few exceptions, such as beavers in their winter lodge.) Instead, they are synchronized by daily environmental cycles. The entraining cycle is called a 'zeitgeber', a German word that translates literally as time giver. By far the most important zeitgeber in nature is the light–dark cycle.

Two models explain how an exogenous cycle could entrain an endogenous one. The first one is parametric entrainment. This is the notion that an environmental factor can speed up or slow down the internal clock in a manner proportional to the intensity of the factor, so as to synchronize the clock to 24 h. The second one is nonparametric entrainment. According to this model, the clock is synchronized by daily jumps, or phase shifts, caused by the environmental factor being perceived by the animal at specific times. For example, to be entrained to a period of 24 h, a 26-h freerunning rhythm would need to jump backward (to be phase advanced, in the jargon of the trade) by 2 h every day. In a 26-h rhythm, the end of the subjective night (the end of the activity phase in a nocturnal animal, or the end of the sleep phase in a diurnal one) soon runs into dawn. If light at the end of the subjective night causes a 2-h phase advance in the clock, then the rhythm would become synchronized to 24 h.

Almost all research to date supports the theory of nonparametric entrainment. One key evidence is the phase-response curve, a graph depicting phase-shift size as a function of the circadian time at which a stimulus is given to the animal. Nonparametric entrainment theory predicts that pulses of light shown at the end of the subjective night should yield phase advances that become larger as the light pulse is administered earlier into the subjective night. The theory also predicts phase delays at the beginning of the subjective night, delays that become larger as the light pulse is given later into the subjective night. Somewhere around the middle of the subjective night, phase delays should quickly give way to phase advances.

Phase-response curves, with the correct shape, have been obtained in almost all organisms tested to date with light. Unfortunately, very few of these organisms have been fishes. This is because the study of phase shifts requires long-lasting rhythms with precise reference points (e.g., activity onsets), and fishes seldom show such rhythms. However, at least three phase-response curves have been obtained with fishes, all with roughly the expected shape. The first two came from the locomotor rhythms of the inshore hagfish and the canary wrasse (*Halichoeres chrysus*), two species that bury themselves in sand to sleep and that show exceptionally clean separation between their activity and rest phases. The third phase-response curve came from the rhythm of melatonin release from the pineal organ of the ayu (*Plecoglossus altivelis*) in flow-through culture.

Besides light, two other possible zeitgebers in fishes are time-restricted food availability and temperature cycles. Food delivery at the same time every day can entrain rhythms of activity in otherwise constant conditions, as has been shown in mummichog, goldfish, wels catfish, European seabass, and oriental weatherfish (*Misgurnus anguillicaudatus*). Entrainment of locomotor activity to cycles of 12 h of 20 °C and 12 h of 26 °C has also been reported for zebrafish. The mechanism of entrainment in these cases has not been identified. In the case of entrainment by food, the possibility exists that the circadian clocks being entrained are anatomically distinct from the ones normally entrained by light. This has led to the notion of separate light-entrained oscillators (LEOs) and food-entrained oscillators (FEOs). There is some evidence for the existence of FEOs in fishes, but work remains to be done to distinguish them from LEOs that could have a memory of mealtime being stamped onto a particular phase of their oscillation.

In mammals, there are known examples of entrainment by daily social interactions, induced physical exercise, and sleep interruptions. These factors appear not to have been tested in fishes. Another potential zeitgeber apparently untested in fishes, despite its presence in many freshwater habitats, is a daily cycle of oxygen concentration in water.

Diurnality and Nocturnality

The circadian clock of mammals and birds is responsible for maintaining the integrity of the sleep–wake cycle and its synchronization to the light–dark cycle. Conceivably, the same could be said of fishes. However, many fishes (mostly freshwater ones) do not sleep very deeply and do not appear too restricted by light or darkness in the timing of their activity. For example, goldfish can be nocturnal, diurnal, or constantly active, even in the same laboratory. There have even been reports of individual goldfish starting a study as diurnal and then switching to a nocturnal mode, or vice versa. Lake chub tend to be diurnal in the laboratory, but they have been seen feeding at night in the wild, and during their spawning season they migrate only at night. The spawning season itself tends to disrupt daily activity cycles in many species. Sticklebacks and cichlids are normally diurnal but during their parental phase they fan their eggs day and night. Some species switch from a nocturnal or crepuscular pattern of activity to a diurnal one when daylight is dimmed (e.g., in turbid waters). Many more species change the timing of their activity phase between summer and winter. Salmonids also can be nocturnal, diurnal, or aphasic; however, they consistently suppress daytime activity either in winter or simply when water turns colder. In captivity, European seabass and white suckers are mostly diurnal when kept in groups, but nocturnal when housed individually. Many cyprinids can be either diurnal or nocturnal, depending on when food is made available. Interestingly, all these flexible species (with the exception of the lake chub) exhibit circadian rhythms of activity that are neither particularly clear-cut nor long-lasting in the laboratory.

However, there are examples of fish species that do sleep soundly, marine ones in particular. Such species tend to keep to the same time of day for their activity phase, and those that have been tested for circadian rhythmicity have yielded rhythms that are better than most. It is interesting to note that the two species, which had activity rhythms strong enough to yield phase-response curves (see above), were both sound sleepers and marine as well. At this stage, the relationship between habitat, sleep soundness, and the self-sustainability of circadian rhythms remains tentative, but it may become better studied in the future. A worthy goal would be to identify the mechanism by which the circadian clock determines the exact phasing of activity relative to the light–dark cycle, something that remains a mystery at present in fishes as well as in other animals.

Location of the Circadian Clock

Circadian clocks can be located anywhere in the body of an animal, and there may be many present. In mammals, one clock drives the others. This so-called pacemaker, or master clock, is located in the suprachiasmatic nucleus (SCN) of the hypothalamus. It receives input from the retina allowing entrainment to the light–dark cycle. In birds, both the hypothalamus and the pineal gland can act as circadian pacemakers, independently or in tandem depending on the species. Light can reach these structures directly through the thin skull or via messages from the eyes.

In fishes, no master clock has been identified yet; no structure analogous to the mammalian SCN has been documented in them. Nevertheless, the pineal is present, it is directly photosensitive, and it contains an intrinsic circadian clock. The fish pineal exhibits a circadian rhythm of melatonin production, even when isolated in culture. This rhythm can be entrained by light–dark cycles and phase-shifted by light pulses, both *in vivo* and *in vitro*. Melatonin is produced only during the subjective night, and, being a hormone, it could act as a body-wide signal to synchronize other, more peripheral clocks. Thus, the fish pineal has all the necessary characteristics of a master circadian clock.

However, pinealectomy usually does not eliminate circadian rhythms of activity. The ablation often alters freerunning periods (**Figure 3**), and has been reported to split rhythms in white suckers (**Figure 4**), but the rhythms usually persist. Moreover, in some species, such as salmonids, the pineal is photosensitive but does not express any freerunning rhythms of melatonin production; melatonin is just secreted whenever there is darkness. Thus, for most fish species, the pineal cannot be the master clock in and of itself, although it may be an important cog in the circadian machinery.

The fish retina is capable of several circadian phenomena. Rod and cone migrations anticipate daily changes in lighting and they freerun in DD. Dopamine release also follows a circadian pattern in constant conditions, even in isolated retina, with production being high during the subjective day. However, ophthalmectomy does not abolish freerunning rhythms of activity, nor does it prevent entrainment of these rhythms to light.

Clock genes are transcripted on a circadian basis under constant conditions in isolated heart and kidney tissue from zebrafish. Moreover, these tissues are responsive to light. Hearts and kidneys must therefore have circadian clocks. We must seriously envision the possibility of a complex network of central (brain) and peripheral clocks in fishes, either linked or responding independently to the same zeitgebers to maintain physiological integrity within the whole body, rather than a single pacemaker driving all other clocks as in mammals.

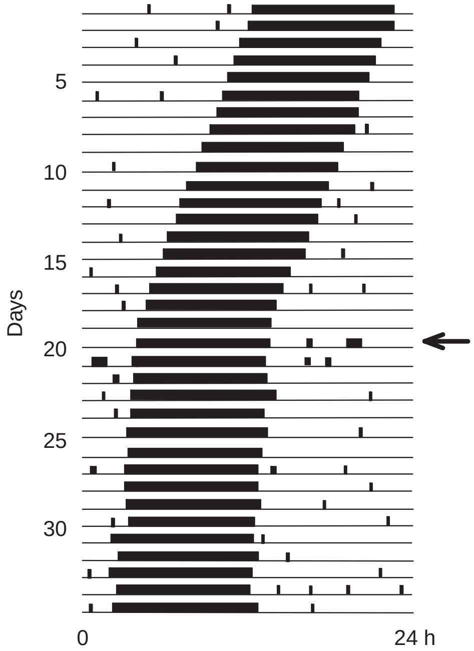

Figure 3 Freerunning activity rhythm of a burbot in constant darkness. The arrow on the right indicates the day when the fish was pinealectomized. The endogenous rhythm persisted after the pinealectomy, but the periodicity increased slightly from 23.61 to 23.89 h. Adapted from figure 1A in Kavaliers M (1980) Circadian locomotor activity rhythms of the burbot, *Lota lota*: Seasonal differences in period length and the effect of pinealectomy. *Journal of Comparative Physiology A* 136: 215–218.

Clock Genes

The molecular basis of circadian rhythmicity has been described in fruit flies and mice. Four main genes are involved. The *Clock* and *Bmal* genes encode proteins that are transcription factors. These activate the expression of the genes *Period* (*Per*) and *Cryptochrome* (*Cry*). The PER and CRY proteins, in turn, repress the transcription of their own genes by the CLOCK and BMAL proteins. This system is a feedback loop in which the expression of the genes is suppressed by their protein products with a periodicity of about 24 h.

Homologs of these genes have been found in zebrafish. All have multiple copies in the genome. Three *Clock* genes (*zfClock1*, *2*, and *3*), three *Bmal* genes (*Bmal1*, *2*, and *3*), three *Per* genes (*Per1*, *2*, and *3*), and six *Cry* genes (*zCry1a*, *1b*, *2a*, *2b*, *3*, and *4*) have been identified in zebrafish. All of the *Clock* and *Bmal* genes are expressed rhythmically in various tissues in DD. The first four *Cry* genes are also expressed rhythmically in the retina, pineal organ, and other parts of the brain.

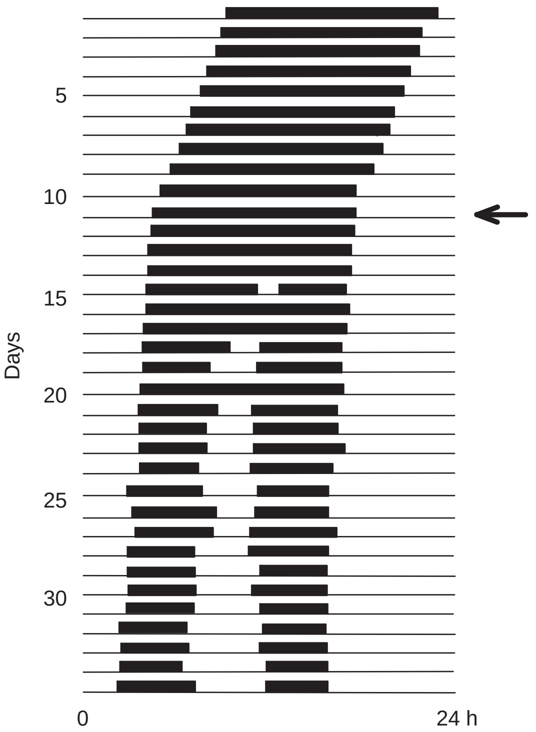

Figure 4 Freerunning activity rhythm of a white sucker in constant light. The arrow on the right indicates the day when the fish was pinealectomized. The rhythm persisted but split after the pinealectomy. Adapted from figure 2 in Kavaliers M (1980) Circadian organization in white suckers *Catostomus commersoni*: The role of the pineal organ. *Comparative Biochemistry and Physiology* 68A: 127–129.

Circatidal Rhythms

Tides along coasts and tidal currents offshore represent another type of environmental cycle that can impact the life of fishes. Many species use intertidal zones as feeding and spawning grounds. These fishes should benefit from being able to anticipate the flooding and ebbing tides. They should therefore have a circatidal clock, one that runs with a periodicity of about 12.4 h, which is the duration of the tidal cycle in most locations (sometimes, geographical features can greatly dampen one of the tides, resulting in a 24.8-h cycle). Indeed, some intertidal species do exhibit self-sustained rhythms of activity with a period of about 12.4 h under constant laboratory conditions. Such species include the rock goby (*Gobius paganellus*), the shanny (*Lipophrys pholis*), the Montagu's blenny (*Coryphoblennius galerita*), the Molly miller (*Scartella cristata*, ex-*Blennius cristatus*), and the mudskippers *Scartelaos histophorus* and *Periophthlalmus modestus.*

Unfortunately, circatidal rhythms in fishes under constant conditions are even noisier and shorter-lived than circadian rhythms. In this regard, fishes are bested by invertebrates. Various species of intertidal crabs and mollusks have proved to be better subjects of study. Despite this, some entrainment and phase-shift studies have been conducted with fishes and they suggest that cyclic changes in hydrostatic pressure and periodic wave action are the most likely zeitgebers of fish circatidal rhythms in nature. However, nothing is known of the anatomical location of the circatidal clock, nor of its molecular mechanism.

Other Rhythms

Lunar rhythms have a periodicity of 29.53 days, as exemplified by the recurrence of the full moon every month. Semilunar rhythms have a periodicity of 14.76 days, such as the recurrence of spring tides (tides of maximum amplitude) on the days of new moon and full moon. Many fishes exhibit lunar or semilunar rhythms, but we do not know if these rhythms are the product of an endogenous clock or simply a direct response to external stimuli, such as tide amplitude, moonlight intensity, and gravitational pull by the moon. The problem is threefold: first, it is essentially impossible to place the animal in truly constant conditions (the gravitational pull of the moon is always present); second, it is difficult to reproduce the complex variables of a lunar or semilunar environment in the laboratory; and, third, these rhythms are slow and require a relatively long time to express many cycles. With the possible exception of ovarian activity in mummichogs, freerunning lunar or semilunar rhythms have not been convincingly demonstrated in fishes (or in other animals, for that matter).

Many intertidal species spawn only during the high tides that surround the days of new moon and full moon. Examples include the California grunion (*Leuresthes tenuis*), the Gulf grunion (*Leuresthes sardina*), the Atlantic silverside (*Menidia menidia*), the mummichog, the inanga, the surf smelt (*Hypomesus pretiosus*), and the foureye (*Anableps microlepis*). The eggs are deposited high on the shore on spring tides, and, during the following 2 weeks, they remain in wet sand, uncovered by water and thus unexposed to marine predators. They hatch only during the next series of spring tides, which will take the larvae away. Semilunar patterns of spawning have also been observed in some blennies and damselfishes that live near but not on the intertidal zone, and, in such cases, the rhythm might help synchronize the mating activity of the population and facilitate dispersal of the larvae by tidal currents. Semilunar rhythms also exist in a few freshwater species, especially in the growth rate and food intake of various salmonids.

Examples of lunar rhythms include the seaward migration of adult eels (more fish move during the waning moon), the downstream migration of juvenile Atlantic salmon (*Salmo salar*, more movement around the time of new moon), and commercial catches of various clupeids (more captures around the full moon).

A final type of clock is circannual; it runs with a periodicity of about 1 year. Many examples are known from birds and mammals. Under conditions of constant temperature and stable photoperiod in the laboratory, starlings keep on molting, ground squirrels still fatten up and hibernate, and deer continue to grow and shed their antlers at a periodicity that is often short of the full year. In fishes, however, no endogenous circannual rhythms have been found. Annual cycles obviously exist in wild fish, in growth for example, but they may not be endogenous.

Glossary

Benthic Lowest level of a body of water.
Chemotrophic Ability to obtain energy from the oxidation of organic or inorganic compounds.
Crypsis Blending into the background, most usually visual crypsis, although crypsis can refer to other senses.
Foraging theory Identifying the rules that govern how animals acquire resources.
Limnetic Open surface waters of a lake away from the shore line.
Morph Shape or form.
Ontogenetic The development of an organism.
Zero–one rule Always rejecting or including specific food items.

The Need for Food and Demands Placed upon Its Acquisition

A fundamental feature of ecosystems, indeed perhaps their defining feature, is the flow of energy from some initial source. Typically, this begins with photosynthetic plants that are capable of using solar energy that then creates the food for herbivores. Ecosystems whose bases are chemotrophic bacteria are less well known. No fish is capable of producing its own energy and so all fish must obtain their food from other organisms, either living or dead. This food provides the raw materials necessary for growth and reproduction, and the energy for all activities.

Ecologists have long known that animals need to be very good at obtaining food. As a consequence, a number of research approaches have been developed to understand foraging theory that are united by an evolutionary approach: those that are the most successful at obtaining food will then have the resources necessary to find mates and produce offspring. Consequently, food is considered a surrogate for evolutionary fitness, and individuals are assumed to be subject to evolutionary pressure to maximize their net rate of energy acquisition.

Here, the focus is on the net rate of energy acquisition. Simply obtaining food at a very high rate is of little use if this is an extremely expensive strategy. What is of benefit to any animal are the resources that are made available by food, less the cost of obtaining them.

Foraging Models – What Should You Try to be Doing?

The simplest foraging models require that animals maximize their net rate of energy intake in an environment that contains only a reliable distribution of food. While overly simplistic, these models form the foundation of more sophisticated and realistic models. One complication is variation in the availability of food. When deciding how to feed, fish have to consider both the net rate of benefit and the variation around this benefit (=reliability of finding food). Normally, high rates of food availability are good, while variation about that rate is bad. The question is how to integrate these two parameters, and whether all individuals are affected equally. In general, reliability can trump a higher but more variable rate of return.

Another complication is access to the information that allows fish to make good decisions about how to obtain food. The information may be acquired directly, requiring that the fish travel to different locations, assess their value, and then retain that information long enough and in an accurate enough form with which to make a decision. Alternatively, they may acquire their information by copying others (i.e., public information). While the former mechanism is expensive in time, energy, and somatic resources, it is also more precise than the latter. The question again is do the benefits justify the expense.

What Should You Eat?

One of the earliest and most successfully applied aspects of foraging models is the diet model. It considers whether a food item should or should not be consumed by a foraging fish and argues that food items can be ranked from highest to lowest based upon their net energetic value. Thus, the energy obtained from a type of food should be divided by the time spent searching for, capturing, and consuming it. The model then determines which food items will maximize the net rate of energy intake and predicts that strict adherence to this diet will mean that some food items are always ignored, while others are always consumed – the zero–one rule.

The logic behind the model is simple. Should an animal choose to devote time to consuming items of lower net energetic value, it will come at the expense of time that could be spent consuming more profitable food. This model has also attracted considerable attention for fish in part because it is relatively easy to obtain the important information. What is required is some estimate of the food that is available in the natural habitat, and then examining the contents of their stomachs to determine whether they select food randomly, or in a fashion more consistent with the diet model. The diet model performs well but seldom satisfies the zero–one rule. This usually means that the underlying assumptions of the model are an oversimplification of the task confronting animals in the wild.

One of the key omissions in the diet model is it just treats energy as the currency and fails to include access to other resources. For fish, and juvenile fish in particular, this can be a large error. Nonenergetic resources are crucial for the survival of juvenile fish populations. Perhaps the most critical decision is first-feed – the point at which larval fish must now obtain their food from the environment, having consumed all of their energetic reserves from their yolk. In many species, not all food has equal value and often there are times when these juvenile fish must consume prey that contains required nutrients. If critical prey are unavailable at the right time, all the juvenile fish will perish independent of the energetic value and accessibility of other prey.

Where Should You Go to Get Food?

Two modeling approaches where a fish should go to feed are discussed in the following.

The Patch Model

The patch model assumes that food is discretely distributed, fish know the average net rate of energy acquisition within their environment, and the net rate of energy gain declines at a nonlinear rate as they consume and deplete food within a patch. As with the diet model, the economics of foraging then argue that if energy is the only consideration, the food within any location should be

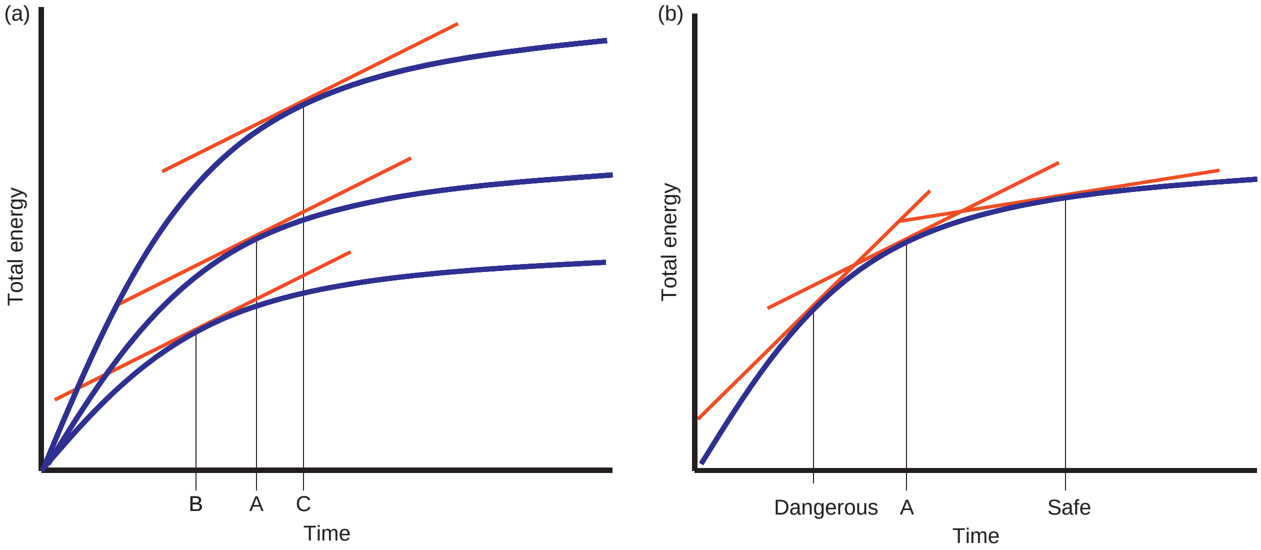

Figure 1 When an animal enters a feeding a location, it will accumulate food through time. Since the density of food will decline as the animal consumes it, so too will the rate of accumulation meaning that these functions will be nonlinear. Foraging is defined as the rate of energy gain, and therefore can be determined at any time as the tangent to the curve. (a) The point at which an animal should stop foraging in a patch occurs when its feeding rate has declined to the average for the environment, as identified by a tangent with a known slope. For a feeding patch of intermediate value (the middle curve), this occurs at point A. The lower curve identifies a location that contains a lower density of food, and as a consequence a feeding animal will drive the feeding rate down to the environmental average in less time (B). Conversely, the upper curve illustrates a more profitable feeding location that provides a feeding animal with more time before its foraging rate declines to the environmental average (C). (b) This technique can be used to assess environmental quality when more than energy affects quality. If energy were the only consideration, a foraging animal would feed in that location until the feeding rate equaled the environmental average, leaving behind a density of food equal to A. But if that location is dangerous, the animal will leave earlier when its feeding rate exceeds the environmental average. If the location is safer, the animal will remain longer until its feeding rate exceeds the environmental average. Measuring these densities makes it possible to assess habitat quality from a feeding animal's perspective.

depleted to the point where the net rate of energy intake equals that for the environment (**Figure 1(a)**).

What if safety from predators is an important consideration? If this is the case, a fish could leave a patch with food remaining if threatened by a predator. This important consideration can be assessed as habitat quality by measuring the density of food remaining within an artificial feeding patch when fish choose to move on to other areas (a GUD – giving-up density, **Figure 1(b)**). This approach is being used to assess habitat quality for foraging fish in the wild after being used for some time to assess habitat quality for terrestrial rodents.

A feature of most fish species is that as they grow, so too do the potential food items that they can consume. A result is that locations that were very profitable for fish when they were small may no longer be so as they grow larger. This phenomenon is known as the ontogenetic niche and recognizes that fish occupy different ecological niches as they move through different size stages. While the decision-making process may be similar to that described above, the solution tends to be size specific.

Another important consideration of where a fish should go to feed is dependent upon where others have selected to feed. If feeding rate is determined positively by the amount of food, but negatively by the number of competitors, then both factors will determine the distribution of feeding animals. If these animals conform to two assumptions, 'ideal' in that they have perfect information about the distribution of their resources, and 'free' because all have equal competitive ability, then the distribution of fish should conform to the ideal free distribution (IFD). A consequence of the IFD is that independent of the amount of food available within any patch, all fish will have the same intake rate across all feeding patches (see **Figure 2(a)**). Furthermore, this distribution is stable (known in economics as a Nash equilibrium) since any individual that moves to a different feeding location will have a lower feeding rate.

IFD Model

As with the patch model above, the IFD model requires that food be distributed discretely in space and time. However, these different feeding locations may provide food either continuously (such as fish that hold a feeding territory within a river or stream) or discretely, as above. A distinction is important since this will determine the relation between foragers and their food. The simplest case is when food is provided continuously. Under the assumptions of the IFD,

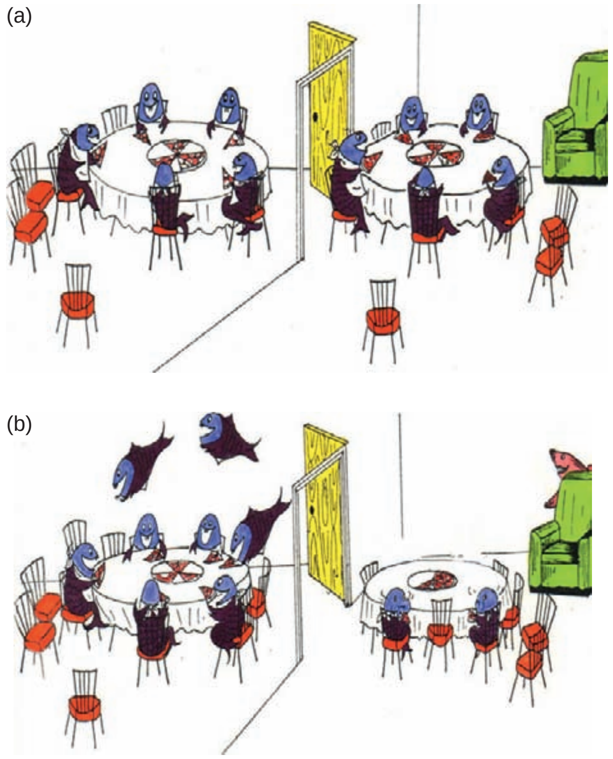

Figure 2 A cartoon illustrating habitat matching associated with the IFD. (a) With two equal-size pizzas distributed between two rooms, 10 fish will distribute themselves equally between these two locations. Note that this distribution is stable since any fish that deviates from this distribution will get less food (e.g., more fish to share the same amount of food). (b) In the same environment as in (a) but with a predator on the right. As foragers move from the dangerous (right) to safe locations (left), they change individual feeding rates to the point where the increased rate of energy acquisition of those feeding in the presence of the predator will compensate them for the risk they incur.

the result is a phenomenon known as habitat matching – the spatial distribution of predators will be the same as the spatial distribution of their prey (**Figure 2(a)**). This occurs because individual feeding rates are assumed to be equal to the total rate of food availability divided by the total number of foragers competing for this food. If 60% of the rate of food is available at a particular location, then this location should account for 60% of the foragers.

How Should You Capture and Consume Your Food?

Deciding where a fish obtains food is in part determined by how the food is consumed. Sit-and-wait feeders, by definition, select feeding locations that vary in quality by the rate at which food becomes available (**Figure 3**). This contrasts with a pursuit strategy where predators move through their environment to hunt and capture prey (**Figure 4**). Some species adopt both strategies, depending upon life stage and circumstances; other species are morphologically adapted to one or other tactic. The sit-and-wait tactic has the obvious advantage of a very low cost. Profitability hinges upon the rate at which prey can be successfully captured

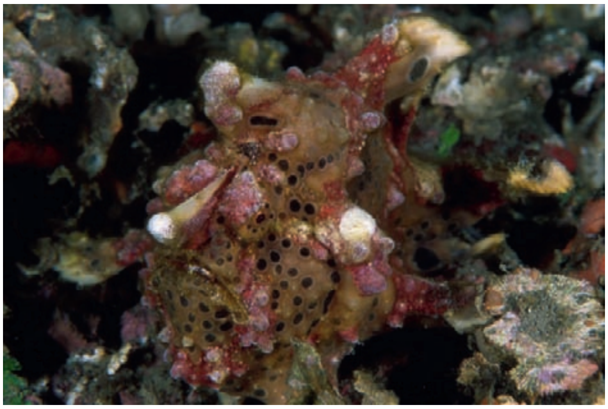

Figure 3 Image of giant frogfish (*Antennarius commersonii*) as an example of a sit-and-wait predator. Adaptations for this foraging strategy include a large mouth to increase the range of potential prey, and a visually cryptic morphology to reduce the probability of detection. Courtesy of Sergey Parinov.

Figure 4 A barracuda as representative of a pursuit predator. Success in this strategy is determined by swimming efficiency, both sustained for contacting prey and burst for prey capture. This image is from a painting by Robert W. Hines and is provided courtesy of the US Fish and Wildlife Service.

and consumed. How to go about doing this is dependent upon the type of prey being consumed. If the prey has no defense, then no special modifications are required. But if they do, success hinges upon defeating the prey. First, sit-and-wait predators need an antidetection mechanism. We observe such tactics primarily using vision and notice tactics that employ visual crypsis. For example, species such as the giant frogfish (*Antennarius commersonii*) that have an irregular, rock-like shape (**Figure 3**). Other species may burrow in sand. Regardless of mechanism, the goal is to allow prey to get close enough to increase the probability of capture success, the next critical adaptation to this mode of foraging.

Maximizing capture success depends upon the type of prey being sought. Animals that are mobile and capable of detecting predators have an antipredator strategy to avoid capture. Predators counter this by capturing their prey very rapidly. Key components of this strategy include the ability to very rapidly draw large amounts of water (plus prey) into their mouth, teeth that are specifically designed to grab and hold prey, and a gape size that makes it possible to consume a wide range of size classes (**Figure 3**). This is a particularly important strategy where prey exist at very low density and therefore the cost of search may be prohibitive (e.g., some deep ocean locations). Deep-sea fishes provide excellent examples of adaptations to avoid detection and the capacity to consume prey larger than themselves. They also have enhanced their sit-and-wait strategy by having evolved morphological and behavioral means to actively attract potential prey: by providing something they may be seeking, such as food as bait.

By their very nature, pursuit predators tend to be more commonly observed since they actively move through their environment to feed, which requires they be efficient at sustained swimming and have a well-developed visual system that enables them to detect prey (**Figure 4**). Unlike sit-and-wait predators, the key to success is to postpone detection to a point where they can initiate an attack with a high probability of success rather than avoid detection.

As noted above, whether to pursue or wait for prey is mainly driven by economics. If your chance of encountering prey is not greatly increased by moving, then it makes no energetic sense to pursue prey. However, moving to a different feeding patch may provide a significant benefit to moving through your environment. Often, other factors at play will influence these decisions. A relevant example is a juvenile salmon feeding in a stream. The preferred strategy is to establish a feeding territory and let the food come to them. Because there are more fish than territories, those not capable of competitively obtaining and retaining a territory are forced to use less profitable tactics.

Dealing with Competition

IFD is a consequence of competition among foragers. Animals may share the resource equally as assumed by the IFD, which is known as scramble competition. Alternatively, the outcome of competition may be determined by interactions between individuals and is appropriately termed contest competition.

If animals do conform to the assumptions of the IFD, then the distribution of foragers will match the distribution of their food (**Figure 2(a)**). However, the assumptions are unlikely to be met in reality. In particular, it is unlikely that all animals will be equal in their competitive ability (**see also Social and Reproductive Behaviors**: Dominance Behaviors). When there is variation in competitive abilities, a different type of spatial distribution will result with those of superior competitive ability being in locations that provide the greatest amount of food, and vice versa. Under this scenario, rather than the number of animals matching the spatial distribution of food, the prediction is that the number of competitive units (i.e., assume all animals scaled in units of the poorest competitor in the population) will match the spatial distribution of food. While such a distribution will involve considerable individual interactions, it is intermediate between an IFD and territoriality, in which an individual defends and monopolizes food within a certain territory. For territoriality to exist, the distribution of food must be similar to that necessary for the IFD. In addition, there must be sufficient difference in competitive ability that will make the cost of defending the location profitable.

The Role of Predation Risk and How It Changes the Rules

The vast majority of fishes seek food while simultaneously avoiding becoming food. While many of the strategies described above are very effective at obtaining food, they typically make fish vulnerable to predators, which can significantly change the foraging rules.

The most obvious influence of a predator is the trade-off between access to safety and energy (**Figure 2(b)**). Examples include reducing the number of animals that may choose to feed in dangerous but profitable locations, choosing to feed at times when predators are not present, and even occupying habitats that generate physiological stress but safety from predators.

Understanding the relative importance of safety and food requires a common currency for both resources. Laboratory techniques employ approaches such as IFDs that provide animals with only energy and safety, making it possible to measure their value in energetic units. In field locations GUDs can be used (as described above and in **Figure 1(b)**). Here, fish are provided with artificial feeding patches designed such that food density determines feeding rate. The initial amount of food provides a high feeding rate, but the more they consume, the lower their feeding rate. In safe locations animals drive the food density of these patches down to a much lower level than in dangerous areas, demonstrating how much energy they are prepared to forego in order avoid predators. The application of dynamic state variables as a modeling technique has also made it possible to integrate internal physiological characters, as well as other environmental factors, into better understanding so as to how animals make decisions that trade off food access against safety.

General outcomes from these three approaches do support the conclusion that animals do forfeit considerable foraging opportunities to gain access to safety. The significant range in this forfeiture has been experimentally determined. Fishes whose reproductive success is tightly linked to feeding rate are not as affected by predation risk when making foraging decisions, and vice versa. Likewise, fishes that are energetically stressed are also less affected by the presence of predators. Fishes also appear to take their vulnerability to predators into account when making such decisions, meaning that larger individuals, and those possessing anti-predator morphology (armor, spines, toxins, etc.) are less affected by predators than are those that are smaller or lacking in such morphology.

Tactics for Avoiding Predators

The probability of being killed by a predator (e.g., risk) is determined by the time spent being vulnerable to predators, the probability of encountering a predator while being vulnerable, and, if a predator is encountered, the probability that such an encounter will be fatal. In the presence of predators, foraging tactics will be modified with respect to their impact upon these three parameters.

Approaches used by fish to reduce the time spent being vulnerable to predators hinge upon spatial and temporal foraging decisions. The spatial option requires that there must be locations in the prey's environment that are not accessible to their predators. These include burrows, rocky crevices, weed beds, or other complex environments that provide locations small enough to permit the prey to gain entry, but not their predator. If there is also food within these locations, then it will also contain the majority of the fish competing for access to this food. The net effect is that an energetic price must be paid for safety.

Locations that vary in key environment variables, such as temperature, turbidity, dissolved oxygen, or natural or anthropogenic contaminants, provide an opportunity for fishes to take advantage of differences in tolerance. For example, if prey tolerate hypoxic environments better than their predators (e.g., warm, shallow regions that contain decaying vegetation), then these locations will provide prey with a spatial refuge (**see also Behavioral Responses to the Environment**: Behavioral Responses to Hypoxia). Ironically, the very areas that may appear to be the least desirable fish habitats may be critical for the survival of some species (e.g., the marshes of Lake Victoria for haplochromine cichlids).

Many predators visually detect small fish and must hunt during daytime. An obvious tactic of small fish then is to use locations that contain the majority of the food at times when their predators are not active. Such behavior results in vertical migration of some fish that move to the upper, more productive regions of lakes and oceans in the evening to feed. It also accounts for the migration off reefs during twilight periods, allowing these resident species to feed under conditions that reduce their risk (**see also Fish Migrations**: The Biology of Fish Migration).

Fish in the superorder Ostariophysi also have specialized cells in their epidermis that contain alarm substance (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior). This chemical is released when a fish is injured or killed. The location of this chemical in the environment identifies high-risk areas that are usually avoided by small fish. Some predators also secrete this chemical after consuming a prey, thereby directly identifying their location.

While reducing the time spent being vulnerable is likely a preferred option to minimizing the risk of death from predators, the energetic cost may be too great to avoid incurring some risk. The options available to fish include avoiding detection if encountered, communicating with the predator in some way that convinces it not to attack, possessing specialized morphology that renders itself less susceptible to attack, or specialized behaviors that assist in escape.

The best way for prey to avoid detection is to blend in with their background. When this is done visually, this also requires that the prey must remain still in order for this approach to be effective.

If prey have detected a predator first and are capable of doing something to avoid capture, it is mutually beneficial to both parties that this information be communicated. It is also in the predator's interest that if it receives this information from the prey, it has some certainty that it is accurate. Examples do exist in terrestrial mammals, but they are not well known in fish.

If predators cannot be discouraged through dialog, then communicating the presence of toxins that are contained by prey may also deter attack. Species that are toxic are, in general, brightly colored in order to make clear the presence of these chemicals. Predators will learn very quickly to associate the bright colors with toxins and hence should avoid such encounters in the future. The

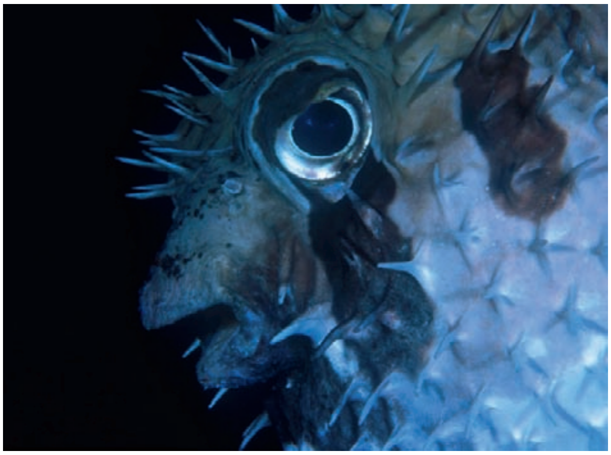

Figure 5 The antipredator morphology of the black-blotched porcupinefish (*Diodon liturosus*). This fish possesses spines over the entire body and, when disturbed, is capable of inflating with water to dramatically increase their size, and erect spines that make them a poor fit for most predator's mouths. Courtesy of Sergey Parinov.

caveat however is that other species will mimic the colors of toxic species without containing the toxins (a model mimic complex). The relative abundance of the mimics will impact the effectiveness of this approach.

Some species have unique morphologies, such as spines and armor plating, that make them very difficult for predators to consume (**Figure 5**). Perhaps the best example is the porcupine fish, which considerably swell their body and spines when disturbed, making them almost impossible to consume for all but the largest predators. Tuna, however, may attack these fish so rapidly that an effective defense cannot be mounted.

Are There Overall Consequences?

At the outset, we had noted the role of evolution in shaping fish design and behavior. Finding food and avoiding predators are fundamental, and the genetic characteristics of individuals that do better than their peers will shape the traits of successive generations. What is important here is that the presence of predators may also be considered to be an important resource. Typically, most individuals avoid locations that are dangerous resulting in greater feeding opportunities in more dangerous locations. Those individuals that are prepared to incur greater risk or that possess specialized morphologies to mitigate the risk can only take advantage of these traits if there is a healthy predator population within their environment. Furthermore, if there is a cost to possessing such traits, reduction in the density of the predator population will mean that for these individuals there will be no compensating benefit to the possession of these traits that will in turn result in their ability to survive in their environment which too is now being compromised.

It is from this perspective that the importance of predators in stabilizing ecosystems can be appreciated. While predators consume individuals at lower trophic levels, they also serve as an important resource for some species and therefore play an important role in competition. The converse is also true. If ecosystems are perturbed resulting in a significant decline or loss of the top predators, then they become destabilized. Those prey species that are adapted to obtaining food under such conditions will no longer be designed for thriving under these new conditions. As a consequence, new, invasive species will better be able to establish themselves and may displace the native species.

This perspective may also be important in understanding how to re-introduce species. Simply adding more individuals through hatchery programs or otherwise artificially increasing the population may not necessarily work if their environment has also changed. Properly understanding how that species is adapted to make foraging decisions in the presence of predators and what species currently occupy the environment into which this species will be introduced should provide insight as to how well this animal is designed for the environment it will now confront.

Glossary

Compensatory growth A faster-than-normal growth that some species exhibit after a period of resource deprivation.

Dominance The state of being dominant where dominant individuals obtain a high status within a social group.

Hormone A chemical substance, often a peptide or steroid, released from endocrine glands that controls and regulates a range of physiological activities.

Hyperphagia Rate of food consumption significantly higher than that shown by animals that have been feeding continuously on an *ad libitum* ration.

Smolting Behavioral and physiological changes crucial to the successful rapid entry of fish that were born in freshwater and are migrating to the marine environment.

Introduction

Fish are capable of reacting after a period of resource deprivation by increasing their growth rates to higher-than-normal levels. This implies that animals under normal conditions are growing at a rate below their physiological potential and therefore they are able, to some extent, to adjust their growth. The main question regarding compensatory growth is why fish do not usually grow as fast as they can, since it is well known that the risk of predation reduces with increased body size (**see also Behavioral Responses to the Environment**: A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food). There is some evidence that indicates that there is a trade-off between growth and fitness such that rapid growth can produce deleterious effects compromising further survival. Growth compensation will be favored if the benefits of catching up in size outweigh these costs. Many consequences of accelerated growth rates are related to behavioral changes that animals show during and after compensation, particularly associated with changes in feeding habits and the trade-off between accelerated growth and the increased risks than the fish must take foraging for the extra food. These changes in behavior can be grouped into two different classes depending on whether these changes occur during the period of compensation or are a consequence of increased growth rates (**Figure 1**).

The main mechanism involved in the compensatory growth response is hyperphagia, an increased rate of food consumption, although increased conversion efficiencies or behavioral adjustments can play a role. Hyperphagia implies various behavioral changes, mainly an increase in the boldness and reduction in the use of shelters. During the period of compensation, fish increase their feeding activity and spend more time searching for food in open waters where the chances to be preyed upon are higher than in normal circumstances. The need to grow at a higher rate also affects intra-specific behavior, increasing aggressiveness and competition between fish. However, in the majority of studies on compensatory growth, study animals are held individually and therefore the behavioral changes that they experience during compensation are very difficult to evaluate due to the absence of social interactions (**Figure 2**).

After full growth compensation, fish can show deferred physiological and behavioral effects as a consequence of the rapid growth experienced. There is evidence in a variety of taxa that rapid growth can affect locomotor performance, possibly because of its effects on muscle cellularity and development, and therefore the benefits of growth acceleration should be matched against the locomotor costs. Swimming performance is strongly related to many fish behaviors, such as anti-predator behavior or breeding performance via sexual displays or offspring care.

Behavioral Changes during Compensation

Hyperphagia can result from increasing meal frequency, food consumption per session, or the combination of both. There is significant inter-specific variation in the

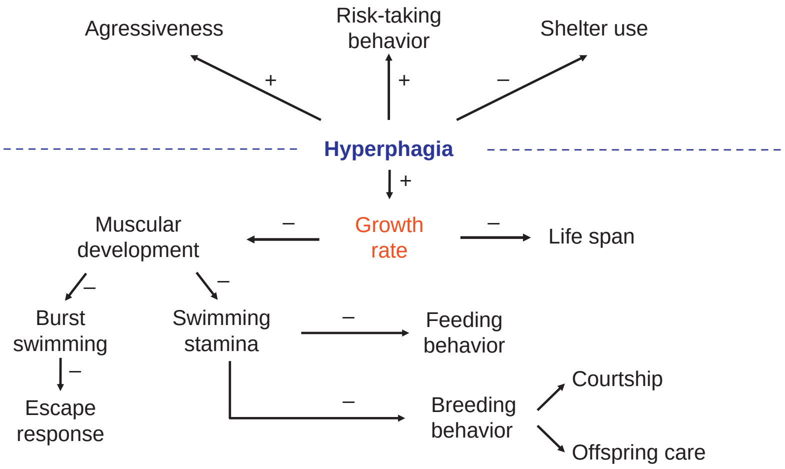

Figure 1 Schematic representation of the direct and indirect effects of compensatory growth on fish behavior where hyperphagia indicates the elevated rate of food consumption associated with compensatory growth. Above the blue line: behavioral changes during compensation; under the blue line: deferred effects of compensatory growth on fish behavior. +, positive relationship; –, negative relationship.

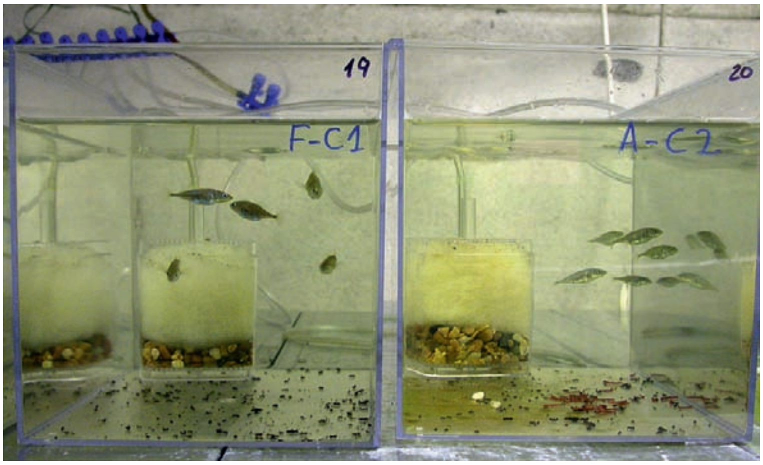

Figure 2 Three-spined sticklebacks (*Gasterosteus aculeatus*) held in groups of five fish during the phase of growth compensation. Many fish species live in shoals as juveniles, and isolation of individuals during laboratory experiments could affect growth performance. The majority of studies investigating compensatory growth separate fish into individual tanks making it impossible to study additional effects on social behavior. Photo: David Álvarez.

temporal pattern of hyperphagia. However, fish, like other vertebrates, can regulate their hyperphagic response according to the quality of the food and the energy needed. Animals that are compensating in growth have a greater food intake than fish that have continuous access to food but which have not undergone a growth depression. This suggests that the maximum daily rates observed during hyperphagia represent a rate close to the maximum possible rate at which the gut can process food. Although the mechanisms that allow compensatory growth are physiological, behavioral adjustments must be involved as high growth rates require an increase in food intake.

Hyperphagia imposes several behavioral costs. Increased foraging to obtain the extra ration of food needed to increase their growth rate may expose the animals to a greater risk of predation. Compensating fish are bolder in the presence of a potential predator than the fish growing at normal rates, and fish exhibiting hyperphagic behavior can increase the number of feeding attempts by more than 50% compared to fish of the same age growing at normal rates.

Risk-Taking Behavior

Feeding activity can increase the risk of being eaten, since foraging often decreases vigilance. Moreover, after a period of growth depression, a hungry fish may have difficulties avoiding an attack if it is weakened by its poor body condition. For the fish, this is a behavioral dilemma: on the one hand, a high growth rate will reduce the time that a fish spends in smaller, more vulnerable stages, but on the other hand to have a high growth rate, a fish has to take more risks and obtain more food. The search for the food necessary to increase their intake rates implies that fish have to use open waters more frequently than fish growing at normal rates and, therefore, they will have a greater chance of being captured. Studies carried out with coho salmon (*Oncorhynchus kisutch*) showed unequivocally that catch-up growth after a period of growth depression involves a change in the trade-off between food consumption and risk of mortality due to predation. In a study carried out with reef fish ambon damsel (*Pomacentrus amboinensis*), Monica Gagliano and her collaborators demonstrated that young fish with an intense selective pressure to grow at a faster rate during their benthic life had a high feeding motivation, and were willing to take a greater predation risk as a cost of gaining more resources.

Shelters are commonly used by inactive fish to give security against predators but usually imply a cost of reduced feeding opportunities. Fish experiencing compensatory growth after a period of growth depression change their habits and are more likely to spend increased time out of refuges than fish growing at normal rates. Studies carried out with three-spined sticklebacks demonstrate that the recovery time taken for a fish to emerge from a refuge after a predator attack is less in fish that are compensating than in normal growing fish. In Atlantic salmon (*Salmo salar*), after a simulated threat of predation, juvenile fish growing at normal rates are reluctant to move away from refuges to intercept prey items drifting past in the current. In contrast, fish that are displaying hyperphagic behavior after a period of food shortage spend less time in refuges after a simulated predation attack and assume more risks. This behavior increases the time spent for feeding but at the same time increases the risks of being preyed upon since they are more exposed to predatory attacks.

Treatment of fish with growth hormone (GH) can be used to evaluate the behavioral consequences of rapid growth. GH stimulates tissue growth by increasing deoxyribose nucleic acid (DNA) synthesis and the rate of cell multiplication and differentiation, increasing the metabolic demands of the animal and the hunger level it experiences. In brown trout (*Salmo trutta*), GH-treated fish increased their growth rate and also reduced their anti-predator responses. Fish treated with GH spent more time swimming and in the upper part of the water column where they were more accessible to predators.

Various studies suggest that GH increases feeding motivation. Similar results are obtained with transgenic Atlantic salmon bred to contain and transmit a GH transgene (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Growth Hormone Overexpression in Transgenic Fish): they grow faster than control fish but spend more time foraging in risky environments. Although it has not been exhaustively investigated, some authors suggest that fish that experience a phase of compensatory growth produce more GH which could increase growth rates above normal levels.

Aggressiveness and Risk of Aggression

Hyperphagia may induce higher levels of intra-specific aggression as individuals compete for food, with associated costs in terms of higher rates of energy expenditure and increased risk of mortality. Intra-specific aggression can result in the formation of dominance hierarchies (**see also Social and Reproductive Behaviors**: Dominance Behaviors) and lead to a trade-off between increased resource acquisition and energy losses associated with agonistic encounters. Growth rates of subordinate fish can be depressed as a consequence of dominant aggression but aggression also involves energetic costs and loss of feeding opportunities during time spent in territory defense.

Studies carried out with Atlantic salmon have demonstrated links between growth bimodality, aggressiveness, and compensatory growth with food-deprived Atlantic salmon juveniles showing increased levels of aggression during the compensatory growth phase. In salmonids, life-history pathways are not fixed and life-history decisions depend on growth rates or size during specific decision windows. For example, several months prior to smolting and migration to sea, juveniles must decide whether to migrate to sea or whether to postpone seaward migration until the subsequent year. Slow-developing fish from the initially poorer competitive fraction of the population are likely to postpone migration, whereas fast-developing fish from the more competitive fraction of the population are likely to migrate to sea at least 1 year before slow-growing individuals. Fish that adopt the faster development pathway show compensatory growth and may experience higher aggression than slower-growing fish. Aggression arises over competition for food and fish that are compensating for growth are more likely to receive attacks from other competing fish. Fish that postpone migration initiate less aggressive actions needing only to maintain their energy reserves above a critical level with a further year in the river to grow; competition for food with the faster-growing fish is not necessary. These different growth strategies in Atlantic salmon result in the fast-growing juvenile Atlantic salmon that are more aggressive than slow-growing fish, but are also more vulnerable to receiving attacks from other conspecifics.

Activity Patterns

Some fish species become nocturnal to reduce the risk from diurnal predators, and shelters may be used by inactive animals to give security against predation risk. However, fish that compensate in growth need to eat more than normal and changes in foraging habits can affect diel activity patterns. Individuals that are nocturnal in normal circumstances can increase their diurnal activity and hence the risk of predation. In contrast, in species such as Atlantic salmon where nocturnal fish tend to be subordinates that could not find a secure foraging place during the daylight, it may be more risky to feed at night. If energy demand increases as a consequence of compensatory growth, fish will be forced to eat during the hours when they would normally reduce their activity, therefore succumbing to a greater risk of predation.

Time–Place Learning

Animals organize their daily activities, particularly foraging, by associating different places with food availability at different times of the day; this is called time–place learning (TPL) (**see also Sensory Systems, Perception, and Learning**: Fish Learning and Memory). In rats it has been observed that animals that were fed *ad libitum* lost their ability to learn time-of-day discriminating tasks, whereas food-restricted rats were able to acquire associations between two different places and two different times of day. Experiments carried out with Nile tilapia (*Oreochromis niloticus*) demonstrated that fish that were fed *ad libitum* failed to learn the time and place synchronization task, but when the experiment was repeated with fish that had experienced a period of 17 days of starvation, those fish were able to switch places at the correct period of the day to get food, suggesting that food restriction facilitates TPL discrimination.

Deferred Costs of Compensatory Growth

Effects on Predator Avoidance

Rapid growth can affect locomotor performance, probably through effects on muscle cellularity and development. In some species of fish, fast-growing individuals have a higher percentage of small-diameter white muscle fibers and greater numbers of similar-diameter red muscle fibers than the slow-growing individuals, which could detrimentally influence fish swimming ability. In the case of compensatory growth, the benefits of growth acceleration can be matched against the locomotor costs. Many fish species use burst swimming as a response to evade predators, and the speed of this response is directly related with the probability of surviving predation attempts. In a study on Atlantic silversides (*Menidia menidia*) faster-growing fish had poorer prolonged and burst swimming performances, suggesting a trade-off between growth rate and swimming performance.

In three-spined sticklebacks, fish that had undergone compensatory growth after a period of food deprivation had a reduced burst swimming speed compared to fish growing at normal rates. Interestingly, there was a strong interhabitat difference in the impact of compensatory growth on swimming performance. Following compensatory growth, fish from stream populations showed impaired escape speeds, but this was not seen in the pond populations. The explanation for this habitat difference appears to lie in the nonlinear nature of the trade-off curve. Small but sustained increases in growth rate (as observed in the pond populations of sticklebacks) had relatively little effect on burst swimming, whereas the greater growth acceleration seen in the stream populations of sticklebacks incurred a much greater cost. Lakes and ponds are structured environments in which fish need to be able to dart quickly into a refuge and then remain still; burst swimming is a key factor in determining likelihood of escape and may be too important a trait to be traded off against growth. In contrast, in rivers and streams the importance of burst swimming in evading predators is less important and fish can assume the cost of impaired swimming ability to achieve a larger size in a shorter period of time.

Many fish species possess a defensive morphology that protects them from predators (**see also Behavioral Responses to the Environment**: A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food). For example, in three-spined sticklebacks there is an interesting potential trade-off in resource allocation between investment in body growth and investment in defensive morphology. In this species, there is marked intra- and interpopulation variation in the average extent of their anti-predator defensive structures (the pelvic and dorsal spines, pelvic girdle and lateral plates), which is linked to the intensity of predation and the willingness of the fish to take risks when foraging. Fish from populations without predatory fish tend to have fewer lateral plates and spines than the fish from populations with intense predation. This reduction of spines and plates has been interpreted as an evolutionary regression of defensive structures in populations from small lakes and streams that lack predatory fish. Due to the phenotypic plasticity of these structures, individual sticklebacks that experience compensatory growth after a period of growth depression may compromise on allocation of resources to defensive armor in order to increase their skeletal growth rate. Hence, these fish will be less protected than the fish that have grown at normal rates.

Effects on Breeding Behavior

Fish and other animals have to reach a minimum size to have the opportunity of finding mates and breeding. A further dimension is the fact that the cost of being small during the breeding season differs between the sexes. In three-spined sticklebacks, an increase in body length has a positive effect on reproductive success in both the sexes. However, the cost of a small size is greater for males, because females can breed when as small as 32 mm, whereas even a 40-mm male will likely never breed. Moreover, while an increase in body size from 40 to 50 mm doubles the clutch size of a female, the same increase in body size leads to an approximately 15-fold increase in reproductive success in males. This necessity to achieve a minimum size is complicated by the need to allocate resources to other external characteristics that affect the sexual attractiveness of an individual. As with predator avoidance, a large body size at the time of breeding is clearly a fitness advantage, but the rapid growth needed to achieve it may be costly.

Effects on Breeding Coloration and Sexual Attractiveness

Numerous male fish develop secondary sexual traits when they reach maturity. These attributes could be hyper-developed fins or conspicuous appendices that males exhibit during sexual displays to attract females. As these attributes would be expected to impair swimming performance, they are considered honest signals of the quality of the male because there is a trade-off between anti-predator escape responses and sexual attractiveness. This trade-off can be affected by a previous diet restriction and further resource allocation during compensatory growth. Green swordtails (*Xiphophorus helleri*) are small, tropical, live-bearing fish whose males have developed a long sword which is an extension of the caudal fin that develops at sexual maturity. In an experiment carried out to study the effects of compensatory growth on female selection, females did not visually discriminate between males that had experienced poor early nutrition and a subsequent compensatory growth strategy and similar control males. However, physical aspect is not the only trait that female swordtails search for in a potential mate. Courtship displays are also very important in female selection, and male swordtails that have undergone a period of growth compensation have poorer swimming performance than control fish. Therefore, growth compensation following poor initial growth can indeed reduce the mating success of male swordtails much later in life.

Other fish species swap the dull coloration that they exhibit during the majority of the year for a bright and colorful coloration during the breeding season (**see also Sensory Systems, Perception, and Learning**: Communication Behavior: Visual Signals). To achieve this, fish must quickly mobilize a large amount of resources to the skin. Some of these resources, such as the carotenoids, cannot be synthesized and must be obtained from the diet. Thus, fast growth may result in more resources being allocated to growth at the expense of sexual ornaments, which could negatively affect female preference. Some authors suggest that males that have experienced compensatory growth early in life after a period of food restriction could be unable to develop phenotypic traits associated with mate attraction when older. They predict that such males may suffer a more severe decline in phenotypic traits than males that have not undergone growth compensation. This would result in females choosing males with normal growth trajectories over the growth-compensating males because the general appearance of the latter could be interpreted as an indicator of lower genetic quality.

Effects on Clutch and Offspring Care

As shown previously in this article, compensatory growth may impair muscle development and swimming performance. While this effect can be similar in males and females, there may be greater implications for males in terms of reproductive success as in many species females are the choosy sex and are likely to avoid males in poor condition or with reduced sexual attributes. However, in females compensatory growth can have a significant impact on reproductive investment (i.e., a reduced quality and number of eggs). Fast-growing males that show parental care after egg laying may be poorer fathers due their reduced ability to swim, which will adversely affect their ability to fan the eggs and defend the nest against intruders, but to demonstrate this potential effect, further experimental research is needed. Many salmonid fish spawn in rivers and streams where the female digs a nest in the gravel by lying on her side against the bottom and swimming forward energetically (**Figure 3**). These important movements might be impaired by the poor

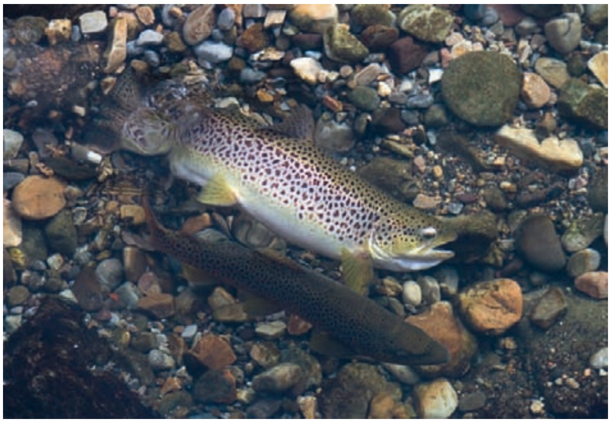

Figure 3 A pair of brown trout spawning. The female uses her tail to dig out a hollow in the gravel using a fanning motion. This behavior could be impaired if muscle development is hindered after a period of growth compensation. Photo: David Álvarez.

development of her muscles after a period of growth compensation, and could affect nest structure and further egg development.

Summary

The study of compensatory growth in fishes has received much recent attention, especially in relation to aquaculture, but many behavioral consequences of this accelerated growth remain unexplored. The main behavioral consequence of growth compensation is that fish have to take more risks to obtain the extra ration of food necessary to increase their growth rates. However, compensatory growth also affects intra-specific relationships between individuals and may have consequences for breeding behavior and parental care through impaired muscle development after a period of rapid growth. Increased research efforts are now needed in the study of long-term effects of compensatory growth on fish behavior and the consequences of these behavioral changes for natural populations.

Glossary

Behavioral thermoregulation Regulation of body temperature by utilizing behavioral movements to control body temperature. It is potentially utilized by all fish.

Final thermal preferendum The temperature preference obtained when a species remains in a temperature gradient long enough that a stable preferred temperature is observed.

Physiological (or autonomic) thermoregulation Utilization of autonomic responses to control body temperature; utilized in rare cases by fish.

Temperature preference The temperature that a particular species selects, under a particular set of conditions, in a situation where a range of temperatures are available.

Thermal acclimation The responses of a fish to maintain in a particular thermal regimen in the laboratory under a specified set of conditions.

Thermal acclimatization Organismal adjustments to temperature that occur in nature, and are thus affected by other factors such as season and day length.

Introduction

Temperature can be considered a master factor for fish as it affects all physiological processes and ecological systems. Thermal extremes can prove detrimental or even lethal (**see also Temperature**: Measures of Thermal Tolerance). Within the range of temperatures that a fish normally encounters, temperature directly speeds up and slows down biochemical reactions (**see also Temperature**: Effects of Temperature: An Introduction), thus impacting all aspects of a fish's behavior and physiology.

While all motile animals have evolved behaviors that deal with the thermal variation present in their environment, fish and other vertebrates possess a particularly sophisticated system to maintain body temperature within narrow limits. The properties of this regulatory system are very similar to those found in other vertebrates, although in fish such responses are largely limited to behavioral adjustments and, with only a few exceptions (**see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks), body temperature quickly equilibrates to within a few tenths of a °C ambient water temperature. When a range of temperatures is available, fish are able to maintain body temperature at or near the preferred level by positioning themselves in water of that temperature, that is, behavioral temperature regulation.

However, despite the power and sophistication of the nervous elements involved with behavioral temperature regulation, a particular species of fish at a given time is not always found at their preferred temperature. During some seasons, the preferred temperature is simply not part of the prevailing environment, while at other times predator avoidance, food acquisition, territorial defense, mating requirements, and gradients of light, oxygen, or salinity may displace a fish from its normally preferred temperature.

Nevertheless, temperature is a predominant factor in determining habitat selection by fish, and is a major influence on their daily and seasonal movements (**see also The Pituitary**: Development of the Hypothalamus-Pituitary-Interrenal Axis) as well as in their overall distribution and their physiological and biochemical capabilities (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping and **Temperature**: Membranes and Temperature: Homeoviscous Adaptation). Examples of these effects can be seen in the behavior of the chimaera (*Hydrolagus colliei*) and the Atlantic mackerel (*Scomber scombrus*). In its southerly extremes, the chimaera is a deep-water fish, usually being found at depths that exceed 90 m. However, in the cold North Pacific, the chimaera is typically found in shallow water. In both the southern and northern environments, this species is found at the same temperature. Thus, the temperature preference of this species may explain its depth distribution. In contrast to the chimaera, the Atlantic mackerel is a rapidly moving fish and can quickly shift its location in order to maintain a particular body temperature. For the Atlantic mackerel, a 1 °C increase in ocean temperature causes the fish to swim north about 110 km to maintain its preferred temperature.

Species Preferences

The preferred temperature can vary under different states, and for each species, the conditions under which the preferred temperature is determined should be specified. Thermal preference can be most clearly demonstrated in laboratory temperature gradient or choice devices, which provide fish with the ability to choose specific temperatures from a broad range of available temperatures. If nonthermal influences are minimized, and unstressed fish are placed in a thermal gradient, results similar to those shown in **Figure 1** are typically obtained. In **Table 1**, the temperature preferences of various species of fish are shown. The thermal preference is seen to relate to the general habitat of the fish, and is one of many responses that serve to maintain a species within its recognized habitat.

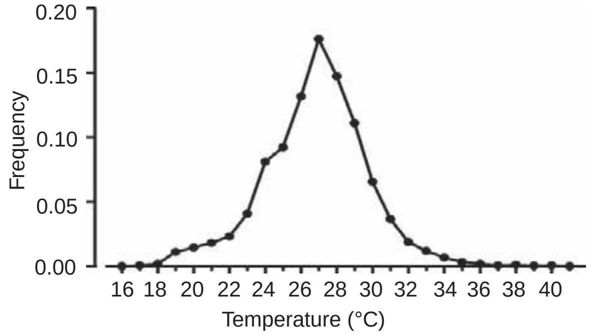

Figure 1 Fish prefer a narrow range of temperatures when presented with a continuous gradient of temperature options. This figure represents the frequency of temperatures selected by seven female *Austrofundulus limnaeus* over a period of 24 h in a linear thermal gradient ranging from 12 to 42 °C. The data are calculated from 10 321 one-min averages calculated from data collected every 6 s. Fish were acclimated to a cycling temperature regime ranging from 20–37 °C daily with a photoperiod of 14L:10D for several weeks prior to determination of temperature preference.

Small Alterations in the Preferred Temperature

In addition to examples of the preferred temperature for various species, **Table 1** also illustrates some of the conditions where the preferred temperature may be altered within a species. These shifts in preferred temperature are typically on the order of 2 or 3 °C, and are often made by a given species in order to better utilize available temperatures under different conditions. Such effects include time of day (**see also Sensory Systems, Perception, and Learning**: Circadian Rhythms in Fish), season, sex, reproductive stage, presence of a bacterial infection (fever), nutritional status, and geographical location of a subspecies. The degree and presence of such shifts in preferred temperature are specific to each fish species.

Major Alterations in the Preferred Temperature

In certain cases, there can be major alterations in the preferred temperature within a species. One case involves developmental state. Typically, younger animals prefer warmer temperatures, which can be considerably higher than the adult preferences. Thus, young salmonids often select temperatures in the upper teens, whereas larger adults typically exhibit temperature preferences in the lower teens. Larger individuals may also exhibit a lower tolerance to high temperatures than juveniles. These differences likely reflect both environmental and physiological differences between the developmental stages. Smaller fish can avoid predation more effectively in shallow, covered areas and are also more likely to find appropriate nourishment in these areas. Higher temperatures, up to a point, can

Table 1 The laboratory temperature preference of a variety of fish species

Common name	*Species*	*Laboratory temperature preference (°C)*	*Conditions*
Desert pupfish	*Cyprinodon macularius*	38–40	Summer
Common killifish	*Fundulus heteroclitus*	28–30	Northern population
		24–26	Southern population
Common goldfish	*Carassius auratus*	28–30	Small
		24–25	Adult
Large mouth bass	*Micropterus salmoides*	27–29	Adult

		13–17	Adults
Coho salmon	*Oncorhynchus kisutch*	11–12	Adult
Polar cod	*Boreogadus saida*	2–3	Early morning
		4–5	Afternoon – early evening

From Richards FP, Reynolds WW, and McCauley RW (1977) Temperature preference studies in environmental impact assessments: An overview with procedural recommendations. *Journal of the Fisheries Research Board of Canada* 34: 728–761.

also support faster growth. Larger fish, on the other hand, are more vulnerable to predation in shallow, warm areas.

A second case involves adjustment to extreme temperatures. While fish can adjust body processes to operate effectively over a range of different environmental temperatures (**see also Temperature**: Membranes and Temperature: Homeoviscous Adaptation), this process takes time and varies for different species, with individuals from areas of high thermal variability showing greater capabilities for such thermal acclimatization. With acclimatization to extreme temperatures, metabolic and other physiological processes are greatly altered, and the normally preferred temperature can become harmful or lethal. Not surprisingly, thermal acclimatization alters the preferred temperature, and to a greater degree for temperatures farther from the normally preferred temperature. Thus, the brown bullhead (*Ictalurus nebulosus*), which normally prefer water temperatures of about 30 °C, prefer a temperature of 16 °C after being maintained in the laboratory at 7 °C for several weeks. When left undisturbed in a temperature gradient, the preferred temperature gradually increases, and returns to 30 °C in about 1 day. The thermal preference that fish finally stabilize at after a long period in a thermal gradient is termed the 'final thermal preferendum'.

A third case involves survival under physiological stress. Many species of fish have the ability to survive severe hypoxia (**see also Hypoxia**: The Expanding Hypoxic Environment) by selecting very cold temperatures. While broad variations in levels of dissolved oxygen in the water normally do not affect the temperature preference, when oxygen levels fall to near-lethal levels, thermal preference decreases drastically. Adult goldfish, for example, normally prefer 25 °C. If the oxygen partial pressure is lowered from a normal saturated value of 160 torr (21.3 kPa) to 31 torr (4.1 kPa), there is little change in the preferred temperature. However, if the oxygen level is decreased further, to 10 torr (1.3 kPa), the preferred temperature drops by about 10 °C. While this low temperature is stressful, it enables the fish to survive by increasing the affinity of hemoglobin for oxygen (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin), augmenting gill extraction efficiency, and by reducing the metabolic demands for maintaining minimal function.

Accuracy and Constancy of the Preferred Temperature

Given the general ability of fishes to adapt to a broad range of temperatures (just below 0 °C to just above 40 °C), the stability of their preferred temperature, as seen in **Figure 1**, is somewhat enigmatic. A closer look at several factors may elucidate the reason for such persistent maintenance of a particular temperature.

First, as mentioned earlier, adjustments to a new temperature take both time and energy. When a fish moves to water of a different temperature, all aspects of its physiological and behavioral capabilities are somewhat compromised. The rapidity with which a change in ambient water temperature affects overall body temperature is often underestimated. Typically, body temperature is measured at a deep site and the temperature at that site is found to change relatively slowly, even if a fish quickly moves to water of a radically different temperature. The net thermal effect on a fish is better estimated by evaluating the change in mean body temperature, which can be done by placing a fish in a calorimeter containing water of a different temperature. The results of such a maneuver for a 0.56 kg carp (*Cyprinus carpio*) are seen in **Figure 2**. While 50% of the change in mean body temperature occurs within 1 min, 50% of the change in brain and deep dorsal muscle temperature requires 4 and 5 min, respectively. The magnitude and rapidity of heat transfer

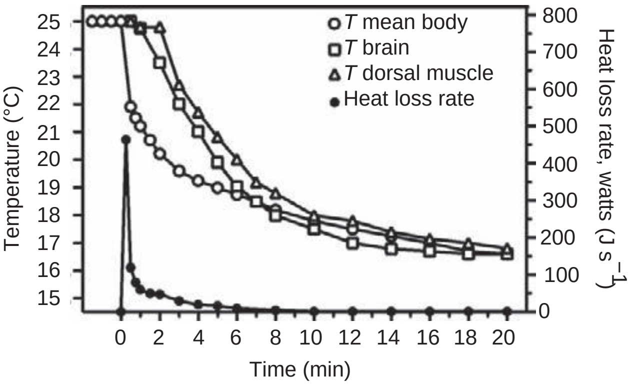

Figure 2 Changes in temperature and heat loss rates in a 0.56-kg carp transferred from 25 °C into a calorimeter at 15 °C. About half of the heat loss occurs within the first minute after transfer. Temperatures asymptote above 15 °C due to an increase in calorimeter temperature. Adapted with permission from Figure 2 in Crawshaw LI (1976) Effect of rapid temperature change on mean body temperature and gill ventilation in carp. *American Journal of Physiology* 231: 837–841.

are emphasized by the heat loss rate illustrated in **Figure 2**. Note that the metabolic heat produced by the carp in this situation would be less than 1 W. For such a carp, when equilibrium is finally reached, about half of the heat exchange occurs at the body surface and about half is due to conductance across the gill surface. The thermal exchange times exhibited for this 0.56-kg carp would be faster for smaller fish and slower for larger fish due to the differences in surface-area-to-volume ratios (**see also Temperature**: Effects of Temperature: An Introduction).

Another reason for the persistent selection of a particular temperature relates to the overall optimization of organismal function. While most fish can make adjustments to function well over a range of temperatures, there is a much narrower temperature range that, after thermal acclimatization, provides an optimal behavioral and physiological set of responses for functioning in the fish's particular habitat. Such responses include optimization of growth (**see also Energy Utilization in Growth**: Growth: Environmental Effects), metabolic scope, cardiac scope, power output of aerobic muscles, and overall performance. In the cases investigated, the preferred temperature fell within the narrow range of temperatures for overall optimal function.

Characteristics of the Thermoregulatory System

The regulatory system which is utilized by fish to maintain a particular body temperature is anatomically and functionally similar in Chondrichthyes and Osteichthyes, and is closely related to the system utilized by other vertebrates (see **Figure 3** and **Brain and Nervous System**: Autonomic Nervous System of Fishes). To function correctly, a thermoregulatory system must sense the controlled variable, make a comparison with an ideal value, and determine an appropriate behavioral response. In fish and other vertebrates, temperature sensing occurs both peripherally and centrally. Sensitivity occurs over the entire fish surface, and is likely subserved by highly responsive, rate-sensitive, free nerve endings. In conditioning experiments, fish have proved capable of responding to a surface temperature change of less than 0.05 °C. While, in most conditions, fish would probably not respond to such small temperature differences, they clearly have a capability for detecting extremely small thermal variation. This capability is undoubtedly useful for specific situations that could involve locating critical thermal refuges or guiding large-scale migrations. An important area for central thermal sensing and processing occurs in the anterior brainstem regions in vertebrates, as shown in **Figure 3**. In fish, an area of particular importance is the nucleus preopticus periventricularis. Lesions within the anterior brainstem area destroy thermoregulatory behavior in fish, and heating and cooling this area (including adjacent tissue) leads to the selection of cooler and warmer water, respectively.

Environmental Observations

Field observations that relate fish location (and sometimes actual body temperature) to local water temperature are particularly valuable. Such data clarify

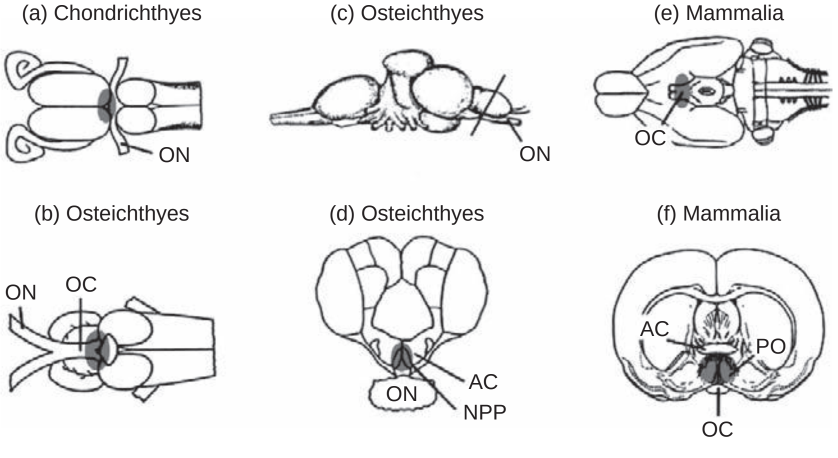

Figure 3 Similar anatomical locations are responsible for body temperature regulation in various groups of vertebrates. Ventral brain surfaces are represented in (a), (b), and (e). Shaded areas represent surfaces that overlie interior regions of the brain that are critical for thermoregulatory control and integration. (c) A side view of the brain with a line depicting the plane of the cross section depicted in (d). A cross section of the shaded region of (e) is depicted in (f). Major thermoregulatory effects are induced by the application of bioactive compounds to the shaded areas of the cross sections in (d) and (f). In: Wood CM and McDonald DG (eds.) *Society for Experimental Biology Seminar Series 61: Global Warming: Implications for Freshwater and Marine Fish*, pp. 351–376. Cambridge: Cambridge University Press.

the operation of temperature selection in a natural environment, illustrate its use in the maintenance of an optimal body temperature, and show how fish avoid deleterious environmental temperatures in a local environment and during migrations. The value and limitations of temperature selection for fish attempting to survive during an era of global climate change will also be touched upon.

Avoidance of Dangerous Temperatures

While the lethal limit for brook trout (*Salvelinus fontinalis*) is just below 25 °C, they prefer to remain in temperatures below 17 °C. In spite of this, during the summer period of low flow and warm water, brook trout are often found in habitats where mainstream temperatures exceed lethal limits. **Figure 4** illustrates an example of how brook trout are able to survive such dangerously warm conditions. In this instance, the trout congregated near the confluence of the main river and a much cooler tributary. Although their thermal preference is considerably lower than the area of the river they occupied, they likely avoided moving into even cooler areas nearer the tributary due to the dangers of predation involved with occupying very shallow water. The location of these fish indicates a compromise between the preferred temperature and a combination of water depth plus river surface characteristics. Over the course of the summer, the brook trout maintained a body temperature of about 3 °C lower than that of the main river temperature. In addition to utilizing confluences with cooler streams, fish in overly warm rivers have also been observed to make use of cold groundwater discharges and thermally stratified deep pools to avoid thermally induced injury or death. Similar examples exist for migrating Pacific salmon (*Oncorhynchus* sp.) that, during their migration through large rivers, can take advantage of cooler water from tributaries and sometimes lakes. However, in this case, this preference behavior can only act as a temporary respite because the river migration must be completed in relatively short order (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle).

Fish utilize similar strategies in reservoirs and lakes. **Figure 5** depicts the body temperature of striped bass (*Morone saxatilis*) that were introduced into a reservoir in the southeastern USA. This area has warmer temperatures than those present in the normal habitat of this species. The larger adults prefer to remain at temperatures below 22 °C, but this becomes very difficult during the months of summer. The cooler, lower depths become progressively deoxygenated, while the surface waters become untenably warm. Nevertheless, as seen in **Figure 5**, the large adults were usually able to maintain body temperatures and (presumably) dissolved oxygen within acceptable levels by utilizing discrete areas near cold groundwater discharge or cool tributary entrances.

Surface and bottom water temperatures are plotted to indicate that the fish utilize a unique subset of their thermal habitat for large portions of the year. Redrawn from Fig. 3 in van den Avyle MJ and Evans JW (1990) Temperature selection by striped bass in a Gulf of Mexico coastal river system. *North American Journal of Fisheries Management* 10: 58–66.

Global Climate Change, Environmental Degradation, and Temperature Preference

Although the above strategies will, to some extent, ameliorate gradual increases in ambient water temperature due to climate change (**see also Temperature**: Effects of Climate Change) and other anthropomorphic effects (**see also Behavioral Responses to the Environment**: Anthropogenic Influences on Fish Behavior), disadvantages also accrue. In scenarios where preferred temperatures become limiting in a fish's natural environment, the usable habitat may also become restricted due to behavioral limitations. For example, fish may be forced to occupy small tributaries with cooler temperatures and be excluded from using or migrating through large mainstem rivers where temperatures can reach lethal heights or at least be many degrees above the fish's preferred temperature. As large numbers of fish are forced to aggregate into small areas, crowding can increase stress, parasitism, disease, as well as decrease food availability and perhaps the oxygen contained in the water. For species which are linked to a particular geographic area, environmental warming brings added hazards.

Migratory salmonids are a prime example, since nonthermal (largely olfactory) factors provide the primary cues that tie them to their natal streams. Adult salmon require relatively low body temperatures during migration to maintain energetic stores necessary for the arduous events required for swimming upstream and spawning. In many cases, migrants have already become dependent upon judicious behavioral thermoregulatory strategies in order to survive.

Chum salmon (*Oncorhynchus keta*), migrating along the coast in Japan, encounter high surface temperatures in early fall as they search for their spawning grounds. When the surface waters are warm, they achieve a compromise by mainly remaining in cool, deep water, but with occasional movements to the surface, presumably to obtain directional cues. Later in the year when the surface water is cooler, these migrating salmon spend most of the time in shallow water. There are also examples of sockeye salmon (*Oncorhynchus nerka*) being unable to complete their spawning migration because the river water temperature was simply too hot for them to swim.

Upstream migrating Chinook salmon (*Oncorhynchus tshawytscha*) also routinely encounter temperatures well above the optimal level. The importance of both behavioral thermoregulation and thermal refuges was highlighted by studies measuring deep body temperature as the salmon moved up the Columbia River. For all measurements obtained, body temperature was below the mean river temperature. The average measurement was 2.5 °C below mid-river temperature. This difference between the river temperature and fish body temperature extended down to river temperatures as low as 9 °C. This indicates that, during upstream migration, the preferred temperature of these large fish is likely below 9 °C.

Problems for juvenile salmon migrating into the ocean can also accrue due to ocean warming. As increased numbers of large and fast predatory fish migrate northward to attain their preferred temperature, the young salmon face the dual challenge of unduly warm temperatures and novel highly effective predators that they did not historically encounter.

Glossary

Anoxia Complete absence of dissolved oxygen in water.

Aquatic surface respiration Behavioral response of ventilating gills using the surface layer of water, which tends to be fully or close to fully saturated with air even in hypoxic environments.

Buccal cavity Mouth or oral cavity.

Chemoreceptors Receptors that detect chemical stimuli and convert them into signals within the nervous system.

Estivation A state of dormancy usually to protect animals against heat and/or desiccation.

Friagem A weather phenomenon occurring in South America associated with rain, wind, and a sharp fall in temperature.

Hypoxia Reduced, below that of fully air-saturated, dissolved oxygen content in water.

Kilopascal SI unit for measuring pressure (pascal) often used as a unit of measurement for the partial pressure of oxygen in water.

Normoxia Water with fully air-saturated levels of dissolved oxygen.

Supra-terminal mouth Mouth that tends to open upward.

Overview

Hypoxia is a common phenomenon in many aquatic environments (**see also Hypoxia**: The Expanding Hypoxic Environment). Aquatic habitats can experience diurnal or seasonal fluctuations in oxygen availability and thus it is vital that the fish that inhabit these environments have biochemical, physiological (**see also Responses and Adaptations to the Environment**: General Principles of Biochemical Adaptations), and behavioral survival strategies.

There are a variety of ways in which fish behaviorally respond to hypoxia. Perhaps the easiest is simply to avoid it and to move away from areas of low oxygen. However, often fish do not have this option and, therefore, need strategies to survive in hypoxia. One immediate response can be to alter activity patterns in order to better balance the demand for energy with that available from aerobic respiration (**see also Gas Exchange**: Respiration: An Introduction). For example, reducing activity lowers energy demand perhaps more in line with the decreased availability of oxygen in the water. However, if this strategy does not provide sufficient savings, a fish may need to alter its physiology (**see also Hypoxia**: Respiratory Responses to Hypoxia in Fishes) or behavior further in order to survive.

One of the most conspicuous and common behaviors is that some fish species move to the water surface to ventilate their gills using surface waters (aquatic surface respiration) or to breathe air in response to aquatic hypoxia. This behavior is a last resort for many species, especially since it additionally exposes them to aerial and terrestrial predators. Nevertheless, some fish species have evolved to inhabit environments that frequently experience hypoxia, and for them the journey to the water surface is a regular and controlled occurrence, allowing efficient acquisition of oxygen at the air/water boundary.

Altered Activity Patterns

Changes in activity patterns in response to hypoxia involve both increases and decreases in swimming activity. Benthic and demersal fish species are most likely to reduce swimming activity and minimize energy expenditure under hypoxic conditions; resting on the bottom and hiding from predators can effectively conserve energy. For example, the common sole, *Solea solea* will reduce its activity level under moderate hypoxia, as will the small spotted catshark, *Scyliorhinus canicula.* Reduced activity also may be accompanied by metabolic rate suppression (**see also Hypoxia**: Metabolic Rate Suppression as a Mechanism for Surviving Hypoxia), a common physiological response to hypoxia.

Alternatively, some pelagic fish species may increase activity when they encounter hypoxia, presumably with the aim of escaping hypoxic areas as quickly as possible. For all species, the effects of hypoxia on activity patterns are likely to be context specific. When schools of Atlantic herring, *Clupea harengus*, are exposed to gradually falling oxygen tensions, they initially show an increase in swimming speed followed by a decrease in swimming speed if they are unable to escape hypoxia. This suggests that the herring first attempt to swim away from hypoxia but, if this behavioral response fails to locate normoxic waters, they are forced to reduce energy expenditure.

Hypoxia as a Refuge

Inevitably, fish of different shapes and sizes will differ in their ability to tolerate hypoxia and the mechanisms they employ for survival. Such differences in hypoxia tolerance allow some species to use hypoxia to their advantage, choosing to live in hypoxic environments and thereby minimize predation risk from hypoxia-intolerant species. An excellent example of this strategy came about with the introduction of the Nile perch, *Lates niloticus*, as a top predator in Lake Victoria. The Nile perch was such a successful and voracious predator that many native haplochromine fish species disappeared from the main lake. However, it was later discovered that several species, initially believed to have become locally extinct, were successfully using wetlands adjacent to Lake Victoria as a refuge from the Nile perch; the waters were too hypoxic for the Nile perch to tolerate.

Within a species, body size affects hypoxia tolerance, although the precise relationship varies greatly among species. In the oscar, *Astronotus ocellatus*, larger individuals appear to be able to tolerate hypoxia better than smaller individuals, but the reverse is true of the yellow perch, *Perca flavescens*. In species such as the yellow perch, where larger fish will cannibalize smaller individuals if the opportunity arises, the greater hypoxia tolerance of small fish may allow them to utilize hypoxic refuges (**see also Behavioral Responses to the Environment**: A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food).

Surfacing Behaviors

Aquatic Surface Respiration

The surface layer of water tends to have the highest oxygen saturation within the water column due to diffusion from the air. Aquatic surface respiration (ASR) takes full advantage of this situation when the remainder of the water column is hypoxic. ASR is a behavior, which is performed by a variety of fish species, involving an individual journeying to the water surface to ventilate its gills with this relatively oxygen-rich surface water. The behavioral response itself is a reflex driven by oxygen-sensitive chemoreceptors that detect oxygen levels both in the blood and the external water. These chemoreceptors are believed to be located mainly in the gills (**see also Control of Respiration**: Oxygen Sensing in Fish).

Many intertidal species perform ASR. This behavior is necessitated because the tide pools they inhabit often become cut off from the sea at low tide, preventing an escape behavior. For tide pools near the low-tide mark, the duration of isolation may be infrequent and for only a short portion of the tidal cycle. However for tide pools near the high tide mark, the isolation may be much greater. Furthermore, there are diurnal considerations. When the tide goes out during the day, oxygen levels in the tide pool typically remain high (**Figure 1**(**a**)), because photosynthesis by algae continuously replenishes any oxygen removed from the water by animals. In fact, the water can easily become super-saturated with oxygen. However, photosynthesis ceases during the night, and all organisms within the tide pool, including the algae, continue to respire. Therefore, oxygen levels fall overnight (**Figure 1**(**b**)), and can reach almost anoxic (no oxygen) conditions in a crowded tide pool (**Figure 1**(**c**)). Consequently, many intertidal fish that have become stranded in tide pools start to perform ASR during the night (**Video Clip 1**). A good example of such a fish is the tidepool sculpin, *Oligocottus maculosus*, which inhabits rocky intertidal shores on the Pacific coast of North America.

Of the variety of intertidal fish that perform ASR, many have head morphologies that appear specially adapted to optimize access to surface water and minimize head exposure above the water. Supra-terminal mouths and dorsoventrally flattened heads enable these fish to get right up to the water surface to ventilate their gills without their heads breaking the water surface. Breaking the water surface would create a downward force, necessitating fish to swim harder to maintain position at the surface, and would also act as a clear signal for predators.

Fish species that perform ASR during hypoxia are not limited to tide pools. In fact, the Amazonian tambaqui, *Colossoma macropomum*, is an example of a fish that not only performs ASR in response to hypoxia but undergoes a morphological transformation to enhance the efficiency of ASR. When the tambaqui encounters hypoxia, its lower lip becomes highly vascularized and is remodeled into a flat skin within just 2 h; this rapid morphological transformation greatly enhances the ability of tambaqui to skim the oxygen-rich surface layers of water (**Figure 2**). Another unusual way of increasing ASR efficiency is seen in the upside-down catfish, *Syndontis nigriventris*, which as the name suggests

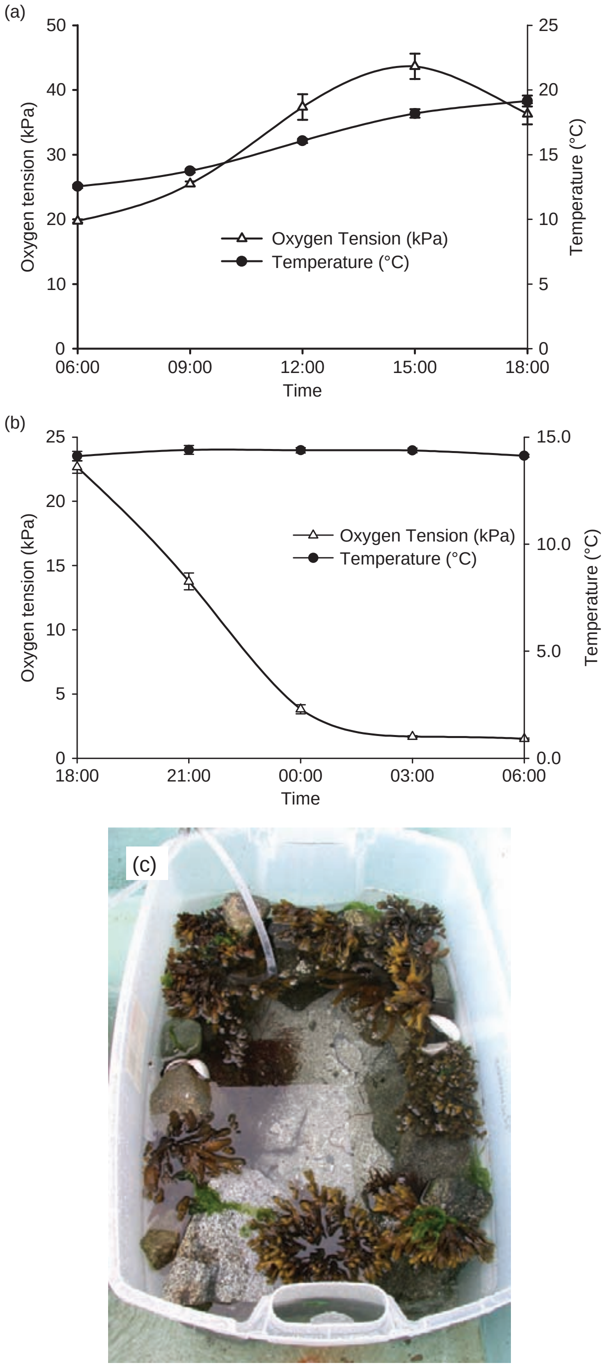

Figure 1 (a) Oxygen and temperature profiles of mesocosms (illustrated in (c)) isolated from water flow for 12 h during the day and (b) overnight. Measurements of physical parameters were taken every 3 h ($n = 16$ for each time point). Data are presented as means ± SEM. (a, b) Reproduced from Sloman KA, Mandic MM, Todgham AE, *et al*. (2008) The response of the tidepool sculpin, *Oligocottus maculosus*, to hypoxia in laboratory, mesocosm and field environments. *Comparative Biochemistry and Physiology A* 149: 284–292, with permission from Elsevier.

improves ASR by swimming upside down. During ASR, *S. nigriventris* is able to keep its body fully submerged and reduce surface activity levels by adopting this upside-down posture.

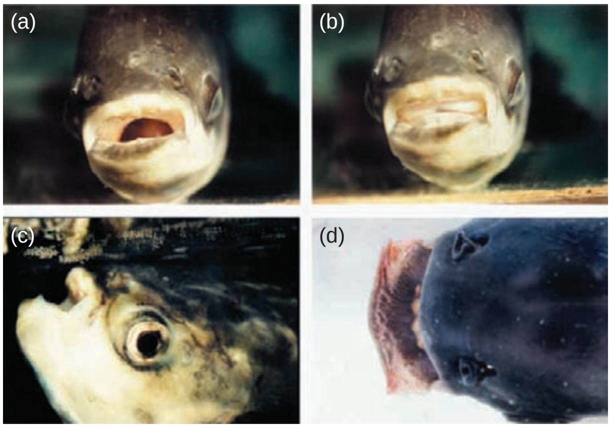

Figure 2 Morphological changes in the lips of the tambaqui, *Colossoma macropomum*, occurring during exposure to hypoxia. (a) A frontal view with the mouth open during lip expansion. (b) Shows a frontal view with the mouth closed. (c) A lateral view of the head approaching the water surface with the initial swelling of the lower lip. (d) A dorsal view of the fish illustrating the forward expansion of the lip near full development. Reproduced from Sundin L, Reid SG, Rantin FT, and Milson WK (2000) Branchial receptors and cardiorespiratory reflexes in a neotropical fish, the tambaqui (*Colossoma macropomum*). *Journal of Experimental Biology* 203: 1225–1239, with permission from the Company of Biologists.

There are costs to ASR. For example, for mid-water species of fish that would normally spend the majority of their time free-swimming, the additional energetic burden of maintaining buoyancy and their position at the water surface during ASR may not be that great. However, for benthic species, which are often negatively buoyant, maintaining position at the top of the water column can be energetically expensive even if the water is shallow. Consequently, many intertidal fish perform ASR on rocks or structures that provide support at the water surface. An alternative, or additional aid, to this strategy is seen in intertidal gobies such as *Cryptocentroides cristatus* and *Mugilogobius paludis*. These fish hold a gas bubble in their mouths while performing ASR, providing neutral or positive buoyancy to the head and allowing their mouth to easily rest at the water surface. The bubble could additionally provide oxygenation of water passing through the mouth and over the gills.

Emergence Behaviors

ASR enables fish to utilize the oxygen-rich upper layers of the water column when the main water body becomes hypoxic. However, if aquatic hypoxia persists, oxygen levels may fall so low that ASR is no longer sufficient. At this point, many fish species are able to extract oxygen from the air (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction). In the majority of marine air-breathing fish, this process involves part or total emergence from the water (**Figure 3**) and the utilization of skin, gills, and buccal cavities as gas-exchange surfaces.

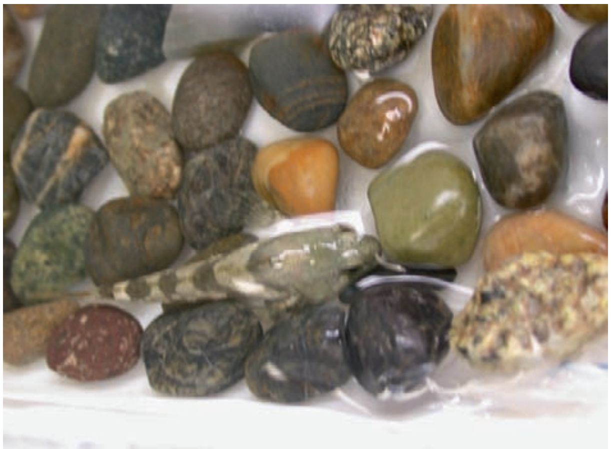

Figure 3 A tidepool sculpin, *Oligocottus maculosus*, emerging from the water during aquatic hypoxia.

In freshwater air-breathing fish, air is usually taken in at the water surface using surfacing behaviors similar to ASR and oxygen is extracted across air-breathing organs (ABOs) including areas of the intestine, modified gas/swimbladders, and lungs (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes). Air breathing is typically a facultative process allowing fish to supplement their oxygen requirement when levels of dissolved oxygen fall. However, for some fish like the piraracu, *Arapaima gigas*, air breathing, and therefore surfacing behavior, is an obligate process; these fish will not survive when denied access to the water surface (**see also Behavioral Responses to the Environment**: Anthropogenic Influences on Fish Behavior).

Trade-Off with Predation Risk

Fish that make frequent journeys to the water surface or that are continuously breathing at the surface face a trade-off between the need to obtain oxygen and the increased risk of predation that may be associated with surfacing. Being at the water surface may make individuals easier prey items for aerial and terrestrial predators and any other larger aquatic predators that have also migrated to the water surface. To address this trade-off, fish have evolved a variety of behavioral and physiological strategies to allow them to reach the water surface but minimize their chances of being eaten (**see also Behavioral Responses to the Environment**: A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food).

Use of Cover

If a fish needs to come to the water surface for ASR or to breathe air, then one way to minimize predation risk is to surface under shelter. This is clearly seen in intertidal fish such as the tidepool sculpin that will surface around the edges of tide pools and, when emerging from the water, is often found hiding under algae; algal cover has the additional advantage of reducing desiccation while the sculpin is exposed to air. The flathead grey mullet, *Mugil cephalus*, threatened by avian predators, will modify ASR behavior to surface under shelter or near the edges of aquaria; when the water is turbid, they may be unable to visually detect predators and will respond in a similar manner. For smaller juvenile fish, access to shelter may be particularly important. Juvenile oscar, *Astronotus ocellatus*, given a choice between staying in a hypoxic environment that had overhead floating plant shelter and a normoxic environment with no shelter, chose to remain in hypoxia for as long as they were physiologically able, rather than give up the protective overhead cover.

Postponement of Surfacing Behaviors

Some fish may choose to remain deeper in the water column in hypoxic waters rather than coming to the water surface when predation risk is perceived to be high. Therefore, avoiding predation may be associated with a physiological cost of remaining in hypoxia (**see also Hypoxia**: Respiratory Responses to Hypoxia in Fishes). In the tidepool sculpin, adults will start to perform ASR when the oxygen tension in the water falls to about 2.5 kPa. However, if an alarm substance, a chemical released from the skin of some fish species when they are injured (**see also Behavioral Responses to the Environment**: A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food), is added to the water, sculpins will delay the performance of ASR until oxygen tensions fall to about 1.5 kPa. As mentioned above, tidepool sculpins display ASR until oxygen tensions fall too low, at which point they emerge from the water. Although these sculpins appear to be able to delay the performance of ASR in response to predation, they do not appear to be able to delay emergence behavior, which occurs as a last resort response to hypoxia. Once oxygen tensions fall too low, the requirement for oxygen is too great and the fish must accept the increased predation risk and emerge from the water in order to stay alive.

Group Surfacing Behaviors

An alternative to surfacing under shelter or delaying surfacing behaviors is to surface in social groups. In a similar manner to the dilution effect associated with fish shoaling where an individual in a large group effectively minimizes its chances of being eaten, surfacing in social groups provides safety in numbers. Many catfish perform these synchronized surfacing behaviors, including *Hoplosternum littorale*. *Hoplosternum* is a facultative air

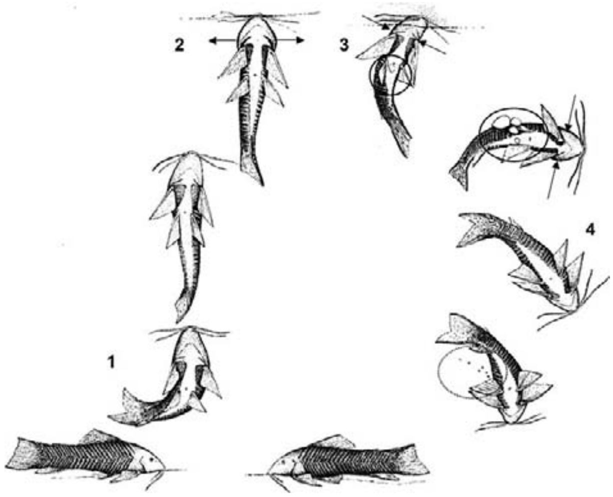

Figure 4 Air-breathing cycle of *Hoplosternum littorale*: (1) ascent to the water surface; (2) in contact with the surface the fish expands its oral cavity, inspiring air; (3) turning head down, with compression of the oral cavity pushing air into the intestine and causing the expiration of old air from the anus (circle, continuous line); (4) return to bottom and release of small air bubbles through the opercula (circle, dotted line). Arrows indicate the buccal pump. Reproduced from Jucá-Chagas R and Boccardo L (2006) The air-breathing cycle of *Hoplosternum littorale* (Hancock, 1828) (Siluriformes: Callichthyidae). *Neotropical Ichthyology* 4: 371–373 with permission from Sociedade Brasileira de Ictiologia.

breather that inhabits the Amazon basin and can supplement aquatic oxygen with oxygen from the air when necessary. Unlike many other teleosts of the Amazon, it can survive a seasonal phenomenon known as a ‘friagem’ where water becomes hypoxic, acidic, and rich in hydrogen sulfide. *Hoplosternum* utilizes its posterior intestine as an ABO and gulps in air at the surface, which is then passed into this highly vascularized area of its digestive tract. As the fish take new air into their intestines at the water surface, old oxygen-depleted air is then released through the anus and as the fish descends away from the water surface, any excess air is also expelled through the operculum (**Figure 4**). Oxygen can then be extracted from the air in the intestine; this air can also be used for buoyancy and to aid passage of food through the digestive tract.

When *H. littorale* are held individually in tanks and exposed to hypoxia, smaller individuals will generally travel to the water surface earlier, whereas larger individuals will postpone air breathing until oxygen tensions have fallen further. This would suggest that smaller individuals are physiologically unable to remain in hypoxic waters for as long as larger individuals and, therefore, benefit from the synchronous air breathing performed by these fish when held in groups. Within a group of *Hoplosternum*, the most active fish tend to surface first which may be related to the higher oxygen consumption associated with activity. Once one fish has moved toward the surface, all members of the group generally follow closely behind.

Surfacing Behaviors and Parental Care

A wide variety of fish species exhibit some form of parental care, which can range from guarding of externally developing eggs to the gestation of live young (**see also Social and Reproductive Behaviors**: Parental Care in Fishes and **Social and Reproductive Behaviors**: Nutritional Provision During Parental Care). Parental care is energetically expensive. For example, parents may provide energy to their offspring by supplying them with nutritional secretions or they may actively defend offspring against predators. For fish inhabiting hypoxic waters, this extra energy demand can be a potential problem.

Gestating female live-bearing fish need to supplement oxygen supply by journeying to the air–water interface. The sailfin molly, *Poecilia latipinni*, is a small live-bearing species found from South Carolina south and west through Florida and the Gulf Coast into Mexico. Its natural environment has the potential to become hypoxic and it is known to perform ASR. Gestating females have a higher metabolic rate compared to nongestating females and as a consequence, when experiencing low levels of dissolved oxygen, nongestating females spend approximately 15% of their time performing ASR as compared to gestating females spending 50% of their time performing ASR.

Mouth-brooding fish maintain embryos and young fry in their mouths for protection during development. For example, in the mouth-brooding African cichlid, *Pseudocrenilabrus multicolour victoriae*, brooding females will start to perform ASR at higher oxygen concentrations compared with nonbrooding females. There are several potential reasons for this. First, there is the increased energy demand associated with the transportation of young. In addition, young have to be provided with a supply of highly oxygenated water or air without being accidentally swallowed; most mouth brooders do not actually eat while they are incubating young. Lastly, holding developing broods within the mouth cavity has the potential to interfere with the pumping of water across the gills and to compromise both normal ventilation and ASR.

Several air-breathing fish species that inhabit oxygen-deplete areas care for their offspring by building floating bubble nests for their eggs that lift the eggs out of oxygen-poor water into the oxygen-rich surface water without creating desiccation. In *H. littorale*, this is achieved by producing a foam-like substance by swimming upside down at the water surface, pumping water over their gills and using their pelvic fins to mix water with mucus. Many species of gourami, for example, the flame-red dwarf gourami, *Colisa lalia*, also build floating bubble nests (**see also Social and Reproductive Behaviors**: Sexual Behavior in Fish).

Terrestrial Behaviors

While many intertidal fish species emerge from the water during severe hypoxia, they typically remain inactive during emergence and seek cover to reduce risk of predation and desiccation. However, a few intertidal fish have evolved a more amphibious lifestyle; they emerge fully from the water and locomote great distances on mud flats at low tide. Mudskippers locomote on land using their pectoral fins and are probably the most well known of amphibious fish, with the genus *Periophthalmus* being the most widely distributed. These fish can utilize their skin and the lining of their mouth cavity to extract oxygen from the air (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction).

Many mudskipper species inhabit burrows. For example, *Scartelaos histophorus* builds J-shaped intertidal burrows where they store air in an upturned area that is not connected to the water surface. To do this, they take air in their mouths from the external environment at low tide and transport it into their burrows. The air pocket within the burrow allows the mudskipper to breathe air if it depletes its aquatic oxygen supplies during the period that it is confined in its burrow at high tide. Once the oxygen in the air has been depleted during a high tide cycle, it needs to be replaced at the next available opportunity. Renewal of the air store occurs in a concentrated period of time, involving 6–15 air-deposition trips per minute. In complete contrast to the amphibious mudskippers that are able to move around easily in a terrestrial environment, some lungfish species can enter a period of estivation during dry periods when they have no access to water. There are three genera of lungfish, *Neoceratodus*, *Lepidosiren* and *Protopterus*, all of which journey to the water surface to breathe air when there is water to inhabit. *L. paradoxa* and the four species of *Protopterus* are obligate air-breathers and cannot survive without access to air, whereas *Neoceratodus* is a facultative air breather. *Protopterus* spp. are known to estivate during dry periods where they enter a period of dormancy or inactivity and build a cocoon around themselves until the dry season is over. Some species such as *P. aethiopicus* and *P. annectens* estivate in mud cocoons underground, whereas *P. dolloi* can estivate on land within a layer of dried mucus (**Figure 5**). During estivation, metabolic rate is depressed and the lungfish rely entirely on their lung to obtain oxygen from the air (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction).

Future Studies

The physiological and biochemical responses of fish to hypoxia have been well researched (**see also Hypoxia**: Anaerobic Metabolism in Fish, Metabolic Rate Suppression as a Mechanism for Surviving Hypoxia, Respiratory Responses to Hypoxia in Fishes, **Bony Fishes**: Crucian Carp, and The Expanding Hypoxic Environment). Less research has focussed on the behaviors that allow fish to behaviorally avoid the metabolic consequences of hypoxia by avoiding or by supplementing their oxygen supply from the air or upper surface waters. Many studies on these behavioral responses have been laboratory based where complex interactions with predation risk and social structures are removed. There is now a need to consider these behaviors in ecologically relevant contexts and to understand how the ways in which fish can utilize behavior in response to hypoxia interact with other essential behaviors.

Glossary

Chronotype Individual pattern of circadian phase preference, defining preferred time of day for certain activities, such as sleep or work: early-morning chronotype in humans reflects preference for early-morning activity.

Circadian Internally generated rhythm with a periodicity of about 24 h. From the Latin *circa* (about) and *dies* (day).

Crepuscular Daily pattern with two peaks of activity centered around dusk and dawn, although not excluding some activity in-between these periods. From the Latin *crepusculum* (twilight).

Histamine A biological amine, with important role in multiple physiological functions (e.g., immune reactions and smooth muscle regulation), also serving as a neurotransmitter.

Hypocretin (or orexin) Excitatory peptides produced in the hypothalamus.

Isodendritic core A diffuse but morphologically similar group of cells in the brainstem. From the Latin *isos* (similar, uniform).

Melatonin A biological amine, hormone produced by the pineal gland (epiphysis cerebri).

Narcolepsy A chronic sleep disorder characterized by excessive daytime sleepiness, sudden attacks of muscle weakness, and unusual hallucination-like experiences at the onset of sleep (hypnagogic hallucinations). Most cases result from hypocretin deficiency.

Suprachiasmatic nucleus Small paired nuclei of the hypothalamus, serving a master clock function in mammals.

Zeitgeber A time cue sufficient to entrain circadian rhythms. From the German for time giver.

> Now, blessings light on him that first invented sleep! It covers a man all over, thoughts and all, like a cloak; it is meat for the hungry, drink for the thirsty, heat for the cold, and cold for the hot. It is the current coin that purchases all the pleasures of the world cheap, and the balance that sets the king and the shepherd, the fool and the wise man, even.
>
> Miguel de Cervantes, Don Quixote, 1605.

What Is Sleep?

None of us would doubt that sleep is an essential need. Lack of it makes us tired and irritable, clouding our optimism and increasing anxiety. Without a proper amount of sleep every day, we lose mental sharpness, as though our brain were working at half speed. Considering that, on average, we spend about one-third of our life in sleep, the question of what is happening with us during this time and why we need sleep has bothered scientists and laymen alike for centuries. Many ideas, hypotheses, and theories have been put forward to explain the ubiquitous phenomenon of sleep. In spite of this, as of now, no hypothesis has convincingly explained the principal physiological function of sleep. Perhaps you, our young and curious readers, will be the ones to explain the purpose of sleep.

Although the function of sleep remains an enigma, the in-depth scientific research into the problem of sleep that started in the nineteenth century and flourished in the twentieth, taught us a great deal about the sleep process and what happens with different physiological systems during sleep. Before we approach our main topic of sleep in fish, let us go over the principal facts about sleep in other species, including humans. This might help to explain why we are interested in the sleep of these cold-blooded and water-bound vertebrates from both a basic science point of view and in the selfish hope that understanding sleep in fish will help us to clarify the enigma of the human sleep process.

How do we know that somebody sleeps? First of all, their behavior is changed. A sleeping human or animal is behaviorally quiet, but unlike during quiet wakefulness, is not easily aroused by mild environmental stimuli. That said, sleep, unlike coma or hibernation, is rapidly reversed into wakefulness by substantially strong stimuli. Other notable behavioral characteristics of sleep are muscle relaxation and, often, a typical sleep posture. Look at an old gentleman sleeping in an arm chair, in front of a still-working television set, with his head sunk on his chest and his relaxed hand letting the remote control fall onto the rug. Watch your sleeping cat, lying curled up, with his head between his paws. Think of yourself getting comfortable in your bed before falling asleep at night.

There is another small sign of sleep that you might have thought of if you ever tried to pretend to be sleeping. It is lack of eye movement and blinking. However, sleep is not a homogenous state and, during one of its distinct stages, the eyes actively move. For this reason, this sleep stage is called rapid eye movement (REM) sleep. It was the last sleep stage to be discovered but it is so remarkable that the rest of sleep stages, combined, are now called non-REM sleep. They are numbered from 1 to 4, with stage 1 being a transition from wakefulness to sleep, and 4 being the deepest non-REM sleep stage.

You might wonder how we know which stage of sleep a person is in. This brings us to another way of studying sleep, one based on the recording of brain activity. In 1875, the British neurophysiologist Richard Caton recorded brain electrical activity using electrodes implanted directly in the animal brain; and in the 1920s, a German psychiatrist Hans Berger recorded human brain waves through electrodes attached to the scalp and reported that they are distinctly different depending on whether a person is awake or asleep. During wakefulness, the brain waves are fast (i.e., have high frequency) and have low amplitude. This is because the millions of neurons of our cerebral cortex that produce these waves fire rapidly and at different times. In other words, their activity is high but desynchronized. When we start falling asleep, these neurons slow down their activity but, more importantly, they synchronize with other neighboring neurons and, as a result, the recorded brain waves become slow (i.e., of low frequency) and their amplitude increases substantially. During stage 4 sleep, brain waves have the lowest frequency and the highest amplitude.

What is happening with us during these sleep stages? With the onset of non-REM sleep, starting with stage 1, our eyes close, and either stay still or have occasional slow movements. We start losing our regular perception of the environment, our muscles relax, our breathing and heart rate gradually slow down, and we progress into deeper stages of quiet sleep. Occasionally, we might move our limbs in sleep or turn to the other side but, overall, our body and brain are in a relaxed state. However, after about an hour or an hour and a half, an amazing change happens with both our body and brain activity. The body virtually loses all muscle tone, while the brain starts working almost as actively as when we are awake. Not only do our brain waves become fast and desynchronized, but also our still closed eyes start moving rapidly, as if we have opened them and are watching something. This remarkable state is called REM sleep, the time when we watch dreams, while our body remains virtually paralyzed.

Another interesting fact about sleep is that, throughout the night, the periods of non-REM and REM sleep alternate. Hence, every night we have four to six sleep cycles, each composed of a period of non-REM and REM sleep. Non-REM periods are longer and deeper at the beginning of the night, during the first two to three sleep cycles, while REM sleep is more prevalent in the early-morning hours. Although it is more difficult to wake up somebody from REM than from non-REM sleep, spontaneous awakening in the morning happens more often in REM. That is why, in the morning, you tend to remember that last dream that you saw in REM sleep right before your awakening.

Other important questions that researchers are working on include what makes us feel sleepy and for how long do we need to sleep. Depending on which time of day a species is active, animals are divided into those with diurnal and those with nocturnal chronotypes. For example, humans are typically alert at daytime, in contrast to mice, which are active at night. There are also species with a so-called crepuscular chronotype, such as cats, which have several, approximately similar sleep episodes during the day and at night. In both nocturnal and diurnal species, the timing of sleep is controlled by the circadian clock. Once this intrinsic biological clock strikes the habitual time of sleep, an individual becomes sleepy.

What is this biological clock and where does it reside? Every cell of our body has such a clock, which consists of a complex molecular mechanism of periodic gene transcription and protein synthesis. The period of activity of these numerous clocks is about 24 h; hence, they are called 'circadian' (from the Latin *circa* – around and *dies* – a day; **see also Sensory Systems, Perception, and Learning:** Circadian Rhythms in Fish). However, each of these clocks runs at a slightly different speed. Even though the difference might be only a few minutes per day, over weeks and months this would lead to complete desynchronization between the cells. Thus, as any orchestra needs a conductor, an organism needs a master circadian clock that can synchronize these individual cellular clocks.

In mammals, including humans, the master clock is located in a small paired brain structure, the suprachiasmatic nucleus (SCN) of the hypothalamus. The neurons of this structure can have their own distinct rhythms as well, but they are very cooperative in nature and, under normal circumstances, manage to effectively synchronize their rhythmicity within the SCN. As a result, this well-coordinated chorus of SCN cells, loudly singing the same time signal through their neuronal and hormonal outputs, dominates all other mini-clocks in the body, synchronizing them within the entire organism.

Every evening, the circadian clock signals to our organism that it is time to fall asleep and every morning helps it to wake up on time. How it does this, however, is not entirely clear. Such signals could be conveyed via the clock mechanisms within the brain structures responsible for sleep regulation, leading to their activation or inhibition at certain hours of the day. The principal hormone of the circadian system, melatonin, can also promote sleep. It is produced by the pineal gland and the retina of the eyes every night and, when taken as a drug, can promote sleep initiation. If light hits the eye in the middle of the night, melatonin production is acutely inhibited. This is one of the reasons why light is such a powerful zeitgeber (from the German for time giver).

Although the timing of the habitual sleep period, controlled by the circadian clock system, is very important, there is another critical mechanism of sleep regulation, the homeostatic one, which makes sure that we spend enough time sleeping every day. Under the pressure of some important task, we can overcome this need for sleep, but later, we have to compensate for sleep loss by sleeping more than usual. Perhaps, if we knew what exactly this homeostatic mechanism is balancing out, we would know the mysterious physiological function of sleep, why we fall asleep, and how we wake up after the sleep function is fulfilled.

Humans tend to sleep 7–8 h a day. Other mammals can have substantially different daily sleep durations. For example, elephants sleep only 3–4 h, while opossums sleep an astounding 20 h per day. The reasons for such interspecies differences in sleep duration remain unknown. Studying them might help to solve the enigma of sleep function but would also, most certainly, uncover new adaptive strategies that involve sleep physiology. Perhaps one of the most remarkable strategies was discovered by Lev Mukhametov and his colleagues when they studied sleep in dolphins. These marine mammals, which need to get to the water surface in order to breathe, have unihemispheric sleep. When one of their brain hemispheres is sleeping, the other one is awake, helping the animal to maintain its posture and stay close to the surface. Perhaps, for the same reason, these animals lack REM sleep, at least in the form that other mammals have. Later, a similar sleep strategy was found in other marine mammals, for example, seals, while they are at sea. Remarkably, when seals sleep on land, they can have normal bilateral sleep, that is, both brain hemispheres sleep simultaneously.

Sleeping Fish

Unlike marine mammals, fish do not need to get to the water surface to breath. With the exception of some fish, such as sharks, that have to move constantly so that their gills can be exposed to enough water and thus oxygen, most of the fish species show typical behavioral features of sleep. They have prolonged behavioral quietness, species-specific sleep postures, elevated arousal threshold, and rapid reversibility from quietness to activity in response to moderately intense stimulation. Since fish lack eyelids, their eyes stay always open but eye movements are largely inhibited during sleep.

The behavioral adaptations of fish species during sleep are as diverse as their daytime activity and reflect their specific adaptive ways of foraging or hiding from predators. Some fish sleep predominantly at night (e.g., herring, *Clupea* spp.; tuna, *Thunnus* spp.; spotties, *Pseudolabrus celidotus*), while others (e.g., bass or perch, family percichthyidae) rest mostly during the day or have many daytime naps. The environmental light–dark cycle powerfully affects sleep physiology in fish. They also have pronounced intrinsic periodicity, modulating their behavior and physiology. It remains to be seen, however, whether the SCN plays the master clock role in fish, as it does in mammals. So far, it appears that other clock structures, such as the pineal gland and the retina of the eye, can be sufficient to orchestrate the circadian system in teleost fish and to entrain their daily sleep–wake cycles. Moreover, in some fish, especially those that are semi-transparent, light sensitivity is not limited to the retina and pineal gland but is present in the skin and even deeper structures, for example, in the heart. These tissues thus can entrain to the light–dark cycle directly.

The sleep postures in fish vary from floating in a horizontal or vertical position, head up or down, to lying on their side or belly. The level of inactivity during sleep also widely varies, with some fish completely ceasing their locomotion, and others only slowing it down. Moreover, the increase in arousal threshold and disengagement from environmental stimuli associated with the sleep state can be so substantial that blueheads, *Thalassoma bifasciatum*, Spanish hogfish, *Bodianus rufus*, and several species of wrasses, family Labridae, can be lifted by hand to the surface at night before waking up.

The typical daytime hiding places also serve as bedrooms for some fish. Those that hide in the mud or sand of the water bed while hunting or escaping from predators, such as sole, use the same adaptive behavior during their sleep period. This provides camouflage that is critically important for the state of reduced alertness that prevents adaptive escape behavior when danger threatens. The coral fish, for example, damsels or clownfish, family Pomacentridae, typically active during the day, rest within the reef structure at night, protected by its crevices. Freshwater fish often hide under a rock or log at night. Some fish species, however, design elaborate, truly remarkable hiding strategies. For example, parrotfish family Scaridae, can envelop themselves in a protective sleeping bag of secreted mucus, which misguides predators, by hiding a clever sleeper.

Many fish species are highly social, forming large schools or shoals, synchronizing complex locomotor activities in the middle of the ocean or freshwater stream. These species can rest together as well, forming a slowly moving or drifting colony. In such cases, individual guards, floating on the periphery of the colony, can warn the others of impending danger. Other schooling fish, however, develop individual sleep strategies. They prefer to spread throughout rather large territories, sleeping far from each other, hidden by rocks or floating in seaweed. How do they know that it is the right time to wake up and join the rest of their shoal? So far, nobody really knows the answer to this question.

Over the years, sleep studies have been conducted in a variety of fish. However, lately, special attention has been paid to sleep in zebrafish, *Danio rerio*, largely due to the extensive knowledge of zebrafish genetics and development that has been accumulated over the years through the effort of many research groups (**see also Bony Fishes:** Zebrafish).

Research into sleep in zebrafish has been particularly explored from a biomedical perspective. Because of this, when considering the zebrafish as a model for studying sleep, the first steps had to address the extent to which those processes that are known to affect human sleep can also modulate the sleep state in zebrafish. Like humans, they have a distinct diurnal sleep–wake cycle, demonstrating a high arousal threshold and reduced breathing rate during the sleep state. While sleeping, zebrafish slow down their activity, sometimes sluggishly moving around the fish tank, often staying suspended in the water (**Video Clips 1(a) and 1(b)**). Interestingly, when zebrafish are very young (and called larvae), they tend to sleep with their head down. Adult zebrafish, on the contrary, tend to sleep with their head slightly upward. This might reflect some age-dependent regulation of the swimbladder sphincter or other mechanisms of posture control that change during maturation.

Although the circadian clock system synchronizes numerous physiological processes equally well in both nocturnal and diurnal organisms, its most core gears are virtually identical in both types of animals: the master clock, the SCN, has high electrical and metabolic activity during the day, the core clock genes are expressed at similar times, and the principal hormone of the circadian system, melatonin, is secreted only at night. Thus, the rest of the organism should know how to read the clock and keep a specific adaptive schedule of activity and physiological functions in order to maintain its adaptive diurnal or nocturnal lifestyle. We have yet to discover where this important interpreter resides, allowing for a diurnal organism to translate a specific clock time into action, while a nocturnal organism reads it as a command to fall asleep. Thus, so far, studying circadian regulation of sleep in a diurnal vertebrate, such as zebrafish, has clear advantages for biomedical research.

Once it was documented that zebrafish sleep has a circadian pattern, it was important to determine whether melatonin, which is produced by the pineal gland and retina exclusively at night, can modulate sleep in zebrafish. This is because melatonin, being the principal neurohumoral output of the clock, is also known to have acute sleep-promoting effects in humans and diurnal nonhuman primates, whether administered at daytime or at night, thus directly linking the circadian system and sleep. Indeed, administered at daytime, tiny amounts of melatonin that increase melatonin levels in fish brain to approximately those that it normally has at night, make zebrafish sleepy. After such treatment, both larval and adult zebrafish start moving slowly and their arousal threshold increases to the level typical of the nighttime sleep period. However, if there is an urgent need for an active response to some environmental perturbations, zebrafish treated with melatonin, even in relatively high doses, can easily become fully alert. Such remarkable reversibility of the sleep-promoting effect of melatonin was reported earlier in humans. Together, this suggests distinct similarities in the melatonin-related sleep mechanisms in zebrafish and humans.

The second piece of evidence that sleep in zebrafish has features in common with sleep in mammals came from experiments targeting the most widespread inhibitory neurotransmitter, gamma-aminobuytric acid (GABA). GABA affects primarily chloride-permeable $\mathrm{GABA_A}$ receptor channels, hyperpolarizing neurons and inhibiting their action potentials. The majority of currently prescribed hypnotic drugs utilizes this effect and targets the GABA-ergic system. Zebrafish respond to such hypnotic substances, for example, barbiturates or benzodiazepines, by reducing activity and increasing arousal threshold. As in mammals, an increase in the dose of GABA-ergic compounds leads to loss of consciousness in fish.

Another neurochemical system that modulates sleep in humans and other mammals is that of histamine. Although histamine is an important part of the immune response and is produced by several cell types in the periphery, it is also an important neurotransmitter. It is synthesized in the tuberomammilary nuclei of the hypothalamus, with neuronal projections reaching many cortical areas. Loss of these neurons reduces alertness, while antagonists of H1 receptors, blocking their ability to convey histamine-based messages, induce sleepiness. This is one of the reasons for the widespread and often excessive use of over-the-counter antihistamine medications. What if zebrafish had a chance to use those over-the-counter antihistamines? Would they help fish to sleep? It turns out that the answer is: yes. When antihistamines are administered to a fish tank, both juvenile and adult zebrafish take a nap.

These findings in zebrafish strongly suggested that there are principal similarities between sleep processes in mammals and fish, making it even more interesting to study sleep-related mechanisms in diverse fish species. Then, however, a number of surprising observations proved once again that sleep regulation might be more complex than expected and that keeping in mind species- and class-specific differences is a must for any biomedical researcher.

Although there is a range of sleep disorders, their nature is still poorly understood. That is why finding a cause of one of the most mysterious sleep disorder, narcolepsy, was an exciting event. The underlying reason for most of the clinical cases of narcolepsy, typically associated with increased sleepiness, altered dreaming, and sudden attacks of muscle paralysis, turned out to be a deficiency in the production of a hypothalamic peptide hypocretin, also known as orexin. Hypocretin is an evolutionarily well-conserved molecule and is present in the fish brain. However, when mutant zebrafish lacking receptors for hypocretin were generated, the expected increase in sleepiness was not observed. On the contrary, these fish seemed to sleep less, not more, than their normal counterparts did. That said, other experiments addressing the role of hypocretin in fish sleep suggested that increasing production of hypocretin could promote and consolidate wakefulness, and inhibit sleep behavior in zebrafish, as would be expected from the mammalian-based studies. Currently, several research groups are trying to untangle this seemingly complex relationship between hypocretin signaling and sleep in zebrafish.

The characterization of sleep-related behaviors in zebrafish larvae and in adult zebrafish demonstrated that, similar to mammals or birds, sleep deprivation can lead to rebound of sleep in this species. Young, larval zebrafish compensate for sleep deprivation by increasing sleep time. Following several hours of forced wakefulness at nighttime, adult zebrafish also show somewhat reduced activity levels and tend not to perform cognitive tasks as efficiently as control animals that were not sleep deprived. However, if sleep deprivation lasts longer, for many hours or even days, alterations in fish locomotor activity appear to become less pronounced. This is in striking contrast to the response of mammalian species to prolonged lack of sleep, with a characteristic increase in sleepiness, behavioral alterations, and physiological abnormalities resulting from prolonged wakefulness. It is plausible that fish, like marine mammals, have some specific adaptive mechanisms for coping with the need for prolonged periods of continuous alertness, or at least a partial one. Learning about the neurochemical mechanisms involved in such adaptations might help us not only to better understand the overall phenomenon of sleep but also, potentially, to design some ways for temporarily increasing periods of human vigilance with minimal or no side effects.

The lower vertebrates have obvious anatomical limitations for the expression of some of the electrographic patterns commonly found in mammalian sleep. For example, it is unlikely that animals, such as fish, with only a rudimentary neocortex, if any, would generate the brain waves characteristic of mammalian slow-wave sleep. Thus, some of the sleep-related processes found in mammals cannot be studied in fish. However, the neurons central to sleep regulation are contained in structures within the isodendritic core of the brain, extending from the medulla through the brainstem, hypothalamus and up into the basal forebrain. All of those structures are well represented in fish (**see also Brain and Nervous System:** Functional Morphology of the Brains of Ray-Finned Fishes). Thus, fish, with their limbic brain, may be ideal for studying the principal, core sleep mechanisms manifesting in the absence of overpowering modulation by the cerebral hemispheres. Perhaps, it might take a sleepy swim to uncover the mystery of sleep.

Glossary

Adaptation A characteristic which increases an individual's fitness and has evolved through natural selection.

Cestoda A class of parasitic worms called tapeworms (within the phylum Platyhelminthes). Most cestodes have complex life cycles in which they use invertebrates as intermediate hosts and vertebrates as definitive hosts.

Definitive host A host in which the parasite reaches maturity and reproduces sexually.

Fitness Contribution of an individual to the next generation relative to other individuals, i.e., the proportion of the individual's genes in all the genes of the next generation. Traits affecting an organism's survival and reproductive success are tightly connected to fitness i.e., fitness = survivorship • fecundity.

Host manipulation Ability of a parasite to induce alterations in host phenotype which enhance parasite transmission.

Intermediate host A host that is used by the parasite, for example, for development, asexual reproduction, and transmission between definitive hosts.

Parasite An organism living in or on another organism – the host – and obtaining its resources by utilizing the host.

Parasite life cycle A period involving the development of a parasite to maturity and reproduction. Parasite life cycles can involve the exploitation of one (direct life cycles) or more host species (complex life cycles).

Phenotype Observable characteristics of an organism including different traits. Phenotype results from the expression of an organism's genes and the influence of environmental factors.

Target host The next host in the complex life cycle of a parasite to which it should be transmitted from its current host.

Trematoda A class of parasitic worms called flukes (within the phylum Platyhelminthes). Most trematodes have complex life cycles in which they use mollusks as intermediate hosts and vertebrates as definitive hosts.

Trophic transmission Form of parasite transmission from one host to another in which an infected host needs to be ingested by the target host. Trophically transmitted parasites utilize the predator–prey interactions existing in natural food webs.

The Parasitic Way of Life

Parasites spend at least a part of their lives in or on other organisms – the hosts – and obtain their resources by utilizing host individuals. This way of life offers several benefits. For example, hosts generally are resource-rich and fairly predictable living habitats, which protect parasites from the adversity of the environment outside their hosts. Moreover, a vast number of potential host species and sites of infection (different organs) offer a wide variety of resources for parasites. These factors have led to the independent evolution of parasitism in several taxa, and to a high rate of parasite speciation. Therefore, parasitism is perhaps the commonest way of life on Earth.

Despite the advantages of the parasitic way of life, parasites also face several challenges in their life histories. For instance, since parasites usually cause harm to their hosts (i.e., virulence), hosts tend to evolve resistance to parasite infections and/or tolerance of their harmful effects. Especially in vertebrates, highly developed immune responses replenished by immunological memory form the main physiological barrier against parasite infections. Furthermore, other defense mechanisms such as avoidance of those circumstances under which infections take place and group formation to dilute parasite exposure have been described in several host species.

However, probably the most severe challenge parasites need to overcome is that hosts are relatively short-lived habitats compared to those utilized by many free-living organisms. Therefore, because parasites are dependent on their hosts, transmission of parasite individuals between hosts is an essential process. This, however, is a very uncertain stage in parasite life histories, because hosts are usually patchily distributed in the environment. Especially in parasites with complex life cycles, including several different host species, an individual parasite only has a small probability of surviving and completing its life cycle because of high parasite mortality during transmission between different hosts. Thus, natural selection can favor parasite genotypes that can reduce these losses by being better at infecting the target hosts (the next host in the life cycle) relative to other genotypes. In fact, a wide variety of adaptations to enhance parasite transmission have been described in parasite–host relationships. These include, for example, release of parasite eggs or infective stages at the time when successful transmission is most likely to occur, and production of phenotypically dissimilar offspring to reduce the risk of transmission failure in unpredictable environments (i.e., 'bet hedging').

Trophic Transmission and Host Manipulation

Several complex parasite life cycles include at least one stage at which the infected host has to be consumed by the target host for successful transmission. Thus, parasites utilize the predator–prey interactions existing in natural food webs. Since the probability of an individual parasite completing its life cycle is typically very small, transmission success is a major determinant of overall parasite fitness. Therefore, to maximize transmission probability and thus fitness in trophic transmission, it would be beneficial for the parasites to alter host behavior or other phenotypic traits to make infected hosts easier prey for target hosts. In fact, phenotypic alterations in infected hosts have been described in several parasite–host interactions, and the ability of parasites to cause such effects has usually been considered as an evolutionary adaptation to increase parasite transmission efficiency. This might be the case in many systems, but not all parasite-induced alterations in host phenotype necessarily enhance parasite transmission. For example, in addition to increased host susceptibility to predation by target hosts, manipulation can also predispose infected hosts to capture by predator species which are unsuitable next hosts for the parasites (i.e., nonhost predators). Nonhost predation always leads to death of the parasites and thus phenotypic alterations in infected hosts can also induce severe costs to parasites. Therefore, it is difficult to distinguish parasite–host interactions in which parasite-induced alterations in host phenotype actually increase parasite transmission efficiency and thus could be considered as adaptive host manipulation. Thus, the effect of parasites on the susceptibility of hosts to different predator species should be understood.

Host Manipulation by Fish Parasites

In general, aquatic habitats are ideal for the maintenance of several different parasite life cycles. First, water provides a physiologically stable and viscous environment which enables the survival and effective dispersal of parasite eggs and free-living larvae. Second, aquatic food webs are often relatively long and complex, which facilitates the evolution of complex parasite life cycles. Furthermore, due to their commonness, high species diversity, and central role in aquatic food webs (both as consumers and prey), fish serve as hosts to a wide range of parasite species that exhibit different life cycles and life history strategies (note that some fish species are parasitic but this article considers fish only as hosts). Fish have also been widely used as study systems to examine the effects of parasites on their hosts. This is not only because of the importance of fish in natural ecosystems but also because of the high economical impact of fish parasites in fisheries and aquaculture. Most of the conducted studies have examined if and how parasites can alter fish phenotype (behavior and appearance) so that infected fish would become more susceptible to predation, and if the ability of parasites to predispose fish to predators could be an evolutionary adaptation by the parasites to enhance their transmission. This article briefly reviews these aspects of host manipulation in two relatively well-studied fish–parasite (*Diplostomum spathaceum* eye fluke and *Schistocephalus solidus* tapeworm) interactions.

Diplostomum spathaceum

The trematode *D. spathaceum* has a three-host life cycle with a bird definitive host, and snail and fish intermediate hosts (**Figure 1**). The parasite matures in the intestine of fish-eating birds, where it reproduces sexually. Several bird species are suitable hosts for the parasite, but gulls and terns are probably most common. After sexual reproduction, eggs of the parasite are released into water along with the bird's feces, where they hatch into free-swimming miracidia. Miracidia then infect aquatic snails (first intermediate host) mainly of the genus *Lymnaea.* Infection in a snail gives rise to sporocysts in which cercariae larvae are produced through asexual reproduction. Parasite development in snails takes 4–10 weeks depending on the water temperature, after which an individual snail can produce thousands of cercariae per day for several weeks. Cercariae infect a wide variety of freshwater and brackish water fish species (second intermediate hosts) by penetrating the gills and skin. In fish, these parasites migrate to eye lenses where they develop into metacercariae. For successful transmission to the avian definitive host, an infected fish has to be eaten by a fish-eating bird. In the lenses of fish, metacercarial stages of the parasite reduce host vision by inducing cataract formation (**Figure 2**) and disrupting lens structure. Therefore, by

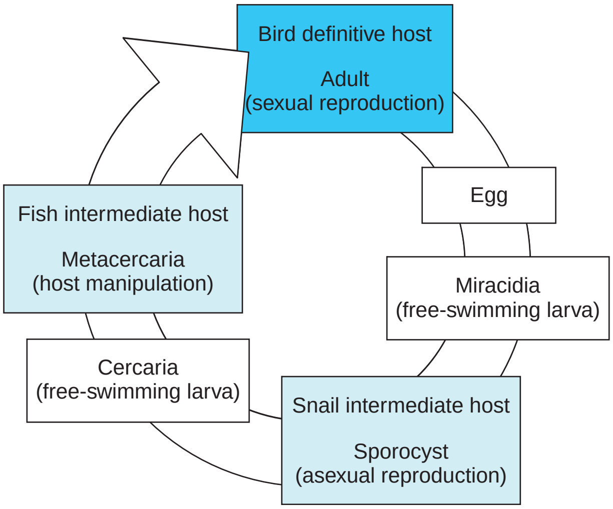

Figure 1 Life cycle of *Diplostomum spathaceum* (Trematoda). Colored boxes refer to the stages in which exploitation of hosts is involved (dark blue: definitive host; light blue: intermediate host).

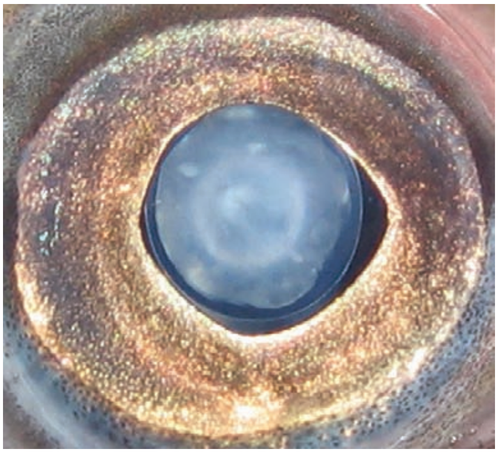

Figure 2 Parasite-induced cataracts in an eye lens of a juvenile rainbow trout infected with *Diplostomum spathaceum* eye flukes. Photo by Anssi Karvonen and Otto Seppälä.

injuring an important sensory organ, *D. spathaceum* has the potential to alter fish behavior and other phenotypic traits so that their vulnerability to predation could be increased.

D. spathaceum is one of the parasite species that is suggested to manipulate its fish hosts to increase transmission efficiency. By locating in the eye lenses and inducing cataract formation (**Figure 2**), it impairs fish vision and thus has the potential to predispose fish to predation. For example, dace (*Leuciscus leuciscus*) infected with *D. spathaceum* eye flukes spend more time near the water surface compared to uninfected fish. This can predispose fish to predation by gulls and terns, thus enhancing parasite transmission. However, the same effect has not been observed in rainbow trout (*Oncorhynchus mykiss*), with infected and uninfected fish preferring the same water depths. Instead, in rainbow trout, eye fluke infection impairs fish antipredator behavior. First, infection reduces shoaling of fish (infected fish are less likely to be part of a shoal and shoals of infected fish are smaller when compared to uninfected fish), which reduces the protection fish could get against predators from their conspecifics (**see also Behavioral Responses to the Environment:** A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food). Furthermore, these effects become more pronounced when the risk of predation is increased because only uninfected fish react to the presence of a predator by forming more cohesive shoals. Second, *D. spathaceum* infection reduces the intensity of fish escape reaction to an approaching avian predator by reducing the escape of fish to deeper water layers. These effects are likely mechanisms to predispose infected fish to predation and thus to enhance parasite transmission.

In addition to the behavioral responses discussed above, fish can also use other defense mechanisms, such as crypsis to avoid predators (**see also Behavioral Responses to the Environment:** A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food). In *D. spathaceum*–fish interaction, the ability of an eye fluke-infected fish to adjust itself to the environment using cryptic coloration and cryptic behavior is reduced when compared to an uninfected fish. In environments with a dark bottom coloration, both infected and uninfected rainbow trout are able to match their color to a substrate when observed from above. However, when maintained against lighter backgrounds, the contrast between fish color and background increases. Interestingly, this increase is higher in infected fish that remain darker than control fish. Furthermore, when fish can select between dark and light bottom colorations, the preference of infected fish for the dark background is reduced. This indicates that the camouflage of fish is reduced by the eye fluke infection. Therefore, infected fish should not only be easier to capture by predators but they can also be more conspicuous and thus more easily observed by avian predators.

To enhance parasite transmission, phenotypic alterations should predispose infected hosts to predation by target hosts. In laboratory experiments, eye fluke-infected rainbow trout are more prone to artificial predation, which simulates attacks by surface-feeding birds such as gulls and terns. When fish were caught with a dip net from shoals containing both heavily infected fish and uninfected fish, infected fish were caught more often as compared to controls. Similarly, when predation vulnerability of fish was determined by counting the number of attempts required to catch individual fish from the tanks, the number of attempts needed was lower in infected fish. These results suggest that infected fish are easier prey for bird hosts. However, these results have not been successfully verified in the field through real predation by gulls and terns, and thus the overall effect of manipulation on parasite transmission efficiency in the wild cannot be evaluated.

In many natural ecosystems, organisms are concurrently exposed to several predator species. Therefore, host manipulation may not only predispose infected individuals to predation by target hosts, but also to predator species which are unsuitable next hosts for the parasites. Nonhost predation always leads to death of the parasites, and thus parasite transmission may not be enhanced through manipulation. Since phenotypic changes induced by *D. spathaceum* are probably caused by impaired vision of fish (see below), manipulation could predispose fish not only to predation by avian hosts but also to nonhost predator species such as piscivorous fish. However, eye fluke infection has not been observed to predispose fish to predation by pike (*Esox lucius*), which represents a dead-end predator for the parasite. Reasons for the difference in the susceptibility of fish to different types of predators are unclear, but possibly differences in predator behavior are involved. Fish-eating birds typically actively search for prey, contrary to pike which ambush prey by staying motionless. Therefore, the effect of phenotypic alterations on the susceptibility of fish to predation may differ between predator species. If, for instance, activity of infected fish is reduced, it may lead to a lower contact probability with pike. Furthermore, when avoiding underwater attacks, fish are able to use not only their vision but also their lateral line and olfaction to detect predators. Hence, the role of vision may be particularly important when avoiding aerial avian predators (**see also Behavioral Responses to the Environment:** A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food.

Findings presented above suggest that eye fluke-induced alterations in fish phenotype can increase parasite transmission success and thus they could be considered as adaptive host manipulation. But how did the ability of the parasite to manipulate fish phenotype evolve? In *D. spathaceum*–fish interaction, the parasites lodge themselves in the lens of fish eyes, and induce cataract formation (**Figure 2**) through their movements and metabolic wastes. In predation experiments discussed above, the susceptibility of fish to predation (capture by dip net) increased with the coverage of parasite-induced cataracts, indicating that impaired vision of fish is likely to be the underlying physiological mechanism leading to manipulation in this system. Therefore, it is possible that the eye as the site of infection has been favored by natural selection if it increases parasite transmission efficiency. On the other hand, natural selection may have also favored parasites escaping the host immune defense by locating in the lens, which has been suggested to be immunologically naïve because of the lack of blood vessels. Moreover, since cataract formation is probably tightly connected to parasite metabolic rate, increased susceptibility of fish to predation could be just a side effect of selection favoring faster parasite growth and development in fish. Whatever the original reason for locating in the eyes and inducing cataract formation is, natural selection may still act on all parasite features that influence transmission efficiency. For example, in *D. spathaceum*–fish interaction, cataract formation is slow when metacercariae are growing, but fast after they have completed development. This leads to an increase in the susceptibility of fish to predation only after parasites are infective to bird hosts. Delayed timing of manipulation has also been observed in several other parasite–host interactions, and it may be highly advantageous under selection favoring higher parasite transmission efficiency, because predation of uninfective larvae always leads to death of the parasites. These results suggest that precise timing of cataract induction, after metacercariae have reached infectivity to birds, leads to increased vulnerability of fish to predation, and thus may be a parasite strategy evolved to increase transmission efficiency in this system.

Schistocephalus solidus

Similar to *D. spathaceum*, the cestode *S. solidus* has a complex life cycle in which it exploits three different host species (**Figure 3**). The parasite matures in the intestine of fish-eating birds, where its reproduction takes place. After reproduction (*S. solidus* is a hermaphrodite and capable of self-fertilization), eggs of the parasite are released into water with bird feces, where they develop into the first larval stage called coracidia. The free-swimming coracidia that hatch from the eggs are ingested by freshwater copepods (first intermediate

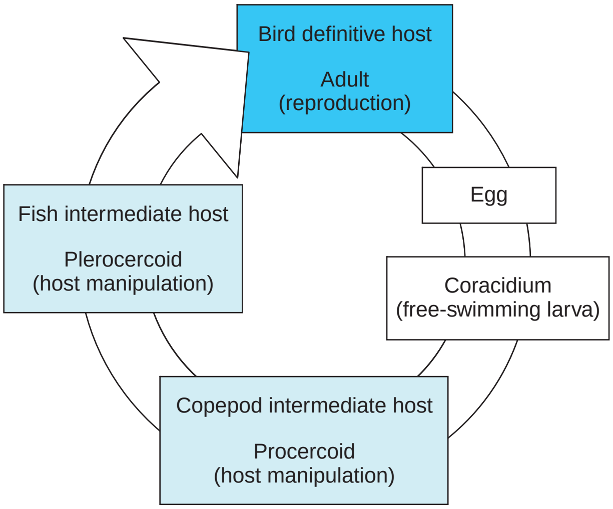

Figure 3 Life cycle of *Schistocephalus solidus* (Cestoda). Colored boxes refer to the stages in which exploitation of hosts is involved (dark blue: definitive host; light blue: intermediate host).

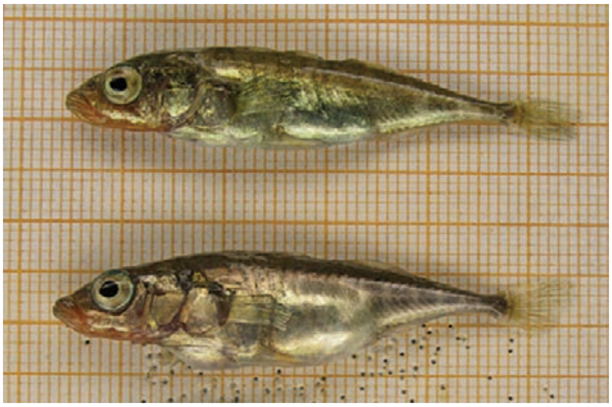

Figure 4 A healthy (top) and a *Schistocephalus solidus*-infected three-spined stickleback (bottom). The abdomen of the infected fish is swollen due to parasite infection. The fish are shown on a graph paper in which the distance between fine lines is 1 mm. Photo by Katja Räsänen.

host) where the parasites penetrate through the intestine to the body cavity and develop into procercoids. A copepod infected with a *S. solidus* procercoid needs to be ingested by a three-spined stickleback (*Gasterosteus aculeatus*; second intermediate host) for successful onward transmission. The parasite is known to manipulate the behavior of infected copepods by increasing their activity, which predisposes them to fish predation. In sticklebacks, parasites reach the last larval stage called plerocercoid, and grow in the abdominal cavity of the fish. For successful completion of the life cycle, an infected fish has to be consumed by a fish-eating bird. In sticklebacks, *S. solidus* plerocercoids grow for several weeks before they are able to infect a bird. During that period, parasites reach a very large size (they can equal the biomass of the fish), and the abdomen of an infected fish swells (**Figure 4**). Therefore, by inducing a strong pathological effect, *S. solidus* has the potential to alter fish phenotype in ways that could increase their vulnerability to predation.

Phenotypic alterations in sticklebacks infected with *S. solidus* plerocercoids show several similarities to those observed in fish infected with *D. spathaceum* eye flukes. For example, *S. solidus*-infected fish spend more time close to the water surface, and their escape responses are weaker when compared to uninfected individuals. Furthermore, in some stickleback populations in North America, *S. solidus* alters fish coloration, but contrary to eye flukes, the parasite induces demelanization of fish. This results in fish with a light body and dark eyes, which together with a swollen body are likely to make infected fish very easy to observe by predators. Furthermore, in addition to the phenotypic alterations mentioned above, *S. solidus* induces an interesting behavioral alteration in fish – increased risk taking. Contrary to uninfected fish, infected sticklebacks do not adjust their foraging areas according to predation risk but they forage close to predators. Infected fish also recover more quickly from predatory attacks as compared to uninfected individuals, returning closer to the water surface and starting to forage sooner after a disturbance. Although solid experimental evidence demonstrating the increase in predation vulnerability of infected fish is still lacking, the risky behavior of infected sticklebacks is very likely to increase parasite transmission success to piscivorous birds. As with *D. spathaceum*, the behavior of those fish, containing parasites ready to infect target hosts, is more strongly affected than those where the parasites are still developing. However, risk taking could also predispose sticklebacks to nonhost predators which can counterbalance its benefits (see above).

But why do *S. solidus*-infected sticklebacks take risks? Altered behavior of fish in relation to avoidance of predators could probably be explained by the energetic requirements of the parasite. In infected fish, *S. solidus* reaches a very large size so that the biomass of the parasite can equal that of the fish host. Thus, the worm can take so much energy from its host that infected sticklebacks simply need to forage despite the risk of predation. Furthermore, infected individuals are weaker competitors than uninfected fish. Thus, to avoid competition with their conspecifics, infected sticklebacks may be forced to forage close to predators. Increased energy requirements of infected fish are likely to explain the observed alterations in the behavior of infected sticklebacks especially because the effect of the parasite increases with plerocercoid size. However, also other mechanisms might play a role in host manipulation in this system. For example, monoamine neurotransmitters are involved in the control of animal behavior, and the monoaminergic systems are highly sensitive to several stressors, including parasitism. In *S. solidus*-infected sticklebacks, the concentrations of 5-hydroxytryptamine (5-HT) and norepinephrine (NE) are reduced in the telencephalon, and the ratio between 5-HT and its metabolite 5-hydroxyindoleacetic acid (5-HIAA) is changed in both the hypothalamus and brainstem. Such effects are consistent with chronic stress in fish and indicate enhanced release of neurotransmitters. These effects could also lead to the observed behavioral alterations in infected sticklebacks, and may even be caused by direct manipulation of the fish neuroendocrine system by the parasite. However, further studies are needed to determine their role in host manipulation.

Future Directions

Similar to the studies presented above, most of the earlier work on host manipulation has mainly concentrated on its adaptive value to parasite transmission. Both the underlying physiological mechanisms leading to manipulation and the ecological importance of host manipulation are still poorly understood in most systems. Such knowledge is important as it could have wider implications for parasitological and ecological research. First, although many previous studies suggest that trophically transmitted parasites can increase their transmission success by manipulating the phenotype of their intermediate hosts, we do not know much about the evolutionary processes that have led to manipulation. If we understand how parasites alter host phenotype in detail, we can propose how natural selection could have led to the evolution of host manipulation, and also examine parasite evolution as a whole, additionally considering other parasite traits that are tightly connected to the fitness (e.g., host exploitation and growth).

Second, the ecological importance of manipulating parasites in natural ecosystems has received only recent interest. The potential role of host manipulation in determining, for example, parasite/host population dynamics, interactions between host species, food web structure, and ecosystem functioning is little understood. However, such effects can be important because manipulated hosts can be seen as complex organisms, not only retaining some of the properties of uninfected individuals but also displaying new parasite-induced characteristics. This can lead to novel interactions with other species and/or conspecifics. Furthermore, because parasites are extremely common, such alterations can potentially influence biodiversity and ecosystem functioning. Most of the research on host manipulation has been conducted under laboratory conditions. Although such experiments are extremely important when investigating the mechanisms and adaptive value of manipulation, they cannot address the extent of manipulation in natural host populations. Furthermore, most studies on host manipulation have investigated the effect of parasites only on one host species although many parasites infect several different hosts. Thus, to estimate the importance of manipulation at ecosystem level it would be necessary to examine the occurrence and effects of manipulation at a host community level in the field. Such studies could help to resolve how strong host manipulation is in nature, which host species are most strongly manipulated, and whether parasites can affect ecosystem processes by altering food web structure and energy flow.

Glossary

Acetylcholine A neurotransmitter particularly associated with motor control.

Acetylcholinesterase An enzyme that degrades the neurotransmitter acetylcholine.

Alarm substance A chemical or group of chemicals released in some species of fish from the skin of injured individuals.

Cholinesterase An enzyme (technically a group of enzymes) that degrades acetylcholine and butyrylcholine.

Endocrine disruptor An exogenous substance that causes adverse health effects in an organism or its progeny, subsequent to changes in endocrine function.

Monoamine neurotransmitter A group of neurotransmitters that contain one amino group in their chemical structure.

Neurotransmitters A group of chemicals that are released from nerve endings that transmit information to neighboring cells.

Ototoxin A chemical that causes damage to hair cells of the ear or lateral line.

Rheotaxis Orientation in a water current; most fish orientate to face into the water current.

Interactions between Physiology and Behavior

The physiology and behavior of fish are closely related and as such represent a fragile link vulnerable to anthropogenic disturbances. There are a myriad of ways in which humans have altered the aquatic environment, including chemical pollution, acoustic disturbances, physical disturbances, such as habitat destruction, and the release of invasive or transgenic species. The effects of human disturbance on fish behavior and physiology have been most studied in relation to chemical contaminants, including organic pollutants (e.g., some pesticides; **see also Toxicology:** The Toxicology of Organics in Fishes), pharmaceuticals, inorganic pollutants (e.g., metals; **see also Toxicology:** The Toxicology of Metals in Fishes), and radionuclides. Many types of anthropogenic disturbance target specific physiological systems and may exert their effects on fish behavior via physiological pathways. The performance of behaviors by individual fish generally follows specific physiological sequences acting as a link between physiological and ecological processes. Indeed, the use of fish behavior as a sensitive and ecologically relevant tool for monitoring anthropogenic effects in the aquatic environment is widely accepted. This article considers the main ways in which human activities are known to affect the fragile link that exists between behavior and physiology, focusing particularly on the effects of chemical contaminants.

Disruption of Sensory Information

Olfaction

The sense of smell is a key factor in allowing a fish to gain information about its surrounding environment and to behaviorally respond in an appropriate way. Olfaction is important in a plethora of behaviors. For example, salmonids rely on their sense of smell to find their way back to natal streams during migration (**see also Fish Migrations:** The Biology of Fish Migration). Many fish species, when injured by a predator, release a chemical known as ‘alarm substance’ into the water, sending olfactory warning signals to neighboring individuals that there is a predator present (**see also Behavioral Responses to the Environment:** A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food). Reproductive pheromones play a vital role in courtship behaviors of many fish species (**see also Social and Reproductive Behaviors:** Sexual Behavior in Fish and **Hormones in Communication:** Hormonal Pheromones). Therefore, any chemicals that damage or interfere with the olfactory system in fish could disrupt a vast array of behavioral processes.

The olfactory system of fish consists of an olfactory rosette in direct contact with the external environment. Receptors in the rosette send information about olfactory stimuli via the olfactory nerve to the olfactory bulb located in the brain (**see also Smell, Taste, and Chemical Sensing:** Chemoreception (Smell and Taste): An Introduction and Morphology of the Olfactory (Smell) System in Fishes). Direct contact between the olfactory rosette and the environment of the fish can allow damage of the olfactory rosette by waterborne contaminants and some may actually be transported along the olfactory nerve to the brain. In pike, *Esox lucius*, mercury is transported along olfactory nerves, and, in salmonids (e.g., salmon and trout), cadmium has been found to accumulate in the olfactory rosette, olfactory nerve, and the anterior part of the olfactory bulb of the brain of fish held in cadmium-contaminated water, as illustrated in **Figure 1**. **Figure 1(a)** shows a cross section through a rainbow trout, *Oncorhynchus mykiss*, that has been exposed to waterborne radiolabeled cadmium. The olfactory system can be clearly seen. **Figure 1(b)** shows exactly the same section of fish but viewed using whole body phosphor screen autoradiography, which highlights the areas where radiolabeled cadmium has accumulated. From this, it is possible to see that cadmium has accumulated in the olfactory rosette, olfactory nerve, and olfactory bulb. Accumulation of toxicants in the olfactory rosette may also lead to a decrease in the number of functional receptors.

Contaminant accumulation in the olfactory system and the knock-on effects they have on cellular and

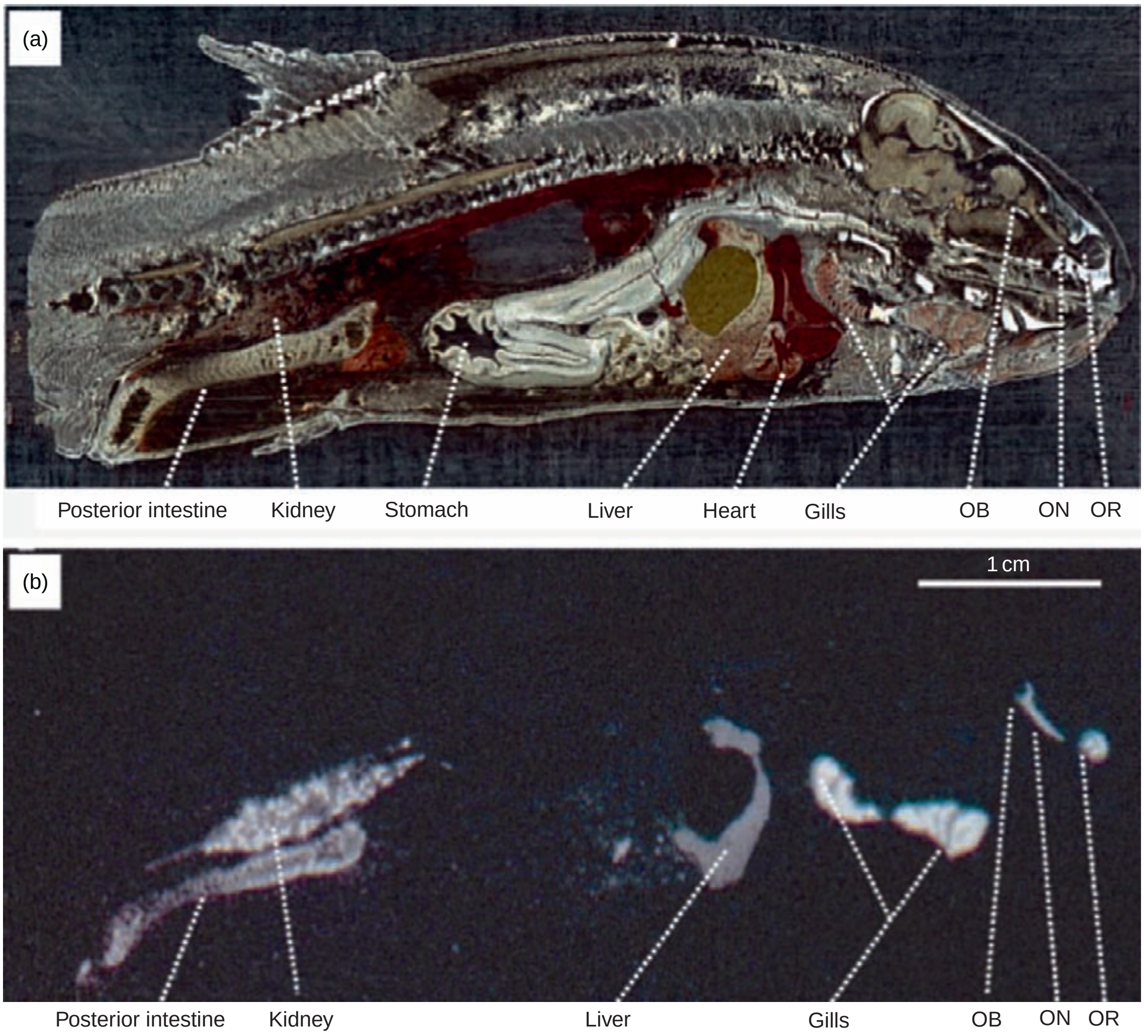

Figure 1 (a) Cross section through a rainbow trout showing a variety of tissues, including the olfactory bulb (OB), the olfactory nerve (ON), and the olfactory rosette (OR). (b) The same cross section of a rainbow trout viewed using phosphor screen autoradiography showing accumulation of radiolabeled cadmium following a waterborne exposure. Reproduced from Scott GR, Sloman KA, Rouleau C, and Wood CM (2003) Cadmium disrupts behavioural and physiological responses to alarm substance in juvenile rainbow trout (*Oncorhynchus mykiss*). *Journal of Experimental Biology* 206: 1779–1790, with permission from The Company of Biologists.

physiological processes can ultimately affect the behavior of the fish. Alarm substance is a chemical or group of chemicals that is released when a fish is injured and its skin cells are ruptured. For example, in rainbow trout, individuals will demonstrate freezing behaviors and an overall decrease in activity when alarm substance is added to the water – characteristic behaviors seen in response to a potential predation threat. However, in rainbow trout that have been exposed to waterborne cadmium prior to the addition of alarm substance, no changes in behavior are seen. In contrast, exposure to dietary cadmium does not affect the behavioral response of fish to alarm substance. The effects of waterborne cadmium on the ability of fish to respond to alarm substance can be seen at relatively low concentrations that do not cause mortality or major physiological disturbances. However, the inability to detect and respond to alarm substance when a predator is present is a potentially lethal situation for the fish. Toxicants that interfere with detection of olfactory stimuli can also disrupt other behaviors, including courtship, prey capture, migration, and social interaction.

Mechanoreception

The lateral line functions to detect vibrations and water movement and allows fish to orientate themselves in a water current (rheotaxis), gain information about their spatial environment, and also plays a vital role in schooling (**see also Hearing and Lateral Line:** Lateral Line Structure). The sensory cells within the lateral line are known as hair cells and are also present in the ear. In the lateral line, hair cells are contained in sensory units known as neuromasts. Toxicants that interfere with hair-cell function, therefore, have the potential to disrupt behaviors reliant on hearing and the lateral line. Ototoxins are contaminants known to specifically affect hair-cell function and include the pharmaceuticals such as gentamicin sulfate, streptomycin, and amiloride.

Trace metals may also interfere with lateral line function. For example, banded kokopu (*Galaxius fasciatus*) exposed to waterborne cadmium show a reduced ability to orientate in a water current. Waterborne copper exposure in zebrafish larvae reduces the number of functional neuromasts in the lateral line. In control zebrafish larvae, functional neuromasts can be visualized by staining with the fluorescent dye, 2-(4-dimethylaminostyryl)-*N*-ethylpyridinium iodide) (DASPEI). **Figure 2(a)** shows control zebrafish larvae with functional neuromasts running along either side of the body in the lateral line stained with DASPEI. **Figure 2(b)** shows zebrafish larvae exposed to waterborne copper before staining with DASPEI; a clear reduction in functional neuromasts can be seen. In consequence, zebrafish larvae exposed to waterborne copper during development have a reduced ability to orientate and maintain their position within a water current.

Sound

Sound plays a major role in many fish behaviors, including social communication and mating (**see also Sensory Systems, Perception, and Learning:** How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling). In species with planktonic dispersal, for example many coral reef fish, sound also plays a vital role in locating a suitable habitat. Studies using artificial reefs with audio recordings of reef sounds have demonstrated how important sound is for settlement and habitat choice. In addition to ototoxins that can damage the hair cells of the ear, anthropogenic noise pollution can be problematic for fish although not all noise pollution has been found to have an effect on fish behavior (**see also Hearing and Lateral Line:** Effects of Human-Generated Sound on Fish). Marine fish from an inshore reef in Loch Ewe, Scotland, displayed a startle response to deployment of seismic air guns; however, there was little effect on day-to-day behavior of the fish. In the laboratory, initial exposure of Chinook salmon, *Oncorhynchus tshawytscha*, and rainbow trout to

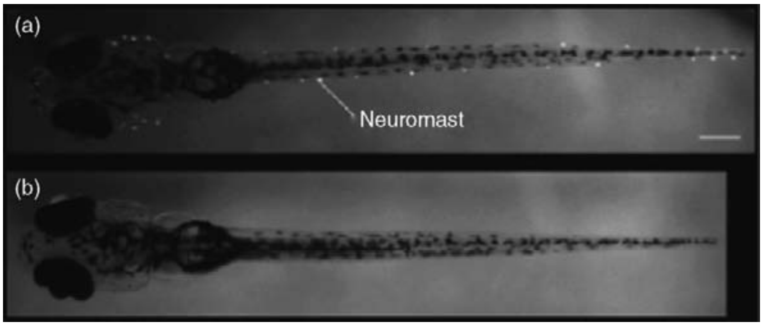

Figure 2 (a) Control and (b) copper-exposed zebrafish larvae stained with DASPEI illustrating the presence (in (a)) and absence (in (b)) of DASPEI-stained neuromasts. Scale = 0.25 mm. Reproduced from Johnson A, Carew E, and Sloman KA (2007) The effects of copper on the morphological and functional development of zebrafish embryos. *Aquatic Toxicology* 84: 431–438, with permission from Elsevier.

10-Hz-frequency sound causes a flight response away from the source; however, upon repeated exposure, this behavior changes to a less-dramatic avoidance response. This kind of sound avoidance by fish is well documented. Indeed, sound is often used as a fish repellent. For example, an acoustic deterrent system producing 20–600 Hz sound resulted in a 60% avoidance of a power station cooling water inlet by estuarine fishes. The clupeiod species, Atlantic herring, *Clupea harengus*, and European sprat, *Sprattus sprattus*, were most affected; a characteristic feature of the Clupeidae family is their advanced hearing capacity (**see Hearing and Lateral Line:** Physiology of the Ear and Brain: How Fish Hear).

Taste

Feeding behavior of fish depends on taste with many fish being able to distinguish between different food sources and display food preferences. Fish may also rely on taste to alter their diet in response to environmental change; for example, there may be potential for them to select a high-sodium diet, which is known to counteract the toxicity of some trace metals. In yellow bullheads, *Ictalurus natali*, detergents cause disintegration of taste buds and reduce the ability of individuals to chemically detect food. In catfish, such as yellow bullheads, taste buds, known as barbels, are located on whisker-like projections from the mouth, which are used for probing the sediment and searching for food. Damage to these sensory receptors may reduce the ability of individuals to detect potential prey.

Vision

The major anthropogenic influence affecting the vision of fish is increased turbidity through increased suspended material in the water column. Dredging, soil erosion, and sewage output are just a few examples of activities that can increase turbidity. The variety of bright colors utilized by fish indicates the importance of vision in fish communication for a myriad of reasons, including individual recognition and mate attraction (**see also Sensory Systems, Perception, and Learning:** Communication Behavior: Visual Signals). A reduction in visibility in the surrounding environment can disrupt fish visual communication and, in extreme cases, can lead to constraints in color vision.

Some toxicants, including methylmercury, may also interfere directly with the eye. Optic nerve function can be affected by the drug ethambutol, which is used to treat tuberculosis, and signal processing in the eye may be disrupted by the herbicide thiobencarb and the insecticide dichlorodiphenyltrichloroethane (DDT).

Neurotoxins and Interference with Brain Function

Neurotransmitters are chemicals that transmit signals both within the nervous system and from the nervous system to other cells. These chemicals play a vital role in many physiological and behavioral processes and, in order to function as reliable signals, they must be effectively degraded to give the signal a temporal property. Production and breakdown of the neurotransmitter allow transmission of a signal from one cell to another. A vast array of different neurotransmitters exists and several have been closely associated with behavioral patterns. Acetylcholine (ACh) is a neurotransmitter particularly involved with motor coordination and is broken down after release by the enzyme acetylcholinesterase (AChE). Total brain cholinesterase (ChE) activity is often measured as an indicator of AChE activity.

Many studies have considered the impact of toxicants on fish brain ChE activity. The insecticides malathion and diazinon are known to inhibit ChE activity, resulting in a buildup of ACh and subsequent effects on motor function. Studies on rainbow trout found that exposure to both of these insecticides resulted in fish swimming shorter distances at slower speeds. Other chemicals known to affect ChE activity include the organophosphate insecticides chloropyrifos and fenitrothion and several carbamate pesticides and herbicides, including thiobencarb and diuron.

A group of monoamine chemicals, which includes serotonin (5-hydroxytryptamine, 5-HT) and dopamine, also function as neurotransmitters. These monoamines are associated with the stress response and social behaviors. Elevated concentrations of serotonin and dopamine have been linked to submissive and aggressive behaviors, respectively. Methylmercury, the organochlorine pesticide lindane, polychlorinated biphenyls (PCBs), and copper can disrupt levels of these monoamines and, therefore, have the potential to impact behaviors associated with these neurotransmitters. Toxicants may also interfere with brain function through direct damage to brain tissue, including the formation of vacuoles within cell body layers and decreases in antioxidant enzymes, which function to break down free radicals and protect tissues from DNA damage.

Disruption of neurotransmitters and damage to brain tissue have many implications for behavior. The vital role of ChE activity in motor control means that chemicals, such as organophosphate pesticides that inhibit ChE activity, have profound effects on the myriad of behaviors that are dependent on locomotion. In particular, the decrease in swimming speeds associated with impaired ChE activity has implications for predator avoidance and prey capture. The escape response in most fish in response to a predatory threat occurs via the Mauthner system, consisting of two large nerve fibers located on either side of the brainstem with connections to hair cells of the lateral line (**see also** Brain and **Nervous System:** Physiology of the Mauthner Cell: Discovery and Properties). Activation of these nerve fibers in response to detecting pressure waves on one side of the body results in a classic reflex response away from the potential predator. This response occurs within milliseconds and is an extremely effective predator-avoidance mechanism. Exposure to the broad-spectrum insecticide, carbaryl or the chemical phenol, affected Mauthner cell function in medaka, *Oryzias latipes*. Sublethal concentrations of ammonia also affect the fast-start escape response in fish by interfering with the function of the Mauthner cells, and, additionally, by exerting toxic effects on white muscle. Exposures to sublethal levels of contaminants that impair swimming ability and reduce the effectiveness of the escape response can become lethal situations for the fish if they are unable to escape predation. Likewise, if fish are unable to catch their prey, then sublethal exposure to a toxicant can soon lead to starvation.

Neurotoxins are also known to interfere with fish social behavior. Exposure of rainbow trout to the neurotoxic metal, cadmium, decreased their ability to form social hierarchies and socially compete with nonexposed fish. Social hierarchies are known to form among groups of juvenile salmonid fish over resources such as food and shelter (**see also Social and Reproductive Behaviors:** Dominance Behaviors). The ability to win dominance contests can, therefore, translate into increased food acquisition and better territories. Initial competitions between pairs of juvenile trout often involve chases and bites by each fish, and occasionally mouth fighting until dominance is ascertained. In cadmium-exposed fish, it has been noted that individuals have difficulty making accurate judgments of the exact location of their competitor, resulting in aggressive chases that fail to make physical contact with their opponent. Consequently, hierarchy formation is either delayed where both competitors have been exposed to this neurotoxin, or cadmium-exposed fish are at a disadvantage when paired with a nonexposed fish.

Toxicants that Interfere with Respiration

There are two major ways in which fish gills or respiratory organs come into direct contact with contaminants. Some toxicants dissolve directly in the water column and thus are passed over the gills during ventilation. Other immiscible toxicants, such as oil, form layers on top of the water surface and can be inhaled by fish coming to the water surface to breathe air (**Behavioral Responses to the Environment:** Behavioral Responses to Hypoxia). Fish coughing has been observed as a general behavioral response to many waterborne toxicants. Aluminum is a trace metal that has been particularly associated with respiratory toxicity in fish, causing changes in gill morphology and impaired respiratory function. Fish exposed to waterborne aluminum reduce metabolically costly fast swimming behavior, suggesting a decrease in respiratory efficiency and, therefore, available energy. Other trace metals that can negatively impact on the energetic capacity of fish include copper and nickel.

Many fish species show adaptations to low oxygen levels in the water which involve moving to the water surface either to ventilate their gills in the thin layer of water in immediate contact with the air (aquatic surface respiration) or to actually breathe air (**see Behavioral Responses to the Environment:** Behavioral Responses to Hypoxia). When a contaminant forms a thin layer on the water surface, such as in the case of oil spills, there can be severe consequences for fish that rely on access to the water surface. Some fish, such as the piraracu, *Arapaima gigas*, are obligate air breathers and will die when denied access to air, regardless of levels of dissolved oxygen in the water. These fish are particularly susceptible to pollutants, such as oil, which can enter their air-breathing organs causing respiratory distress and suffocation.

Reproductive Impairment

Research into the effects of contaminants on fish reproduction has focused in recent years on compounds that can act as endocrine disruptors. An endocrine disruptor is an exogenous substance that causes adverse health effects in an organism or its progeny subsequent to alterations in endocrine function. Many endocrine disruptors mimic endogenous hormones, while others may interfere with the production of endogenous hormones or block their effects. In particular, a vast array of estrogenic endocrine disruptors have been identified, chemicals that mimic the natural hormone estrogen with potentially more potent effects. Androgenic endocrine disruptors also exist along with known anti-androgens and anti-estrogens that interfere with the functioning or production of male or female hormones, respectively.

Estrogenic chemicals, such as nonylphenol, used as a surfactant in detergents, bisphenol A, an important component of many plastics and the synthetic estrogen found in the contraceptive pill, ethinyl estradiol, are known to have feminizing effects in many fish species. Natural estrogenic chemicals, known as phytoestrogens, are found in some plant species and may be released into the environment through pulp and paper-mill processing. Male fish exposed to these compounds in the water may develop intersex reproductive organs that demonstrate the characteristics of both testes and ovaries. A commonly used indicator of estrogenic exposure in male fish is the production of vitellogenin, an egg-yolk precursor protein. Vitellogenin is normally only produced in female fish where high concentrations of the female hormone estrogen cause the liver to produce vitellogenin, which is then transported in the blood stream to the ovaries and packaged into eggs. Synthetic estrogens have the capacity to induce a similar effect in male fish, resulting in uncharacteristically high levels of plasma vitellogenin.

Exposure to these feminizing chemicals also has the potential to alter male reproductive behavior. Effects of endocrine disruptors on reproductive behavior have been particularly studied in fathead minnows, *Pimephales promelas*. Reproductively mature male fathead minnows develop secondary sexual characteristics, such as a fat pad on their head and tubercles on their snout, which aid in attracting a mate. Following courtship behaviors, these fish form pairs, and the female lays eggs, which the male then fertilizes. Exposure to estrogenic chemicals, such as nonylphenol, has been shown to reduce fat-pad size and the number of face tubercles in male fathead minnows, reducing their chances of attracting a mate and successfully reproducing. In three-spined sticklebacks, *Gasterosteus aculeatus*, males build a nest to attract a female to lay eggs in and use elaborate courtship behaviors to attract females to their nest (**see Social and Reproductive Behaviors:** Sexual Behavior in Fish). Exposure to estrogenic endocrine-disrupting chemicals has been shown to reduce courtship success and nest building behavior in male sticklebacks.

Other pollutants may interfere with reproductive behavior without necessarily disrupting endocrine function. Many fish use sexual pheromones to attract mates (**see Hormones in Communication:** Hormonal Pheromones). As mentioned previously, there are many chemicals that can interfere with olfactory function and thus disrupt courtship behaviors that depend on olfactory cues. For example, female Atlantic salmon, *Salmo salar*, release prostaglandin $F_{2\alpha}$ as an olfactory cue that has a priming influence on males, resulting in elevations of male hormones and sperm availability. Exposure of male Atlantic salmon to many insecticides and pesticides, including carbofuran, atrazine, cypermethrin, and diazinon, reduces the ability of males to detect prostaglandin $F_{2\alpha}$ and, therefore, their ability to behaviorally and physiologically respond to female cues.

Future Studies

The ways in which human activity can and has disrupted the fragile link that exists between fish behavior and physiology are vast and, here, I have only scraped the surface of the detrimental effects that we know we have exerted on fish biology. However, there are many areas where we are still lacking in knowledge. For example, a plethora of research has focused on chemicals that interfere with the functioning of reproductive hormones but little considered are chemicals that might interfere with other hormonal systems, such as stress hormones and thyroid hormones. Many fish species undergo sex change during their life history (**see Social and Reproductive Behaviors:** Socially Controlled Sex Change in Fishes), what impacts do estrogenic or androgenic chemicals have on this process? Also lacking is our understanding of how laboratory toxicity studies translate into field exposures. For example, laboratory exposure to toxicants can affect the ability to both detect predators and forage for food. In the field, these behaviors do not occur in isolation and it is likely that both prey and predator will be exposed to toxicants at the same time. It is imperative that we continue to strive to understand the anthropogenic influences on fish behavior and physiology and to add ecological relevance to our understanding of these issues.

EDITORS' BIOGRAPHIES

Editor-in-Chief

Anthony P. Farrell, Department of Zoology, University of British Columbia, Vancouver, BC, Canada

Tony Farrell is a graduate of Bath University, where he was fortunate to study with Peter Lutz. His fortunes grew further when he moved in 1974 to Canada and the Zoology Department at the University of British Columbia (UBC) to complete his PhD degree under the excellent tutelage of Dave Randall. In 2004, Tony returned to UBC when he accepted an endowed research chair in sustainable aquaculture. In between these positions at UBC, Tony was employed at the University of Southern California (PDF), the University of New Brunswick (sessional lecturer), Mount Allison University (first real job), and Simon Fraser University (moving through the ranks to a full professor). In addition to highly controlled laboratory experiments on fish cardiorespiratory physiology, Tony is committed to working on animals in their own environment. Therefore, his research on fish physiology has taken him on an *Alpha Helix* expedition to the Amazon, the University of Gothenburg and the Kristineberg Marine Research Station in Sweden, the Portobello Marine Biological Station in New Zealand, the University of Christchurch and Massey University in New Zealand, the Bamfield Marine Science Station and the Huntsman Marine Station in Canada, the University of Aarhus in Denmark, the University of Adelaide Charles and Darwin University in Australia, and to the Danish Arctic Marine Station on Disco Island in Greenland. These travels have allowed him to work with many superb collaborators wordwide, as well as study the physiology of over 70 different species of fish. Tony has received a number of awards for his scientific contributions: an honorary degree from the University of Gothenburg in Sweden; Awards of Excellence from the American Fisheries Society for Fish Physiology, Conservation and Management; the Fry Medal from the Canadian Society of Zoologists; and the Beverton Medal from the Fisheries Society of the British Isles.

Associate Editor

Joseph J. Cech, Jr., Department of Wildlife, Fish, and Conservation Biology, University of California, Davis, CA, USA

Joe Cech grew up in northern Illinois <1 km from the Salt Creek Preserve, where he spent many hours as a boy. Summer trips to northern Wisconsin, northern Minnesota, and southern Ontario increased his interest in aquatic habitats and their fishes. He graduated from the University of Wisconsin (UW, Madison), where he was fortunate to study oceanography under Robert Ragotzkie and fish biology under Art Hasler and Fran Henderson in the UW Laboratory of Limnology. Before completing his BS degree in zoology, he was fortunate to serve as the resident zoologist aboard the R/V *Dante Deo*, for a year, as it crossed the Caribbean Sea and the South Pacific Ocean. Completing his degree upon his return, he was hired as a research assistant at the University of Texas' Marine Science Institute (UTMSI), where he earned his MA and PhD degrees in zoology, under the supervision of Curly Wohschlag. During his graduate education in Austin (Texas), he studied fish biology under Clark Hubbs and physiology under Jack Myers and Jim Larimer. After a 2-year postdoctoral position in Maine, he was hired as a fish physiological ecologist faculty member at the University of California (UC), Davis, in the Department of Wildlife, Fish, and Conservation Biology.

During his 32 years as an active faculty member at UC Davis, his research on the physiological ecology of fishes took him to Canada (University of British Columbia, Bamfield Marine Station), Finland (University of Helsinki), and to other laboratories in the USA (University of Tennessee, Scripps Institution of Oceanography, R/V *David Starr Jordan* in the North Pacific Ocean, UTMSI, Oregon Institute of Marine Biology, and the UC Bodega Marine Laboratory) where he collaborated with many excellent scientists. During this period, he taught courses in physiology of fishes, physiological ecology, and field studies in fish biology; he supervised 25 graduate students (10 MS and

15 PhD) in the disciplinary areas of ecology, physiology, zoology, and pharmacology/toxicology at UC Davis. He is a fellow of the AIFRB and AAAS, and he received Awards of Excellence from the American Fisheries Society (Physiology Section, and California-Nevada Chapter) and the UC Davis Prize for Undergraduate Teaching and Scholarly Achievement. Finally, he co-authored a popular ichthyology textbook, with Peter Moyle, and he published more than 160 peer-reviewed publications on the physiological ecology of fishes. He is currently Professor Emeritus of Fish Biology at the University of California Davis.

Associate Editor

Jeffrey G. Richards, Department of Zoology, University of British Columbia, Vancouver, BC, Canada

Jeffrey Richards is an associate professor in the Department of Zoology at the University of British Columbia, Canada. He started his academic career in the Department of Biology at Wilfrid Laurier University obtaining a BSc in 1995. He then went on to do an MSc at the University of Waterloo under the guidance of the late Prof. Richard Playle. With Prof. Playle, he studied environmental physiology and toxicology in fish. Following his MSc, he entered the laboratory of Prof. Chris Wood at McMaster University and focused his research on energy metabolism in swimming fish. He completed his PhD in 2002 and took up a postdoctoral fellowship at the University of British Columbia with Prof. Patricia Schulte. After a 2-year postdoctoral work, he started at the University of British Columbia as an assistant professor in 2004. His lab studies the relationship between plasticity and adaptive variation in the mechanisms that initiate, maintain, and coordinate metabolic energy balance in animals during exposure to environmental stress. He is particularly interested in the adaptations to low oxygen (hypoxia) in fish and other lower vertebrates. He prefers, whenever possible, to study animals in their natural habitat; thus, he travels extensively to unique and challenging environments, including the Amazon and the Tibetan plateau.

Associate Editor

E. Don Stevens, Department of Biomedical Sciences, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, PE, Canada

Don Stevens did an MSc with the late Edgar Black on the effects of severe exercise on metabolites in trout in the Physiology Department at UBC after an undergraduate degree in mathematics and zoology at the University of Victoria. He then moved across the street to do a PhD on effects of moderate exercise on respiration and circulation in trout with Dave Randall, who just had been hired in the Zoology Department at UBC (summarized in a JEB classics article, *Journal of Experimental Biology* 211: 1521). His first position was at the Zoology Department at the University of Hawaii where he discovered that there was more to the fish world than trout, and that there was no such thing as the physiology of fish, rather there was a physiology of fishes. In Hawaii, he worked mostly on the biology of tropical tunas with a focus on their warm-bodiedness, in particular how they achieved higher than ambient body temperatures and the adaptive advantage of them. He then joined the Zoology Department at the University of Guelph working in the general area of comparative physiology with a focus on exercise effects until he retired in 2004. He now has an adjunct position at the Atlantic Veterinary College and continues to do research in fish physiology.

HOW TO USE THE ENCYCLOPEDIA

STRUCTURE OF THE ENCYCLOPEDIA

The material in the Encyclopedia is arranged as a series of articles within a certain topic.

There are three features to help you easily find the topic you're interested in: a contents list, cross-references to other relevant articles in the Encyclopedia, and a full subject index.

1. CONTENTS LIST

The contents list, which appears at the front of all volume, lists the entries in the order that they appear in the Encyclopedia. It includes both the volume number and the page number of each entry.

2. CROSS-REFERENCES

All of the entries in the Encyclopedia have been extensively cross-referenced. The cross-references which appear at the end of an entry, serve three different functions:

i. To indicate if a topic is discussed in greater detail elsewhere
ii. To draw the readers attention to parallel discussions in other entries
iii. To indicate material that broadens the discussion

Example

The following list of cross-references may appear in text and at the end of the entry
The Muscles | Cartilaginous Fishes Cranial Muscles

See also: **Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics. **Chondrichthyes**: Physiology of Sharks, Skates, and Rays. **Food Acquisition and Digestion**: Energetics of Prey Capture: From Foraging Theory to Functional Morphology. **The Muscles**: Bony Fish Cranial Muscles. **The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis. **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics.

3. INDEX

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4. CONTRIBUTORS

At the start of each volume there is list of the authors who contributed to the Encyclopedia.

This page intentionally left blank

CONTENTS

VOLUME 1 – THE SENSES, SUPPORTING TISSUES, REPRODUCTION, AND BEHAVIOR

SENSING THE ENVIRONMENT

BRAIN AND NERVOUS SYSTEM

Functional Morphology of the Nervous System: An Introduction *AB Butler* 1

Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern *B Fritzsch and DC de Caprona* 6

Functional Morphology of the Brains of Agnathans *MA Pombal and M Megías* 16

Functional Morphology of the Brains of Cartilaginous Fishes *I Rodríguez-Moldes* 26

Functional Morphology of the Brains of Ray-Finned Fishes *AB Butler* 37

Functional Morphology of the Brains of Sarcopterygian Fishes: Lungfishes and *Latimeria* *A González and RG Northcutt* 46

Motor Control Systems of Fish *S Grillner* 56

Physiology of the Mauthner Cell: Discovery and Properties *AE Pereda and DS Faber* 66

Physiology of the Mauthner Cell: Function *DS Faber and AE Pereda* 73

Autonomic Nervous System of Fishes *S Nilsson* 80

Opioids and Opioid Receptors in Fishes *MJ Herrero-Turrión, FM Sánchez-Simón, and RE Rodríguez* 89

VISION

Vision in Fishes: An Introduction *H-J Wagner* 98

Physiological Optics in Fishes *RHH Kröger* 102

Photoreceptors and Visual Pigments *JK Bowmaker* 110

Adaptations of Photoreceptors and Visual Pigments *JK Bowmaker* 116

Inner Retina and Ganglion Cells *MW Levine* 123

Optic Tectum *D Northmore* 131

Behavioral Assessment of the Visual Capabilities of Fish *S Schuster, P Machnik, and W Schulze* 143

Color Vision and Color Communication in Reef Fish *J Marshall and K Cheney* 150

Extraretinal Photoreception *H-J Wagner* 159

Visual Adaptations to the Deep Sea *RH Douglas and JC Partridge* 166

see Communication Behavior: Visual Signals, Volume 1, p. 692
see Coloration and Chromatophores in Fishes, Volume 1, p. 489
see Bioluminescence in Fishes, Volume 1, p. 497

SMELL, TASTE, AND CHEMICAL SENSING

Chemoreception (Smell and Taste): An Introduction *TJ Hara* 183
Morphology of the Gustatory (Taste) System in Fishes *TJ Hara* 187
Morphology of the Olfactory (Smell) System in Fishes *TJ Hara* 194
Neurophysiology of Olfaction *TJ Hara* 208
Neurophysiology of Gustation *TJ Hara* 218
Chemosensory Behavior *TJ Hara* 227
see The Effects of Toxicants on Olfaction in Fishes, Volume 3, p. 2078
see Oxygen Sensing in Fish, Volume 2, p. 871

HEARING AND LATERAL LINE

Fish Bioacoustics: An Introduction *AN Popper and BM Casper* 236
Vestibular System Anatomy and Physiology *H Straka and R Baker* 244
Auditory System Morphology *AN Popper* 252
The Ear and Hearing in Sharks, Skates, and Rays *BM Casper* 262
Biomechanics of the Inner Ear in Fishes *MC Hastings* 270
Psychoacoustics: What Fish Hear *RR Fay* 276
Auditory/Lateral Line CNS: Anatomy *CA McCormick* 283
Physiology of the Ear and Brain: How Fish Hear *Z Lu* 292
Sound Source Localization and Directional Hearing in Fishes *DG Zeddies, RR Fay, and JA Sisneros* 298
Effects of Human-Generated Sound on Fish *AD Hawkins* 304
Acoustic Behavior *J Luczkovich, MW Sprague, and CS Krahforst* 311
Vocal Behavior of Fishes: Anatomy and Physiology *F Ladich and AH Bass* 321
Lateral Line Neuroethology *JC Montgomery and S Coombs* 329
Lateral Line Structure *J Webb* 336
see How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling, Volume 1, p. 684

DETECTION AND GENERATION OF ELECTRIC SIGNALS

Detection and Generation of Electric Signals in Fishes: An Introduction *BA Carlson* 347
Morphology of Electroreceptive Sensory Organs *JM Jørgensen* 350
Physiology of Ampullary Electrosensory Systems *MH Hofmann* 359
Physiology of Tuberous Electrosensory Systems *ES Fortune and MJ Chacron* 366
Active Electrolocation *G von der Emde and J Engelmann* 375
Electric Organs *AA Caputi* 387
Generation of Electric Signals *M Kawasaki* 398

Development of Electroreceptors and Electric Organs *F Kirschbaum and J-P Denizot* 409
see Shocking Comments: Electrocommunication in Teleost Fish, Volume 1, p. 699

MUSCLES, SKELETON, SKIN, AND MOVEMENT

Functional Anatomy of Bones, Muscle, and Skin: An Introduction *ED Stevens* 416

THE SKELETON

Cartilaginous Fish Skeletal Anatomy *KM Claeson and MN Dean* 419
Cartilaginous Fish Skeletal Tissues *MN Dean* 428
Bony Fish Skeleton *EJ Hilton* 434

THE MUSCLES

Cartilaginous Fishes Cranial Muscles *DR Huber, MC Soares, and MR de Carvalho* 449
Bony Fish Cranial Muscles *LA Ferry and L Hernandez* 463

THE SKIN

The Many Functions of Fish Integument *DG Elliott* 471
Functional Morphology of the Integumentary System in Fishes *DG Elliott* 476
Coloration and Chromatophores in Fishes *D Burton* 489
Bioluminescence in Fishes *AF Mensinger* 497
Hagfish Slime *DS Fudge, JE Herr, and TM Winegard* 504

BUOYANCY, LOCOMOTION, AND MOVEMENT IN FISHES

Buoyancy, Locomotion, and Movement in Fishes: An Introduction *ED Stevens* 516
Buoyancy in Fishes *RMcN Alexander* 520
Swimbladder Function and Buoyancy Control in Fishes *B Pelster* 526
Experimental Hydrodynamics *ED Tytell* 535
Undulatory Swimming *DJ Ellerby* 547
Functional Properties of Skeletal Muscle: Work Loops *DA Syme* 555
Paired Fin Swimming *EM Standen* 564
Maneuverability *PW Webb* 575
Stability and Turbulence *PW Webb and AJ Cotel* 581
Fast Start *P Domenici* 587
Feeding Mechanics *TE Higham* 597
Biomimetics: Robotics Based on Fish Swimming *JH Long Jr.* 603
see Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems, Volume 2, p. 935
see Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder, Volume 2, p. 929
see The Retia, Volume 2, p. 1119
see Deep-Sea Fishes, Volume 3, p. 1953

see Applied Aspects of Fish Swimming Performance, Volume 3, p. 1652
see Integrated Cardiovascular Responses of Fish to Swimming, Volume 2, p. 1215
see The Effect of Exercise on Respiration, Volume 2, p. 812

REPRODUCTION

The Diversity of Fish Reproduction: An Introduction *KA Sloman* 613

THE REPRODUCTIVE ORGANS AND PROCESSES

Anatomy and Histology of Fish Testis *RW Schulz and RH Nóbrega* 616
Regulation of Spermatogenesis *RW Schulz and RH Nóbrega* 627
Vitellogenesis in Fishes *BJ Reading and CV Sullivan* 635
see Parental Care in Fishes, Volume 1, p. 670
see Endocrine Regulation of Fish Reproduction, Volume 2, p. 1500
see Socially Controlled Sex Change in Fishes, Volume 1, p. 662
see Nutritional Provision During Parental Care, Volume 1, p. 678
see Sexual Behavior in Fish, Volume 1, p. 656

BEHAVIOR AND PHYSIOLOGY

Linking Fish Behavior and Physiology: An Introduction *KA Sloman* 647

SOCIAL AND REPRODUCTIVE BEHAVIORS

Dominance Behaviors *KA Sloman* 649
Sexual Behavior in Fish *I Katsiadaki and M Sebire* 656
Socially Controlled Sex Change in Fishes *J Godwin* 662
Parental Care in Fishes *S Balshine and KA Sloman* 670
Nutritional Provision During Parental Care *KA Sloman and J Buckley* 678
see Hormonal Pheromones, Volume 2, p. 1553
see The Diversity of Fish Reproduction: An Introduction, Volume 1, p. 613

SENSORY SYSTEMS, PERCEPTION, AND LEARNING

How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling *IM Kaatz* 684
Communication Behavior: Visual Signals *GG Rosenthal and NJ Marshall* 692
Shocking Comments: Electrocommunication in Teleost Fish *K Pappas and K Dunlap* 699
Fish Learning and Memory *VA Braithwaite* 707
Nociception or Pain in Fish *LU Sneddon* 713
Spatial Orientation: How do Fish Find their Way Around? *T Burt de Perera* 720
Magnetic Sense in Fishes *MM Walker* 726
Circadian Rhythms in Fish *SG Reebs* 736
see Bioluminescence in Fishes, Volume 1, p. 497

see Acoustic Behavior, Volume 1, p. 311
see Behavioral Assessment of the Visual Capabilities of Fish, Volume 1, p. 143
see Chemosensory Behavior, Volume 1, p. 227

BEHAVIORAL RESPONSES TO THE ENVIRONMENT

A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food *MV Abrahams* 744
Effects of Compensatory Growth on Fish Behavior *D Álvarez* 752
Temperature Preference: Behavioral Responses to Temperature in Fishes *LI Crawshaw and JE Podrabsky* 758
Behavioral Responses to Hypoxia *KA Sloman* 765
Sleep in Fish *IV Zhdanova* 772
Manipulation of Fish Phenotype by Parasites *O Seppälä* 777
Anthropogenic Influences on Fish Behavior *KA Sloman* 783
see The Biology of Fish Migration, Volume 3, p. 1921

VOLUME 2 – GAS EXCHANGE, INTERNAL HOMEOSTATIS, AND FOOD UPTAKE

GAS EXCHANGE

Respiration: An Introduction *JJ Cech Jr. and CJ Brauner* 791

VENTILATION AND ANIMAL RESPIRATION

Plasticity in Gill Morphology *GE Nilsson* 796
Gill Respiratory Morphometrics *NC Wegner* 803
The Effect of Exercise on Respiration *H Thorarensen* 812
Efficiency of Gas Exchange Organs *H Malte* 820
Respiratory Gas Exchange During Development: Models and Mechanisms *PJ Rombough* 829
Respiratory Gas Exchange During Development: Respiratory Transitions *PJ Rombough* 838
Techniques in Whole Animal Respiratory Physiology *JJ Cech Jr. and CJ Brauner* 846
see Branchial Anatomy, Volume 2, p. 1095

CONTROL OF RESPIRATION

Generation of the Respiratory Rhythm in Fish *EW Taylor* 854
The Ventilatory Response to CO_2/H^+ *WK Milsom* 865
Oxygen Sensing in Fish *MG Jonz* 871

TRANSPORT AND EXCHANGE OF RESPIRATORY GASES IN THE BLOOD

Red Blood Cell Function *M Nikinmaa* 879
Hemoglobin *M Nikinmaa* 887
O_2 Uptake and Transport: The Optimal P_{50} *T Wang and H Malte* 893
Carbonic Anhydrase in Gas Transport and Exchange *KM Gilmour* 899

Carbon Dioxide Transport and Excretion *D Randall* 909
Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange *CJ Brauner and JL Rummer* 916
Evolution of the Bohr Effect *M Berenbrink* 921
Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder *W Waser* 929
Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems *M Berenbrink* 935
Hemoglobin Differentiation in Fishes *C Verde, D Giordano, R Russo, and G di Prisco* 944
see Cellular Composition of the Blood, Volume 2, p. 984

TISSUE RESPIRATION

Cellular Respiration *GB McClelland* 951
Mitochondrial Respiration *CD Moyes and CMR Le Moine* 959
Specializations in Mitochondrial Respiration of Fish *CD Moyes and CMR Le Moine* 966

CIRCULATION

The Circulatory System: An Introduction *AP Farrell* 973
Circulatory System Design: Roles and Principles *KR Olson* 977

BLOOD

Cellular Composition of the Blood *AP Farrell* 984
Erythropoiesis in Fishes *C Verde, D Giordano, R Russo, and G di Prisco* 992
see Hemoglobin Differentiation in Fishes, Volume 2, p. 944
see Red Blood Cell Function, Volume 2, p. 879
see Hemoglobin, Volume 2, p. 887

DESIGN AND PHYSIOLOGY OF THE HEART

Cardiac Anatomy in Fishes *AP Farrell and S Pieperhoff* 998
Cellular Ultrastructure of Cardiac Cells in Fishes *GLJ Galli* 1006
The Outflow Tract from the Heart *DR Jones and MH Braun* 1015
Physiology of Cardiac Pumping *AP Farrell* 1030
Action Potential of the Fish Heart *M Vornanen* 1038
Cardiac Excitation–Contraction Coupling: Routes of Cellular Calcium Flux *HA Shiels* 1045
Cardiac Excitation–Contraction Coupling: Calcium and the Contractile Element *TE Gillis* 1054
Cardiac Cellular Length–Tension Relationship *HA Shiels* 1060

INDEX 2091

PREFACE

The *Encyclopedia of Fish Physiology: From Genome to Environment* is the first of its kind. It follows in the strong tradition built by the book series *Fish Physiology* that was pioneered in the late 1960s by Bill Hoar and Dave Randall and is still ongoing; however, the Encyclopedia differs markedly from this book series in three important respects.

Foremost, the Encyclopedia targets a much broader audience, not just the research community. My hope is that the Encyclopedia will serve as a general educational tool for biologists, as well as being of general use as an information resource for those interested in fishes. After all, the Encyclopedia is replete with magnificent examples of how fishes are marvelously adapted to almost every water body on the Earth, no matter how deep, how hot, how cold, how salty, or, in some cases, how dry!

Second, the articles span well beyond just the physiology of fishes. The intent here is to connect physiological functions, environmental factors, behavior, and the genome. This is the case even though the main focus here is on physiology.

Third, and as a result, the breadth of topics covered by the Encyclopedia far exceeds that of any focused volume of the *Fish Physiology* book series. Thus, the Encyclopedia is ambitious in both its content and its target audience.

The Encyclopedia contains a very impressive array of entries, each in the form of a discrete, self-standing article that is typically 3000–4000 words in length, not counting the ancillary material contained in figures, glossary, further reading, etc. In total, there are 252 articles written by over 200 international experts from over 20 countries.

The articles are arranged thematically. The larger thematic sections have an introductory article, written by a section editor, who explains contributions in that theme and places them in a broader and often historical context. Tributes are deservedly given to those who made key scientific advances.

The electronic format of the Encyclopedia was deliberate and a crucial requirement before this project even started. I have to thank Andy Richford for garnering Elsevier's support of this idea, as well as initiating this project when he was an acquisition editor. The electronic format, through 'hot keys', provides an easy and almost instant access to the glossary and related articles. Each article is generously linked to many others in this manner, offering the reader easy digressions or more detailed information and explanations. The 'Further Reading' section associated with each article provides additional resources.

This ambitious opus could not have been possible without the dedication and commitment of a great number of individuals. I had an idea that I have steered to completion, but others did most of the hard work. I am especially indebted to my associate editors, Don Stevens, Joe Cech, and Jeffrey Richards. They embraced my dream early on and stayed with me until completion. Without their wisdom, breadth of knowledge, and hard work, the Encyclopedia could not have come to fruition. I think we worked well together, and, on my part, it was a distinct pleasure to have such enthusiastic support.

I am equally indebted to the section editors: Colin Brauner, Ann Butler, Bruce Carlson, Brandon M Casper, Greg Goss, Jeff Graham, Toshiaki Hara, Sue Holmgren, Norman Maclean, Jay Nelson, Ken Olson, Catharina Olsson, Arthur Popper, Trish Schulte, Bob Shadwick, Kath Sloman, Adam Summers, Matt Vijayan, and Hans-Joachim Wagner. They shaped their section and carried the core of the editorial responsibilities for the contributed articles during the many rounds of review and revisions.

Finally, and importantly, there are over 200 authors and their collaborators, who contributed the articles. My hope is that your rewards go well beyond the recompense, which is a pittance for the time that I know you devoted to generating such marvelous articles. You are thanked for your dedication and trust in the project, and are congratulated for your respective skills and knowledge.

There is another side to the production of this Encyclopedia, and that is the Elsevier team, with whom the editors and authors interacted. This team was headed by Kristi Gomez, the acquisitions editor in San Diego. Milo Perkins, the

development editor in the Oxford office, was our go-to-man after Esmond Collins had set the ball rolling. Milo endured the rough and the smooth, and his rapid responses, as well as his flexible deadlines, were greatly appreciated. Kate Mittell worked quietly and efficiently in the background supporting Milo and was responsible for keeping me on track with the enormous glossary of terms. Nicky Carter, our project manager, superbly rounded out the team. We relied on her for the professional appearance and content of the final copy.

As Editor-in-Chief, I am ultimately responsible for any errors contained herein. If you find any, please let me know so that they can be corrected; likewise, if you feel there are important omissions, please let me know of these. They might be incorporated in future updates.

Bringing this Encyclopedia to its conclusion means one thing for me personally: Miriam, Dustin, Naomi, Nicole and Natalie will all be seeing a lot more of me over the next while! Miriam, your patience throughout was astounding, although it was pushed to the limit at times.

Glossary

Bohr effect Effect of the proton concentration (pH) on the oxygen affinity of hemoglobin.

Carbonic anhydrase A zinc metalloenzyme that reversibly catalyzes the reaction of CO_2 and H_2O to form H^+ and HCO_3^-.

Diffusion Net movement of a solute from an area of higher concentration to an area of lower concentration.

Equilibrium Pertaining to the situation when all forces acting are balanced by others resulting in a stable unchanging system.

Haldane effect Proton binding to hemoglobin (as a function of oxygenation).

Hypoxia Low partial pressures of oxygen in external or internal environments.

Interlamellar cell mass (ILCM) A mass made up of undifferentiated cells and ionocytes, and possibly other cell types, filling up a variable part of the space between the lamellae of fish gills.

Lamellae Also known as secondary lamellae, these are attached in rows to the gill filaments. They are the primary sites for gas exchange in fish gills. Each lamella is made up of two epithelial layers separated by pillar cells. Oxygen is taken up by erythrocytes flowing inside the lamellae from water flowing between the lamellae.

Mitochondria Organelles that produce most of the aerobic energy required by the cell.

P_{50} The oxygen partial pressure at half-maximal oxygen saturation of blood or hemoglobin.

Partial pressure The atmospheric pressure exerted by O_2 alone proportional to the total concentration of this gas. It is typically measured in either mmHg (torr) or kPa.

Respiratory cascade A model of gas exchange in which gas is viewed as flowing through a series of resistances from the environment to the tissues or vice versa. The model is based on the analogy of water flowing down a series of cascades with the difference being that gas flow is driven by differences in partial pressure rather than gravity.

Rete Structure consisting of blood vessels arranged to facilitate the exchange of heat or oxygen.

Root effect A property of fish hemoglobin in which protons decrease the maximal oxygen saturation of hemoglobin. For practical purposes, it is defined as a reduction of oxygen saturation at atmospheric oxygen tension.

Ventilation The movement of the respiratory medium (air or water) over the surface of the gas exchanger.

Introduction

Respiration and gas exchange is an essential process to maintain an aerobic existence in all vertebrates, including fishes. The uptake of oxygen (O_2), along with metabolism of organic substrates such as glucose and lipids, is needed to power the biochemical machinery (e.g., in the mitochondria) in cells for body maintenance, as well as for other aerobic functions such as growth, movement, reproduction, and disease resistance (**see also Energetic Models**: Bioenergetics in Aquaculture Settings and Bioenergetics in Ecosystems), all of which are important determinants of fitness.

The complex process of respiration in fish is discussed in detail in this section. It starts with the environment where O_2 and CO_2 move into and out of the animal, respectively, by simple diffusion. Gases diffuse across a gas-exchange organ which represents the interface between the organism and the environment and may consist of skin, gills, and in some cases an air-breathing organ. Ventilation of the respective media (water and in some cases air if an air-breathing organ is present) in conjunction with blood perfusion across the gas-exchange organ, both of which can be altered proportionally depending upon the animal's metabolic state, ensures sufficient gas exchange to meet the demands of the animal.

The circulatory system provides the conduit through which the blood is ultimately delivered to the tissues; hemoglobin (Hb), maintained within the red blood cell, plays a vital role in the transport of both O_2 and CO_2 in all fishes, except icefishes, which represent the only vertebrate that lacks Hb. Hemoglobin is a remarkable molecule and is one of the best-understood proteins in terms of how changes in the environment of the red blood cell alter the tertiary and quaternary structure of Hb to influence the nature in which Hb binds and releases ligands such as O_2, CO_2, and H^+'s in particular. These changes optimize conditions for gas exchange to tissues in general, as well as specifically to the eye and swimbladder allowing for acute vision and buoyancy control respectively in many teleosts.

Finally, blood reaches the tissues where waste products are removed and substrates supplied to cells and mitochondria providing the basics for cellular and mitochondrial respiration, and thus life. The following describes these various steps in respiration in more detail, providing background information and introducing each article that appears within the section.

The Environment: Water and Air as Respiratory Media

Characteristics of the environment can have a profound effect on respiration. Respiratory gas exchange in aquatic environments presents different problems when compared with respiration in air. Water is a dense, viscous medium, which also has a high heat capacity and 20–30-fold lower oxygen concentration (due to low gas solubility) relative to air. Increases in temperature or salinity further decrease oxygen solubility in water, and therefore oxygen content for a given gas pressure as indicated in **Figure 1**.

The P_{O_2} and P_{CO_2} of water can vary dramatically compared to those of atmospheric air. This is because the gases contained in air do not necessarily exchange readily with water. The P_{O_2} of aquatic environments can be zero (anoxia), low (hypoxic), normoxic, or high (hyperoxic), depending on the photosynthetic and respiratory rates of the biotic community and on water circulation characteristics. Some shallow, freshwater habitats may vary between 20 and 40 mmHg P_{O_2} just before dawn to 200–400 mmHg at mid-day. Thus, water can be less saturated and more saturated with oxygen, even on a diel basis. Many fishes, especially those that spend at least part of their lives in shallow habitats, have evolved structural and functional abilities to deal with variable water P_{O_2} values.

Fish in boreal, subpolar, or polar lakes may experience a seasonal challenge of oxygen availability – a

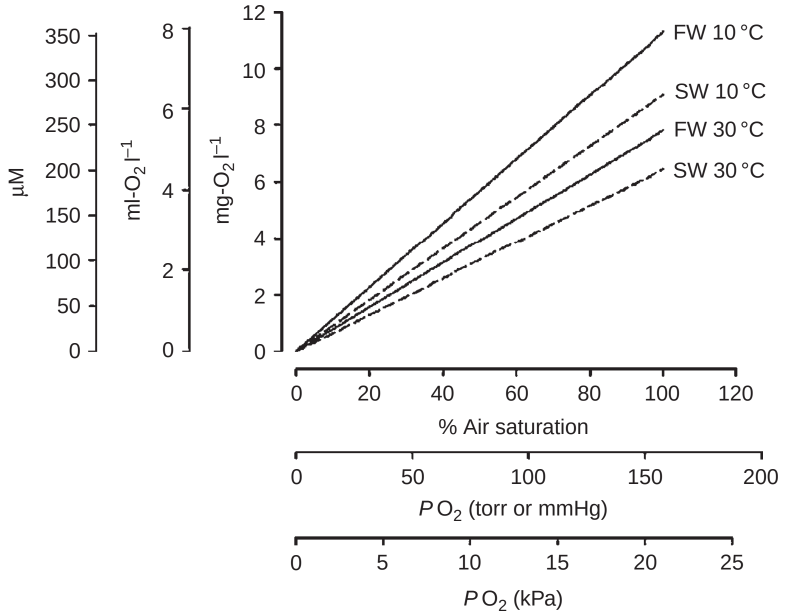

Figure 1 The relationship between partial pressure of oxygen (*x*-axis) and total oxygen content (*y*-axis) at 10 and 30 °C in either freshwater (FW) or seawater (SW). The three legends for each of the axes represent the different units that are used to describe both partial pressure and content in water. Reproduced from Diaz RJ and Breitburg DL (2009) The hypoxic environment. In: Richards JG, Farrell AP, and Brauner CJ (eds.) *Fish Physiology, Volume 27 Hypoxia*, pp. 1–23. Academic Press, with permission from Elsevier.

gradually deepening hypoxia (lowered P_{O_2}, s) during the winter as ice cover seals off gas exchange with the atmosphere and snow cover, along with shortened photoperiods, attenuate incoming light decreasing photosynthetic production of O_2. Extreme winters may prolong these conditions leading to a total consumption of the remaining dissolved O_2 (anoxia) by the lake's biota, leading to a winter fish kill (**see also Hypoxia**: The Expanding Hypoxic Environment).

Fishes living in high-altitude environments must also cope with low-P_{O_2} water. In this case, it is due to the lower total barometric pressure (and the correspondingly lowered partial pressures of the atmospheric gases). Finally, certain types of pollution, including those that introduce excessive nutrients into waterways (eutrophication), typically lead to wider, diel dissolved-O_2 ranges, often including quite hypoxic P_{O_2},s. Thus, fish living and respiring aquatic media are subjected to large and routine changes in O_2 availability relative to air-breathing animals and many are adapted to these potentially extreme conditions.

Ventilation and Gas-Exchange Organs

The physical and chemical characteristics of aquatic environments, specifically low oxygen solubility of water, probably contributed to the evolutionary development of gill structure and function, and to the many mechanisms some fishes use to extract oxygen directly from the air. Article **Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs discusses in greater detail the implications of water and air as respiratory media on gas exchange and how various gas-exchange organs differ in terms of efficiency of, and capacity for, gas exchange. The control of gill ventilation is crucial for survival to ensure adequate water flow over the gills. While control of ventilation and ventilatory responses to hypoxia are discussed in other sections, article **Control of Respiration**: The Ventilatory Response to CO_2/H^+ discusses the effect of CO_2 on ventilation and the role of CO_2 in controlling ventilation in fish.

The gill represents the predominant surface for gas exchange, which occurs predominantly across the gill lamellae in adult fish, and a great deal of variability in gill design has evolved among fishes. However, there is also a great deal of plasticity in gill morphology where large changes are observed in some fishes during exposure to hypoxia in particular. In hypoxia, there can be expansion of the total lamellar surface area in some fish species, such as carp, by as much as sevenfold due to the disappearance of an interlamellar cell mass that exists under normoxic conditions. These relatively large and often rapid changes in gill morphology may be more common among fish than previously thought. This exciting, relatively novel finding is discussed in **Ventilation and Animal Respiration**: Plasticity in Gill Morphology.

While the gills are usually the predominant site for gas exchange in adult fish, this is not the case early in development when the total body surface area:volume ratio in larval and juvenile fish is high and gill secondary lamellae in particular have yet to be fully developed. At this point, all gas exchange is across the skin. The fundamental principles associated with gas exchange in aquatic media and their implications for larval fishes are discussed in **Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Models and Mechanisms. This article lays the foundations for a discussion of when the gills become important for gas exchange during development which is discussed in **Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Respiratory Transitions. Interestingly, the gills may take on a more significant role for ionoregulation than for gas exchange early in development, based upon the time that 50% of whole body unidirectional Na^+ uptake and O_2 uptake transitions to the gills. This ontogeny has interesting implications for the evolution of gill function.

Gas Transport and Exchange

Once O_2 has diffused across the gill lamellae, about 98% is reversibly bound to Hb (oxyhemoglobin) contained within the red blood cell. The relatively high affinity of Hb for oxygen helps to maintain the partial pressure gradient for diffusion, maintaining high rates of oxygen uptake at the gills. The importance of Hb-O_2 affinity (usually characterized by the partial pressure at which 50% of the Hb molecules are oxygenated; P_{50}), and the shape of the oxygen equilibrium curve to O_2 uptake and transport are discussed in **Transport and Exchange of Respiratory Gases in the Blood**: O_2 Uptake and Transport: The Optimal P50. Once within the red blood cell, O_2 is bound to Hb which consists of two α and two β globin chains. The structure of Hb, models that describe Hb-O_2 binding, and factors that influence O_2 binding in different fish groups are discussed in **Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin.

At the gills, any physically dissolved CO_2 diffuses down its partial pressure gradient to be excreted across the gill lamellae into the water. About 95% of the CO_2 transported in the blood exists as HCO_3^-, mostly in the plasma. The dissolved CO_2, which moves easily across gill epithelia, diffuses across the lamellar epithelium into the aquatic environment, which usually has a high absorbing capacity (i.e., acts as an infinite sink) for CO_2. The corresponding decrease in plasma CO_2 creates conditions for HCO_3^- dehydration ($H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow CO_2 + H_2O$), which occurs relatively slowly in the plasma but very rapidly in the red blood cell due to high levels of the catalyst carbonic anhydrase. Carbonic anhydrase accelerates the reaction by up to 25 000 times and fish have many different isoforms, which are discussed in **Transport and Exchange of Respiratory Gases in the Blood**: Carbonic Anhydrase in Gas Transport and Exchange. With continued HCO_3^- dehydration, plasma HCO_3^- is transported into the red blood cell by Cl^-/HCO_3^- exchange and H^+'s are supplied within the red blood cell by Hb, which can act as a buffer, or release H^+'s upon Hb oxygenation known as the Haldane effect. This process continues until the blood leaves the gills which is discussed in greater detail in **Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion. The microenvironment of the red blood cell is regulated independently of that in the blood plasma, which is crucial for both O_2 and CO_2 transport. The processes responsible for the regulation of red blood cell pH and volume are discussed in **Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function.

At the tissues, the processes discussed above occur in reverse. CO_2 produced by the tissues diffuses into the blood, where it is hydrated to HCO_3^- and H^+. The H^+'s may be bound by Hb reducing Hb-O_2 affinity by the Bohr effect and reducing Hb-O_2 affinity facilitating O_2 delivery to the tissues. The Bohr effect is thought to have evolved 3 times independently, and in teleosts was accompanied by a reduction in Hb buffer value so that small blood-acid loads exert relatively large effects relative to those in other vertebrates. This is discussed in greater detail in **Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect. The relatively large Bohr effect and low buffer value in teleosts have large implications for the interaction between O_2 and CO_2 exchange, where CO_2 production in the tissues facilitates O_2 delivery via the Bohr effect, and O_2 delivery promotes CO_2 removal via the Haldane effect, the reverse processes occurring at the gills. The implications of this are discussed in **Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange, and taking into account large disequilibrium states that may exist in fish, the benefit to oxygen delivery may be much larger than previously thought.

While the Bohr effect refers to a decrease in Hb-O_2 affinity with a reduction in pH, the Root effect found in the blood of most teleosts refers to a decrease in the O_2-carrying capacity of Hb at low pH so that even at atmospheric O_2 tensions and higher, Hb cannot be fully oxygenated. The Root effect, together with a vascular countercurrent system called a rete and the generation of a localized acidosis, dramatically increases P_{O_2} and facilitates O_2 delivery to the poorly vascularized retinas and to the swimbladder in most teleosts. The molecular basis and evolution of the Root effect are discussed in **Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems, and the processes through which the Root effect facilitates O_2 delivery to these structures is discussed in **Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder.

Tissue Respiration

As blood enters the tissues, O_2 diffuses down its partial pressure gradient into every cell in the body. Adenosine triphosphate (ATP) production by oxidative phosphorylation requires adequate delivery of both oxygen and metabolic fuels to cells and is regulated to meet metabolic demand. The biochemical pathways and fuels used in cellular respiration, along with the influence of the environment and limits to cellular respiration are discussed in **Tissue Respiration**: Cellular Respiration. The ultimate destination for O_2 within the body is the mitochondrion, an organelle found in most cells of all eukaryotic organisms. The mitochondrion is the site of ATP production and is responsible for most of the O_2 consumed by fish. Many of the characteristics of mitochondria are similar among eukaryotes as they arose through endosymbiosis prior to the divergence of plants, fungi, and animals. The basic features of mitochondria are discussed in **Tissue Respiration**: Mitochondrial Respiration, which provides the background for a discussion of some of the unique specializations that are seen in fish which is presented in **Tissue Respiration**: Specializations in Mitochondrial Respiration of Fish.

Whole Animal and Techniques in Respiratory Physiology

The whole is greater than the sum of its parts, and this certainly applies to respiration and the respiratory system in fishes. At each level of biological organization discussed above, respiration in fish is complex. However, adding to this complexity is that all these processes and reactions must be integrated within the whole animal, the level at which natural selection operates. Exercise increases the rate at which all these steps in the respiratory system must operate and is often used as a tool to shed light on which if any steps in the respiratory cascade from environment to tissues may be rate limiting. Changes in respiration during exercise are discussed in **Ventilation and Animal Respiration**: The Effect of Exercise on Respiration and some of the techniques used in the field are described in the section Techniques in Whole Animal Respiratory Physiology.

Glossary

Apoptosis The process of programmed cell death.

Edema An accumulation of fluid in the interstitial space. This results when filtration of fluid across the capillary wall exceeds the capacity of lymph drainage.

Hypoxia-inducible factor 1-alpha (HIF-1α) Integrated hypoxia response that activates genes whose protein products either increase O_2 transfer (i.e., erythropoiesis, Hb affinity increases, angiogenesis, etc.) or up regulate metabolic adaptation by regulating anaerobiosis and O_2 consumption rate. HIF-1α induction is an ancient adaptation that first appeared in eukaryotic cells and thus long preceded the origin of metazoans.

Hyperplasia Growth by increase in the number of cells of an organ or tissue.

Ionocytes (mitochondrion-rich cells) A function-specific type of epithelial cell, which expresses ion transporters or enzymes and is responsible for trans-epithelial transport functions of specific ions. In fish gills, ionocytes responsible for ion regulation are named mitochondrion-rich cells based on the characteristic of abundant mitochondria

Lamellae Also known as secondary lamellae, these are attached in rows to the gill filaments. They are the primary sites for gas exchange in fish gills. Each lamella is made up of two epithelial layers separated by pillar cells. Oxygen is taken up by erythrocytes flowing inside the lamellae from water flowing between the lamellae.

Na^+/K^+-ATPase (NKA, the sodium pump) This is a major ATP-consuming ion pump that, directly or indirectly, drives many ion-regulatory processes, including maintaining sodium and ion gradients across cell plasma membranes and being present at high levels in ionocytes.

Introduction

Oxygen uptake in fish gills occurs primarily over the surface of the lamellae (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy and **Gas Exchange**: Respiration: An Introduction), and in some species this area can be altered drastically by plastic morphological changes in the gill structure (gill remodeling). These dramatic changes in gill morphology occur in a rapid (days) and reversible manner. Gill remodeling was first unequivocally demonstrated in the crucian carp (*Carassius carassius*) (**see also Bony Fishes**: Crucian Carp) by J Sollid and co-workers in 2003, and subsequent studies, as well as examination of published data, indicate that this ability could be widespread among fishes.

The initial studies revealed that crucian carp gill filaments have a sausage-like appearance, without protruding lamellae, when the fish are kept in cold (≤20 °C) aerated water. However, when crucian carp are moved to hypoxic water ($[O_2]$ = 6–8% of air saturation) (**Figure 1**(**c**)) or if they are kept at a high temperature (≥25 °C) (**Figure 1**(**d**)), their gills transform into gills with protruding lamellae within a few days. The process is reversible: if the crucian carp are moved back to relatively cold normoxic water for a week, their gill filaments regain the sausage-like morphology. A rise in temperature will have two major consequences for the fish: it will increase the metabolic rate and therefore the need for oxygen, and it will reduce the concentration of oxygen in the water. Like hypoxia, a high temperature will call for an increased capacity to extract oxygen from the water, suggesting that it is the oxygen need, rather than the water oxygen level in itself, that is driving gill remodeling in crucian carp.

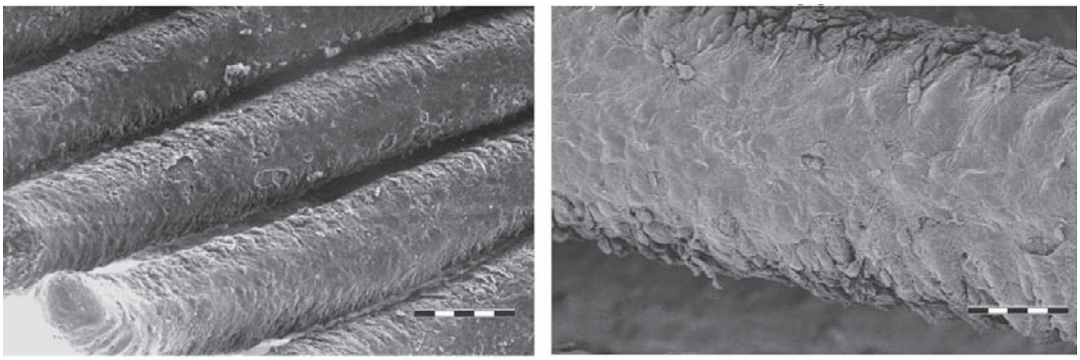
Mechanisms of Gill Remodeling

A series of studies by J Sollid and co-workers showed that the lamellae are always present in crucian carp gills, but during normoxia and low temperature, they are embedded in a cell mass denoted as an interlamellar cell mass (ILCM). In cold normoxic crucian carp, the ILCM completely fills up the space between the lamellae (**Figure 2**(**a**)). It has been shown that an increased rate of apoptosis (programmed cell death or cell suicide) combined with suppressed mitosis is responsible for regression of the ILCM during hypoxia (**Figure 2**(**b**)). The complete transformation of the gill morphology in crucian carp takes between 3 and 7 days at 8 °C.

In crucian carp and the closely related goldfish (*Carassius auratus*), the ILCM appears to be primarily made up of undifferentiated cells, but on top of the ILCM, facing the water, numerous osmoregulatory ionocytes are found. These ionocytes stay on the top of the ILCM, following the ILCM as it retracts in hypoxia (**Figures 3**(**a**) and (**b**)), and the ionocytes do not appear to be affected by the widespread apoptosis. Mitrovic and co-workers recently found that the gill epithelium appears to become less leaky when the

(a) Normoxic crucian carp gill filaments at 8 °C

(b) Normoxic crucian carp gill filament at 8 °C



(c) Hypoxic crucian carp gill filament at 8 °C

(d) Normoxic crucian carp gill filament at 25 °C

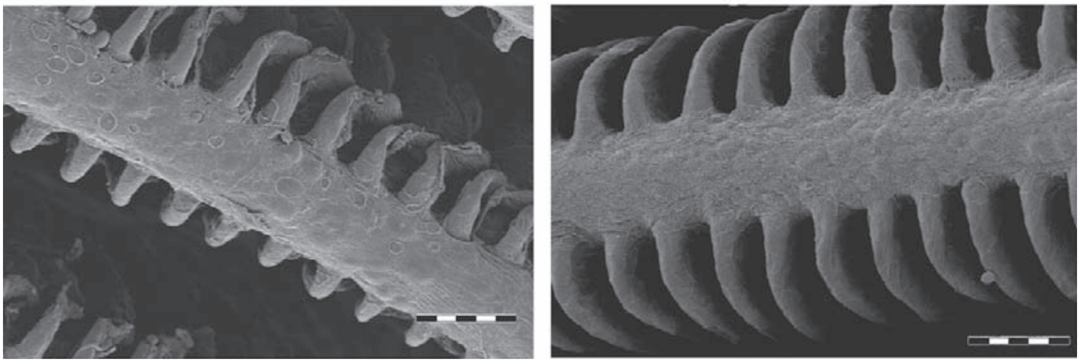


Figure 1 Scanning electron micrographs of gill filaments from crucian carp kept in normoxic water at 8 °C (a)–(b), in hypoxic water at 8 °C (c), or in normoxic water at 25 °C (d). Scale bars are 150 μm in (a) and 50 μm in (b)–(d). From Sollid J, De Angelis P, Gundersen K, and Nilsson GE (2003) Hypoxia induces adaptive and reversible gross-morphological changes in crucian carp gills. *Journal of Experimental Biology* 206: 3667–3673; and Sollid J, Weber RE, and Nilsson GE (2005) Temperature alters the respiratory surface area of crucian carp *Carassius carassius* and goldfish *Carassius auratus*. *Journal of Experimental Biology* 208: 1109–1116.

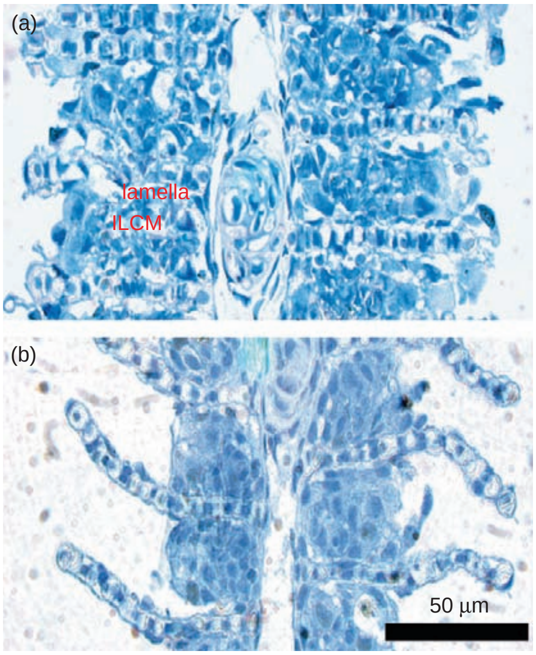

Figure 2 Light micrographs of gills from crucian carp kept in normoxic (a) or hypoxic (b) water at 8 °C. Note that the lamellae are present in both conditions but that a regression of the interlamellar cell mass (ILCM) during hypoxia makes the lamellae protrude, thereby greatly increasing the respiratory surface area. A filament arteriole (with blood clots) is seen running vertically in the center of each micrograph. From Sollid J, De Angelis P, Gundersen K, and Nilsson GE (2003) Hypoxia induces adaptive and reversible gross-morphological changes in crucian carp gills. *Journal of Experimental Biology* 206: 3667–3673.

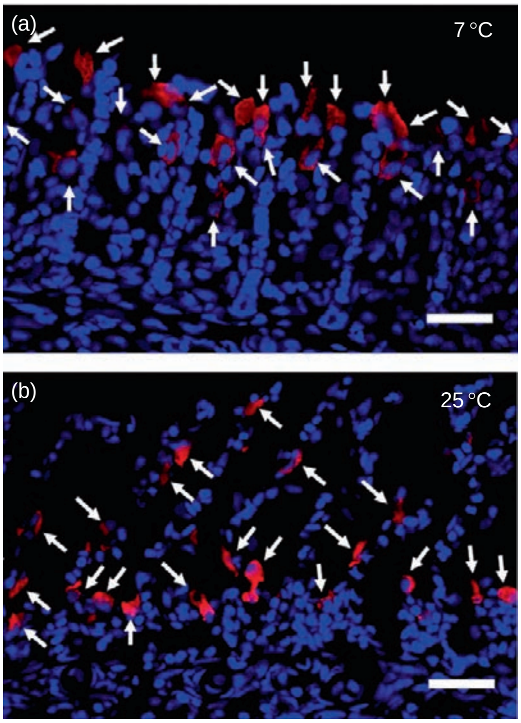

Figure 3 (a, b) Osmoregulatory ionocytes (red staining) stays on top of the ILCM (blue staining) and follows the ILCM as it retracts downward when goldfish are exposed to warm (25 °C) water. Some ionocytes are also attached to the lamellae. Like the ILCM, the lamellae are also stained blue but can be seen as vertical bands of cells attached to the filament at the bottom of the pictures. Ionocytes were stained with antibodies against Na^+/K^+ ATPase. Scale bars are 20 μm. From Mitrovic D and Perry SF (2009) The effects of thermally induced gill remodeling on ionocyte distribution and branchial chloride fluxes in goldfish (*Carassius auratus*). *Journal of Experimental Biology* 212: 843–852.

lamellae are protruding. This decreased permeability may reduce ion fluxes associated with the increased gill surface area.

The molecular signals and mechanisms involved in gill remodeling are not understood. Hypoxia-inducible factor 1-alpha (HIF-1α) is a transcription factor that is generally regarded as a master switch for many hypoxia-induced changes in animals. Increased messenger RNA (mRNA) and protein levels of HIF-1α have been seen in the gills of crucian carp exposed to hypoxia, indicating that HIF-1α could be involved in triggering the regression of the ILCM. However, it has also been found that gill HIF-1α increases with falling temperature during normoxic conditions, when the ILCM is maintained, arguing against a role for this transcription factor in gill remodeling. Moreover, the gill mRNA level of inducible nitric oxide synthase (iNOS), an enzyme induced by HIF-1α and known to trigger apoptosis, appears to be unaffected by hypoxia in crucian carp. Thus, also iNOS is unlikely to be responsible for inducing apoptosis in the ILCM.

Further, it is not clear if the ambient signal (low oxygen or high temperature) for gill remodeling is sensed by the ILCM cells themselves or transmitted to the cells from elsewhere in the body. As the ILCM cells are situated outside the lamellar epithelium, and appear to lack direct contact with nerves or blood vessels, it is unclear how a humoral or neural signal could reach the ILCM cells. Indeed, how these cells receive nutrients for their energy metabolism when they apparently lack a direct blood supply is also not clear.

Why Remodel the Gills

Constitutional species-to-species differences in the surface area of the lamellae have long been known to correlate with the need for oxygen uptake. Thus, the relationship between total lamellar area and body mass differs by more than an order of magnitude in fish species, with highly active fishes having the largest relative lamellar area and sedentary species having the smallest. In addition, the ability to tolerate low oxygen levels (hypoxia tolerance) has been found to correlate with a large lamellar area in fishes, presumably boosting the ability to extract oxygen from the water.

It has also been known for a long time that fishes can regulate their functional respiratory surface area by changing the fraction of the total lamellar area that is perfused with blood (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). This ability allows the fish to cope with rapid fluctuations in oxygen levels and temperature, as well as with matching the momentary needs for oxygen uptake with changes in the activity level. Moreover, ionic or acid–base challenges may cause fishes to adjust the cellular makeup of the gill surface, including the number of ion-pumping mitochondria-rich cells (ionocytes).

The facts that some fish species have a much smaller gill area than others, that fish regulate gill blood-flow patterns, and that some fishes remodel their gills in response to the oxygen demand indicate that there are drawbacks to having a large respiratory surface area (or all fishes would have a well-perfused large gill surface area all the time). Several problems have been suggested to arise from having a large gill surface area. These include:

1. *High costs for ion and acid-base regulation.* These arise from the osmoregulatory compromise, which emphasizes that an increase in the respiratory surface area results in increased water and ion fluxes that has to be counteracted by energetically expensive ion pumping (**see also Role of the Gills**: The Osmorespiratory Compromise).
2. *Increased exposure to toxic substances.* A large lamellar surface area may facilitate the entrance of many naturally occurring toxic substances, such as ammonia, algal toxins, and metal ions. Since the industrial revolution, anthropogenic pollutants can be added to the list of unwanted substances entering fish through the gills.
3. *Increased susceptibility to pathogens.* This also includes microorganisms that enter the fish via the gills and parasites that attach to the gills.
4. *Increased risk of bleeding.* As the whole cardiac output of fish has to pass through the gills, hemorrhage from gill injury could be life threatening, and arguably, large gills are likely to be more vulnerable to injury than small ones.
5. *Reduced capacity for feeding.* Larger gills take up more space in the oral cavity and, therefore, impede feeding.

The life history and physiology of the crucian carp should provide important clues that could help us understand the functions of the extreme gill remodeling shown by this species (**see also Bony Fishes**: Crucian Carp). Compared to most other fishes, the crucian carp is extremely hypoxia tolerant, and even tolerates long periods of anoxia in the winter. In Northern Europe, the crucian carp inhabits small ponds that become hypoxic and finally anoxic for several months every winter. Anoxic crucian carp (and goldfish) turn glycolytically produced lactate into ethanol, which is released to the water over the gills, thereby avoiding lactic acidosis. However, this is an energetically wasteful strategy since a highly energetic hydrocarbon is lost to the water, and it puts the crucian carp in danger of running out of fuel during long anoxic winters, even if it has enormous glycogen stores. It should therefore make the anaerobic period as short as possible, and this could be a major selection pressure for remodeling the gills. In the winter, the anoxic period is preceded by weeks or months of falling oxygen levels, and during this period an increased lamellar surface area allows the crucian carp to maintain aerobic adenosine triphosphate (ATP) production, thereby saving the glycogen stores. Respirometry has shown that crucian carp with protruding lamellae can continue to run aerobic metabolism at lower oxygen levels than crucian carp with the lamellae imbedded in an ILCM.

The extreme hypoxia tolerance of the crucian carp is also reflected in its hemoglobin, which has a record high O_2 affinity. The crucian carp hemoglobin is 50% saturated with O_2 at an oxygen partial pressure (P_{O_2}) of 0.8 mmHg (at 10 °C). The goldfish has almost an equally high blood oxygen affinity. This will not only aid in boosting its oxygen uptake at a very low water P_{O_2}, but also is probably a prerequisite for the extensive gill remodeling displayed by these fishes. Thus, during normoxia, the extremely high hemoglobin oxygen affinity should result in a very large difference in P_{O_2} between water and blood, allowing enough oxygen to diffuse into the blood even when the lamellae are fully covered with a cell mass.

During those seasons of the year when ambient oxygen levels are high (spring, summer, and autumn), covering up the lamellae should allow the crucian carp to reduce its osmoregulatory costs (and possibly its exposure to pathogens and toxins). Hence, more energy can be devoted to growth, reproduction, and rebuilding the glycogen stores.

Gill Remodeling in Other Species

It is now clear that crucian carp and goldfish are not the only ones that can remodel their gills. Among cyprinids, the Qinghai carp (*Gymnocypris przewalskii*) has been found to be able to remodel its gills, reversibly, in a similar fashion as the *Carassius* species, although to a less-extensive extent (**Figure 4**). Moreover, light micrographs published in a study investigating the characteristics of gill Na^+/K^+ ATPase activity in common carp (*Cyprinus carpio*) gills reveal a considerably larger cell mass between the lamellae of carp acclimated to 15 °C compared to carp acclimated to 29 °C (**Figure 5**). This suggests that gill remodeling in response to oxygen and temperature could be widespread among the carp fish family (Cyprinidae),

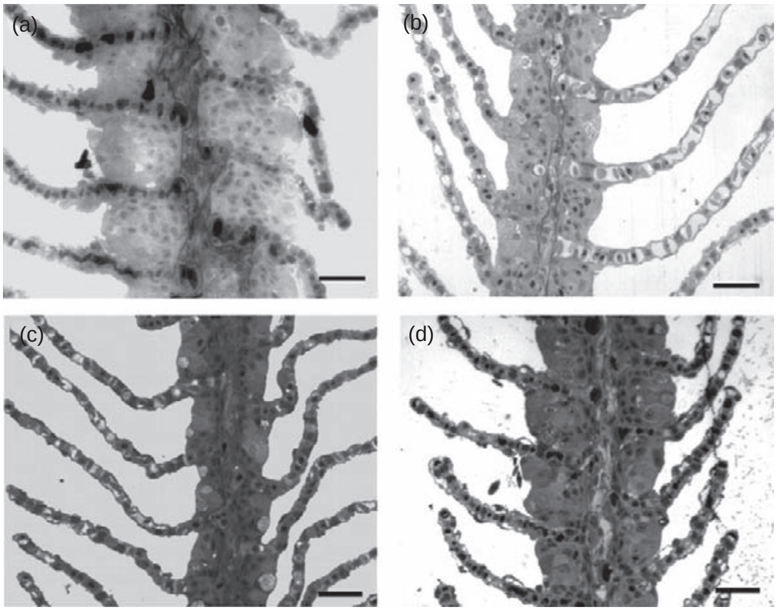

Figure 4 Light micrographs showing gill remodeling in the Qinghai carp (*Gymnocypris przewalskii*). Fish were exposed to normoxia (a), 12 h hypoxia (b), 24 h hypoxia (c), and 12 h normoxic recovery after 24 h hypoxia (d). During hypoxia, the water oxygen level was 0.3 mg l^{-1}. Water temperature was 11–15 °C. Scale bars are 20 μm. From Matey M, Richards JG, Wang Y, *et al.* (2008). The effect of hypoxia on gill morphology and ionoregulatory status in the Lake Qinghai scaleless carp, *Gymnocypris przewalskii*. *Journal of Experimental Biology* 211: 1063–1074.

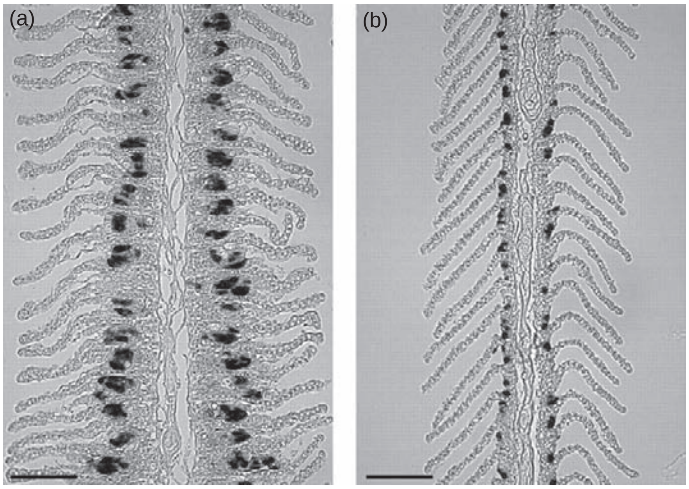

Figure 5 Light micrographs published in a study of Na^+/K^+ ATPase immunoreactivity (dark cells) in common carp (*Cyprinus carpio*) gills, revealing a considerably larger cell mass between the lamellae of carp acclimated to 15 °C (a) compared to carp acclimated to 29 °C (b). Scale bars are 100 μm. From Metz JR, van den Burg EH, Wendelaar Bonga SE, and Flik G (2003) Regulation of branchial Na+/K+-ATPase in common carp *Cyprinus carpio* L. acclimated to different temperatures. *Journal of Experimental Biology* 206: 2273–2280.

although the remodeling rarely may be as extensive as that seen in crucian carp and goldfish.

With regard to other teleost fishes, gill remodeling was recently found in the mangrove killifish (*Kryptolebias marmoratus*) (family Cyprinodontidae) in response to air exposure (**Figure 6**). Its ILCM increases in volume to fill up most of the interlamellar space within a week of air exposure. The process is reversible and may function to increase the ability of the killifish to take up oxygen from air by stabilizing the lamellae. This small fish can venture into the terrestrial environment for several days, taking up its oxygen from the air. Like the cyprinids, the killifish retains the lamellae while it changes the volume of the ILCM (although it is not clear if it is the cell volume or cell number that is changing). Despite their similar Latin family names, the Cyprinodontidae and the Cyprinidae

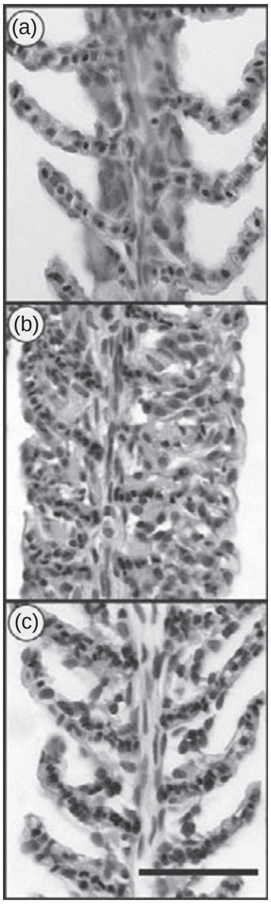

Figure 6 Light micrographs showing gill remodeling in the mangrove killifish (*Kryptolebias marmoratus*) (family Cyprinodontidae) in response to air exposure. The pictures show gills of fish kept in water (a), in air for a week (b), and in water for a week after air exposure (c) (all at 25 °C). Scale bar is 40 μm. From Ong KJ, Stevens ED, and Wright PA (2007) Gill morphology of the mangrove killifish (*Kryptolebias marmoratus*) is plastic and changes in response to terrestrial air exposure. *Journal of Experimental Biology* 210: 1109–1115.

are quite distantly related. They are both within the Teleostei, but cyprinids belong to the superorder Ostariophysi, while the cyprinodontids belong to the superorder Acanthopterygii, with at least 150 million years since they shared a common ancestor.

To some extent, also the European eel (*Anguilla anguilla*) appears to be capable of temperature-induced gill remodeling. It has been noted that the eel have thicker lamellae and filaments when acclimated to 5 °C compared to those acclimated to 25 °C. Micrographs have shown an ILCM that is larger and appears to contain more cells in the cold-acclimated fish (**Figure 7**). The change is relatively modest (the published micrographs suggest an ILCM covering about 20% of the lamellae at 5 °C, compared to 10% at 25 °C). Because eels belong to the teleost subdivision Elopomorpha, it widens further the range of teleosts that are capable of gill remodeling involving changes in the size of an ILCM.

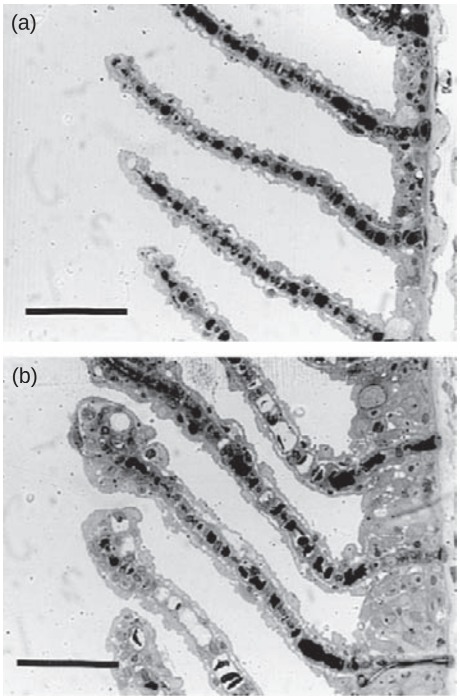

Figure 7 Light micrographs showing a considerably larger cell mass between the lamellae of cold (5 °C) acclimated eel (*Anguilla anguilla*) ((a)) compared to warm (25 °C) acclimated eel ((b)). Also note the striking thickening of the lamellae in cold fish. Scale bars are 5 μm. From Tuurala H, Egginton S, and Soivio A (1998) Cold exposure increases branchial water–blood barrier thickness in the eel. *Journal of Fish Biology* 53: 451–455.

Still, the most striking change in the gill structure of cold-acclimated eel is the considerable thickening of the lamellae (**Figure 7**). Such thickening of the lamellae has also been seen in cold-exposed juvenile largemouth bass (*Micropterus salmoides*) and rainbow trout (*Oncorhynchus mykiss*), species for which dynamic changes in the ILCM so far have not been reported. However, Mueller and co-workers have found that in the brook trout (*Salvelinus fontinalis*), 7–10 days of aluminum exposure at pH 5.2 causes undifferentiated cells and mucus-producing cells to fill up the interlamellar space in a reversible manner. If this is a protective and adaptive response or if a pathological response is not clear, then its histological appearance is strikingly similar to the ILCM of cyprinids. Indeed, there are several other examples of fish that show morphological changes in their gills when exposed to environmental pollutants such as metals and organic chemicals. These changes include hyperplasia (extensive tissue growth), edema (fluid accumulation in the tissue), and fusion of adjacent lamellae. Some of these changes are likely to be protective, functioning to reduce the exposure to chemicals or pathogens, while others may be primarily pathological.

Finally, it could be mentioned that an example of developmental gill remodeling, involving a loss of protruding lamellae, is provided by *Arapaima gigas*, the largest Amazonian fish. From being a water breather, having normal gills with protruding lamellae, early in life, it develops into an obligate air breather, using its swimbladder for oxygen uptake. This coincides with a striking alteration in gill morphology, as its gills no longer have any protruding lamellae. However, this change has never been seen to be reversed, and the lamellae are no longer present under a cell mass as in the reversible remodeling seen in cyprinids, cyprinodonts, and eels.

More examples of reversible gill remodeling among fishes are likely to be described, and it cannot be excluded that this is a widely distributed capacity among fishes in light of the benefits it provides for matching oxygen uptake capacity with oxygen needs in the face of changing environmental conditions. However, we may not find many such extreme examples of gill remodeling as those provided by the crucian carp and goldfish. A complete coverage of the lamellae can probably only occur in fishes possessing extremely high blood oxygen affinities, or in very small fish where the body surface provides a significant route for oxygen uptake. Moreover, the apoptotic and mitotic processes involved probably make gill remodeling best suited for adjusting the respiratory surface area to long-lasting changes in the environment (over weeks or seasons). It is probably more cost effective to adjust gill ventilation and blood flow patterns in response to short-term variations in oxygen needs.

Glossary

Diffusion capacity Rate of gas transfer across a respiratory surface per unit of gas partial pressure (usually expressed in ml min^{-1} mmHg^{-1}). Dependent on the Krogh coefficient, the respiratory surface area, and the diffusion distance. Also often referred to as the gas transfer factor.

Gill arch Bony or cartilaginous support from which gill filaments extend into the branchial cavities.

Gill filaments (= primary lamellae) Elongated, blade-like structures that extend from the gill arch in the posterior–lateral direction.

Gill lamellae (i.e., secondary lamellae; sing. lamella) Thin folds or plates arising from the gill filaments that contain blood capillaries and serve as the site of gas exchange in the gills of most fishes (singular = lamella).

Gill resistance Resistance to water flow through the gills (= pressure head across the gills divided by the total volumetric flow of the ventilatory stream).

Gill respiratory morphometrics Dimensions of the gills that affect gas transfer between the water and blood.

Krogh coefficient Conductance of a solute (e.g., oxygen) through a particular respiratory medium (e.g., water and blood) or structure (e.g., the water–blood barrier).

Lamellar frequency Number of lamellae per unit length of filament (usually reported per mm). It is also referred to, in some texts, as lamellar density.

Total filament length Sum of the lengths of all filaments in the gills of a fish.

Total gill surface area Area of the gill respiratory epithelium in a fish; Normally reported as the bilateral surface area of all the gill lamellae.

Water–blood barrier thickness Thickness of the tissue barrier through which gases are exchanged between the interlamellar water and blood capillaries. This barrier consists of epithelial cells, a basement membrane, and the flanges of pillar cells. This is also referred to as water–blood barrier distance.

Abbreviations

$\dot{V}_{O_2}$	rate of oxygen uptake (ml O_2 min^{-1})
K	Krogh (= diffusion) coefficient (ml O_2 μm cm^{-2} mmHg^{-1} min^{-1})
A	total gill surface area (cm^2)
ΔP_{O_2}	difference in the partial pressure of oxygen between blood and water at the gills (mmHg)
t	diffusion distance (μm)
D	diffusion capacity (ml O_2 min^{-1} mmHg^{-1})
L_{fil}	total filament length (cm)
n_{lam}	lamellar frequency (number of lamellae per unit length of gill filament) (mm^{-1})
A_{lam}	mean bilateral surface area of an individual lamella (mm^2)
R	gill resistance (Pa s cm^{-3})
μ	dynamic viscosity of water (Pa s)
l	length of the interlamellar channels (= lamellar length) (μm)
d	diameter (= width) of interlamellar channels (μm)
w	width or thickness of a lamella (μm)
h	height of gill lamellae (μm)
b	species-specific scaling exponent, regression coefficient

Introduction

Gills are the primary site of respiratory gas exchange in most fishes. Oxygen acquisition from the environment involves diffusion along a concentration gradient from the ventilatory water stream, across the gill epithelium, and into the blood. The rate of this process is described by the Fick equation:

$$\dot{V}_{O_2} = (K \times A \times \Delta P_{O_2})/t \qquad (1)$$

where $\dot{V}_{O_2}$ is the rate of oxygen uptake, *K* is the diffusion or Krogh coefficient, *A* is the respiratory surface area of the gills, ΔP_{O_2} is the mean difference in the partial pressure of oxygen (=oxygen tension) between the blood and water, and *t* is the diffusion distance (see Abbreviations section for units associated with each term). This equation can be rearranged into the following form:

$$\dot{V}_{O_2}/\Delta P_{O_2} = (K \times A)/t = D \qquad (2)$$

where the ratio of O_2 uptake to the mean difference in ΔP_{O_2} is referred to as the diffusion capacity (*D*). This term is independent of both the metabolic rate of the fish and the oxygen diffusion gradient across the gills and thus provides a useful metric to compare fish species in their ability to acquire environmental O_2 based on gill dimensions, where *D* depends on both the gill area and thickness of the respiratory epithelium (also called the water–blood barrier distance). This article discusses these morphometrics and their constituent parts (i.e., gill area can be subdivided into measures of the filaments and lamellae) in terms of methods for their measurement and theories on optimizing gas exchange, as well as the effects of fish habitat, metabolic demand, and growth on diffusion capacity.

Gill Morphology

Analysis of gill morphometrics with respect to gas exchange requires a basic understanding of fish branchial anatomy (for a comprehensive review of gill structure, the reader is directed to **Design and Physiology of Arteries and Veins**: Branchial Anatomy). Although varying in design and configuration, the gills of all jawed fishes have the same basic structural components: arches, filaments, and lamellae, which are illustrated for a typical teleost fish in **Figure 1**. Most fishes have four gill arches bilaterally positioned on each side of the oral cavity. Each arch supports two rows or sheets of gill filaments, long blade-like structures that extend away from the arch in the posterior-lateral direction (**Figures 1**(**a**) and **1**(**b**)). Together, the two filament sheets constitute a holobranch; each individual row being called a hemibranch (i.e., half a holobranch). In teleosts, the hemibranchs of each arch are largely independent of each other and are connected only near their base by an interbranchial septum (**Figure 1**(**b**)). In elasmobranchs (sharks and rays), this septum extends from the gill arch out to the lateral edge of the fish (where it forms a gill flap), thereby binding the filaments of adjacent hemibranchs along their entire lengths (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy). In both configurations, the filaments of opposing hemibranchs from adjacent arches come together near their tips to form a continuous curtain or sieve through which the entire ventilatory stream passes (**Figure 1**(**b**)).

Each side of the filament blade supports a row of respiratory folds called lamellae (**Figure 1**(**c**)). Their plate-like morphology maximizes surface area while minimizing diffusion distances, thus allowing for effective and rapid gas exchange between blood and water. Blood, which flows in the opposite direction to the ventilatory water stream, is directed through the lamellae by the placement of pillar cells (**Figure 1**(**c**)) that extend across the blood lumen and connect the respiratory epithelium on either side (**Figure 1**(**d**)). The lamellar water–blood barrier is typically composed of two or more layers of epithelial cells, a basement membrane, and the flanges of pillar cells which form the inner lining of the lumen wall (**Figure 1**(**e**)). It may also contain mitochondria-rich cells (involved in osmoregulation and acid–base balance) and goblet cells (associated with mucus production) (**see also Role of the Gills**: Morphology of Branchial Ionocytes); however, in fishes with short diffusion distances, these specialized cells are often confined to the filament epithelium (as shown in **Figure 1**(**e**)).

Total Gill Surface Area

Total gill surface area refers to the area of the respiratory epithelium in a fish, which, in most species, is the bilateral surface of all the lamellae. Gill area (*A*) can thus be estimated using the equation:

$$A = L_{\text{fil}} \times 2n_{\text{lam}} \times A_{\text{lam}} \qquad (3)$$

where L_{fil} is the total length of all the gill filaments, n_{lam} is the lamellar frequency (i.e., the mean number of lamellae per unit length on one side of a filament, which is multiplied by two to account for lamellae on each side), and A_{lam} is the mean bilateral surface area of a lamella. This classical method of estimating gill area takes advantage of the highly organized structure of the gills to methodically sample morphometrics at predetermined locations. With the exception of some flatfishes, the gills on either side of the head are symmetrical; thus, measurements for each dimension are generally only required from one side of the fish.

Total filament length is usually determined by counting all filaments from the gills on one side of the head,

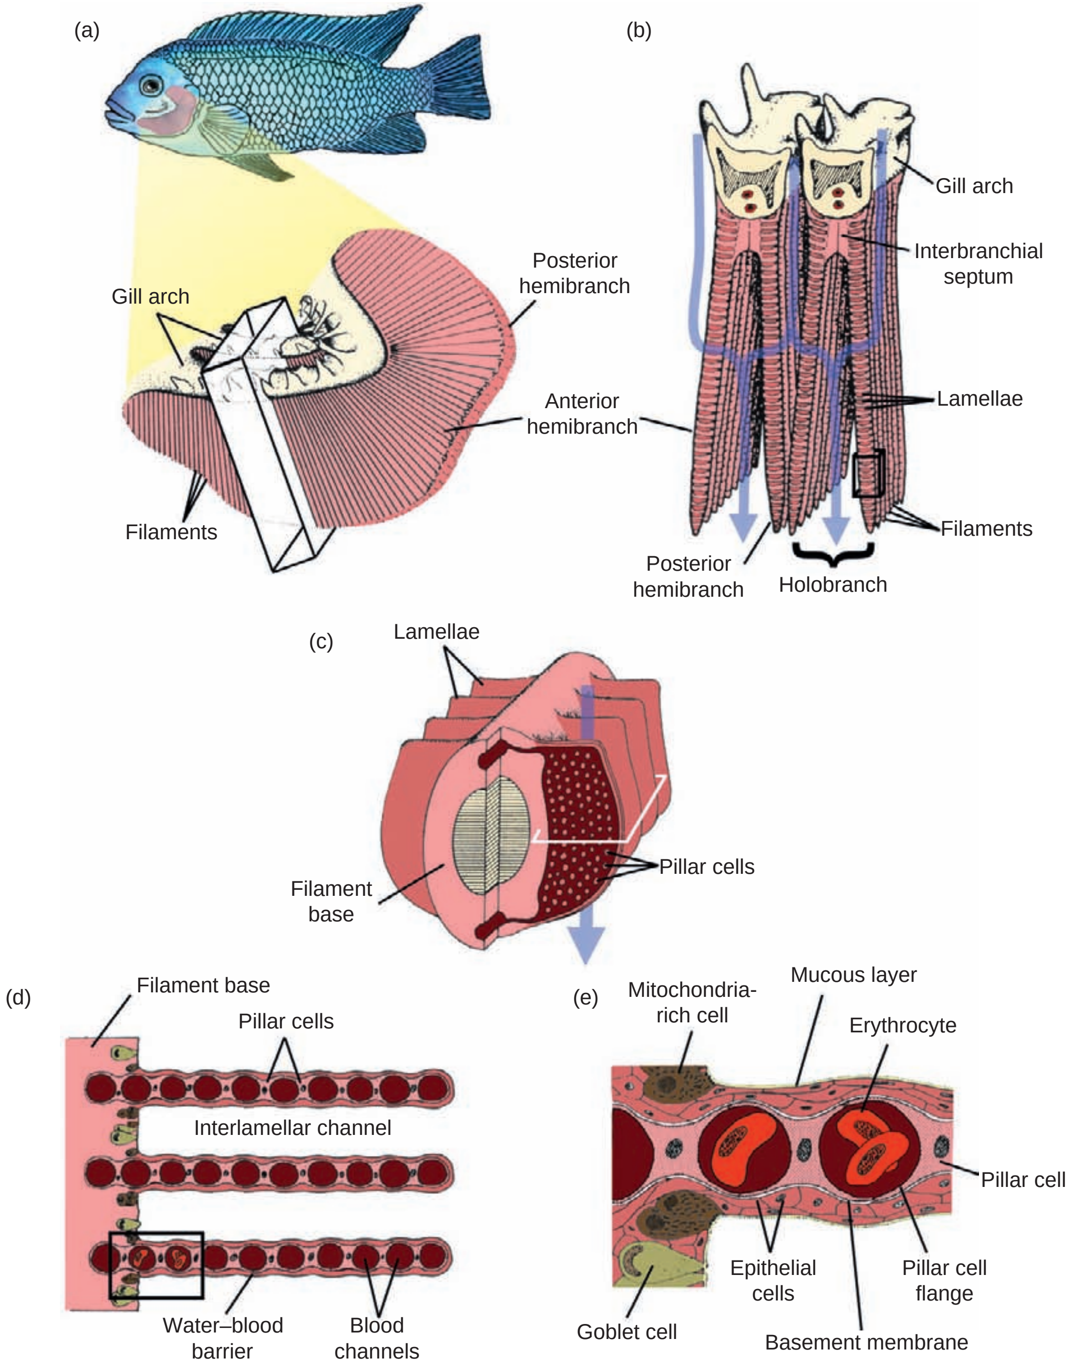

Figure 1 Gill morphology of a typical teleost: (a) anterior two gill arches from the left side of the head; (b) rotated and magnified section from (a) showing the placement and morphology of the two rows of gill filaments extending from each arch; (c) enlarged and rotated section from (b) showing the respiratory lamellae on both sides of a filament; (d) cross section through three adjacent lamellae from (c); (e) enlarged view from (d) showing the detail of the lamellar and filament epithelium. Water flow direction is indicated by blue arrows. Parts of this figure are modified or redrawn from Palzenberger M and Pohla H (1992) Gill surface area of water-breathing freshwater fish. *Reviews of Fish Biology and Fisheries* 2: 187–216.

and, depending on their abundance, dividing them into bins of 10, 20, or more on each arch (**Figure 2**(**a**)). The middle filament from each bin is measured and assumed to represent the mean filament length for that bin. The total length of all filaments in each bin can thus be calculated and these amounts are summed to estimate the total filament length for the gills on one side of the head. This amount is subsequently doubled to determine the total filament length for the entire fish. Lamellar frequency and bilateral surface area measurements are

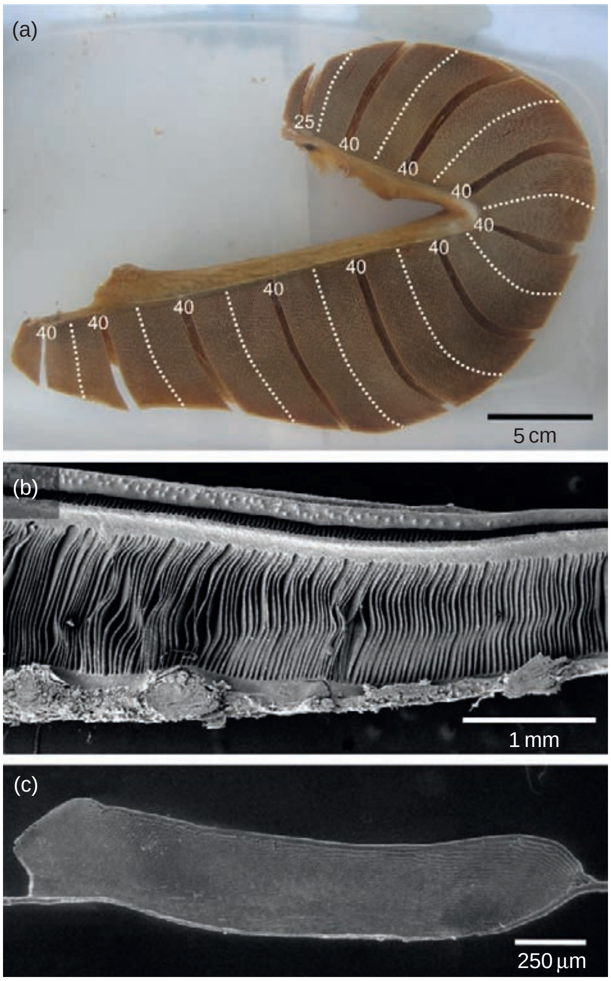

Figure 2 (a) Anterior hemibranch of the third gill arch from a 68-kg striped marlin, *Kajikia audax*, showing the division of 425 filaments into 10 bins of 40 and one bin of 25 (indicated by dotted white lines). The middle filament from each bin has been removed for measurements of lamellar frequency and bilateral surface area. (b) Scanning electron microscope (SEM) image of a selected gill filament used for determination of lamellar frequency. (c) SEM image of a corrosion-cast striped marlin lamella removed for determination of the bilateral surface area.

similarly made on each middle filament and assumed representative of their respective bins. Three measurements of each dimension are typically determined along the length of each filament to account for variation in lamellar shape, size, and spacing. For lamellar frequency, the filament is typically dissected from the arch (**Figure 2**(**a**)) and photographed under magnification near its base, middle, and tip (**Figure 2**(**b**)). Lamellae from these same locations are then dissected from the filament, mounted flat, and photographed to measure lamellar bilateral area (**Figure 2**(**c**)). Lamellar frequency and area measurements from each bin are weighted according to the filament length of that bin before being averaged (thus ensuring lamellar measurements from a bin with a longer filament length will contribute proportionately more toward the mean for the entire gills). Through extensive sampling of lamellar frequency and area on all four gill arches, one arch (usually the second or third) is typically found to be representative of the gills as a whole, and, thus, subsequent n_{lam} and A_{lam} measurements for that species can be made using only that arch.

More recently, gill surface area has also been estimated using stereological techniques. Randomly oriented gill tissue samples are embedded in glycol methacrylate or an alternative, and vertical sections through the tissue are mounted on slides and used to determine total gill volume. Subsequent point counting of filament and lamellar tissue densities using a superimposed grid allows calculation of their relative volumes and surface areas. This method is particularly useful in estimating the gill area of fishes that lack either highly organized and uniform filaments or two-dimensional lamellae. However, there have been few studies comparing the results obtained using stereological techniques with those of the more classic regional sampling method. In addition, stereological methods do not reveal the individual morphometrics contributing to gill area (i.e., L_{fil}, n_{lam}, and A_{lam}).

Diffusion Distances

Oxygen uptake at the gills requires diffusion through the interlamellar water, the water–blood barrier, and the blood plasma before passing through the red blood cell membrane and binding to hemoglobin. Although the widths of the interlamellar channels and lamellar blood vessels thus affect the length of the diffusion pathway, exact measurement of the total diffusion distance is confounded by convective processes of moving media (i.e., the diffusion distance depends on the thickness of boundary layers developing along the lamellar epithelium and other flow-related conditions). Thus, when referring to the diffusion capacity of the gills, emphasis is placed on the thickness of the water–blood barrier.

In most studies, this dimension is determined by viewing lamellar cross sections from multiple gill samples using light, scanning electron, or transmission electron microscopy and calculating the arithmetic mean thickness from measurements immediately overlaying lamellar blood channels (i.e., where the water–blood barrier is generally thin and most O_2 uptake likely occurs). Because diffusion also occurs through longer pathways overlying pillar cells, some studies calculate the harmonic mean thickness, in which averaging the reciprocals of measured lengths includes, but places less emphasis on, longer diffusion distances. In both methods, care must be taken to ensure that thickness measurements are made perpendicular to the plane of the gas-exchange surface, as oblique cross sections result in longer measurements. In order to eliminate the potential for such errors, as well as sampling biases, application of stereological techniques developed for determining the air–blood barrier thickness in mammalian lungs probably provides the most accurate results. This involves vertical sectioning of randomly oriented gill tissue samples and calculates the harmonic mean thickness as $(2/3)l_{\mathrm{h}}$, where l_{h} is the harmonic mean of all length measurements determined along parallel lines of a superimposed grid.

The use of varying techniques to measure barrier thickness can obscure interspecific comparisons (largely because arithmetic means tend to be shorter than harmonic means), and such complications can further be compounded in the calculation of gill diffusion capacity. A frequent error is coupling total gill area with the commonly reported arithmetic mean barrier thickness, which, because it only represents short diffusion distances overlaying blood vessels, causes an overestimation of diffusion capacity. More appropriate is pairing harmonic mean thickness with total gill area and the arithmetic mean with the surface area directly overlying blood channels, which, depending on the size and abundance of the pillar cells, is typically 20–40% lower than the total gill area. Other sources of error in determining gill morphometrics often result from poor tissue sample quality (i.e., gill tissue begins degradation within minutes of air exposure and requires immediate fixation upon collection).

Theories on Gill Dimensions

Despite various methods and difficulties associated with quantifying gill morphology, studies on a wide range of fish species have provided insight into the selective factors sculpting gill morphometrics. Of particular importance is the balance of having a sufficiently large gill area to meet metabolic demands while minimizing branchial resistance and thus the energetic costs of the cyclic buccal–branchial pumping mechanism used by most fishes to ventilate the gills. Because the interlamellar channels are the primary site of both oxygen uptake and gill resistance, this relationship can be examined through the Hagen–Poiseuille equation describing resistance (R) to water flow between parallel plates (i.e., through the lamellae). For a single interlamellar channel

$$R = 12\mu l/d^3 h \tag{4}$$

or for all interlamellar channels in the gills

$$R = 12\mu l(d + w)/d^3 h L_{\mathrm{fil}} \tag{5}$$

where μ is the dynamic viscosity of the water, l is the interlamellar channel length, d is the diameter or width of the channel, w is the width or thickness of a lamella, and h is the lamellar height (dimensions shown in **Figure 3**). In fishes requiring a large gill area, an increase to lamellar length (l) or frequency (thus decreasing d) amplifies gill resistance and, consequently, the energy required to ventilate the gills. In contrast, an increase to lamellar height (h) or to the length of the gill filaments (L_{fil}) decreases gill resistance. Thus, from a purely energetic standpoint, gill area is optimally augmented through large (tall) lamellae and high total filament lengths.

Gill Morphometrics, Fish Habitat, and Metabolic Requirements

With the radiation of fishes into nearly every aquatic and semiaquatic niche, ranging from the open ocean to hypoxic swamps, both gill area and the water–blood barrier thickness can range more than an order of magnitude to meet specific demands associated with a species' physiochemical surroundings and metabolic requirements. As a result, distantly related taxonomic groups show remarkable evolutionary convergence for gill morphology, which has led to the categorization of fishes into different morphological ecotypes. Six major groups are recognized: (1) fast-swimming oceanic species, (2) marine fishes of intermediate activity, (3) sluggish marine species, (4) freshwater fishes,

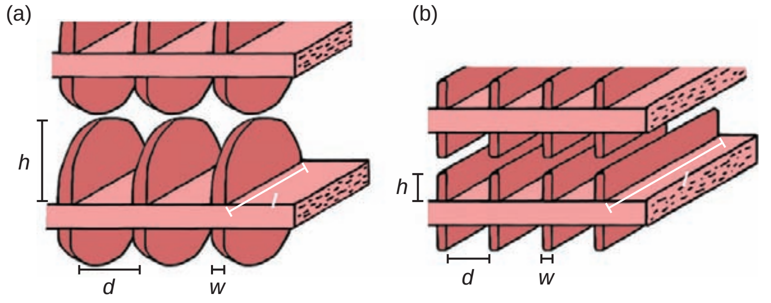

Figure 3 Typical arrangement and shape of the gill lamellae in (a) most teleosts and (b) most fast-swimming oceanic teleosts. *d*, interlamellar channel diameter (= width); *h*, lamellar height; *l*, lamellar length; *w*, lamellar thickness. Modified from Wegner NC, Sepulveda CA, Bull KB, and Graham JB (2010) Gill morphometrics in relation to gas transfer and ram ventilation in high-energy demand teleosts: Scombrids and billfishes. *Journal of Morphology* 271: 36–49.

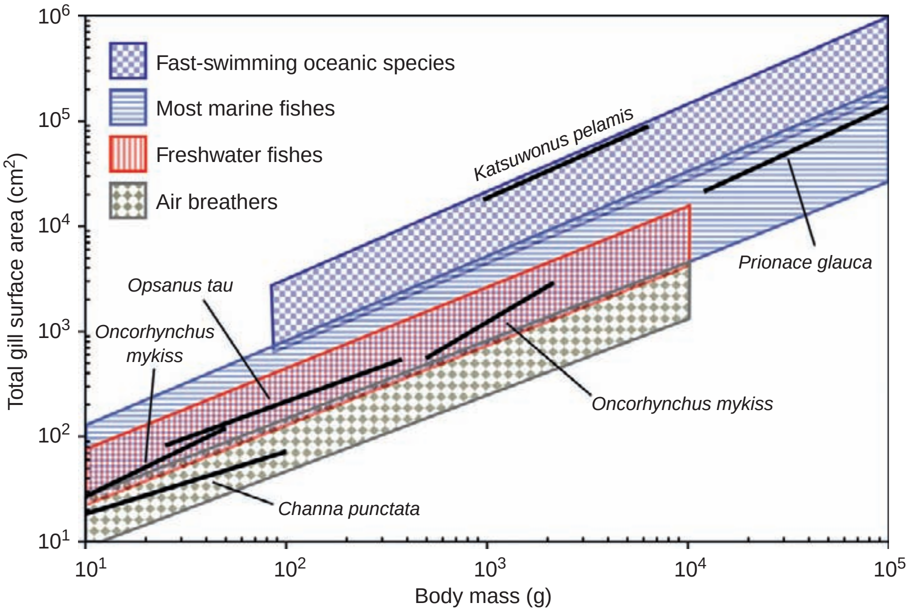

Figure 4 General relationships of gill surface area and body mass for different ecomorphological groups. For visual simplicity, marine fishes of intermediate activity and sluggish marine species are categorized together as most marine fishes. A regression line is shown for a representative of each group: (1) fast-swimming oceanic species, skipjack tuna, *K. pelamis*; (2) marine fish of intermediate activity, blue shark, *P. glauca*; (3) sluggish marine species, oyster toadfish, *O. tau*; (4) freshwater fish, rainbow trout, *O. mykiss*; and (5) air breather, spotted snakehead, *C. punctata*.

(5) air breathers, and (6) hypoxia dwellers. **Figure 4** compares the general range of gill surface area for each ecomorphological group with the exception of hypoxia dwellers, which includes fishes from groups 1–4 showing similar hypoxia-induced changes to gill morphology.

Fast-Swimming Oceanic Species

This group includes tunas and mackerels (family Scombridae), billfishes (Istiophoridae and Xiphiidae), dolphinfishes (Coryphaenidae), some jacks (Carangidae), and sharks of the family Lamnidae (e.g., the shortfin mako, *Isurus oxyrinchus*, and white shark, *Carcharodon carcharias*). These fishes generally have elevated energetic demands associated with fast, continuous swimming and high gill diffusion capacities resulting from large gill areas (which can be an order of magnitude greater than those of other marine fishes) and a thin water–blood barrier (approximately 0.5–1.2 μm). Both large gill areas and short diffusion distances reach their zenith in tunas, which accelerate metabolic processes through the retention of body heat produced by continuous swimming and have the highest O_2 demands of any fish group (**see also Pelagic Fishes**: Physiology of Tuna and Endothermy in Tunas, Billfishes, and Sharks). The largest relative gill area measured to date is that of the skipjack tuna, *Katsuwonus pelamis* (**Figure 4**).

For tunas and other fast-swimming oceanic teleosts, large gill areas generally result from numerous and long gill filaments with high lamellar frequencies (>30 mm^{-1} in some species). The increased number of filaments is achieved through changes to lamellar design, from a semicircular or triangular shape, typical of most fishes (**Figure 3**(**a**)), to a long, rectangular contour with a low profile (height) (**Figures 2**(**c**) and **3**(**b**)), thus allowing filaments to be closely spaced (**Figure 3**(**b**)). This shaping also allows for a marked reduction in the thickness of the water–blood barrier (i.e., low-profile lamellae require less structural support than tall lamellae) contributing to generally thin lamellae (only 5–6 μm in scombrids and billfishes). This reduced lamellar thickness, in conjunction with a narrow spacing between lamellae, increases lamellar frequency, which, in addition to augmenting gill area, decreases diffusion distances and minimizes physiological dead space in the interlamellar channels.

These changes to gill morphology deviate from the theoretical predictions for optimally augmenting gill area; the high frequency and unique shape of the lamellae narrow and lengthen the interlamellar channels (**Figure 3**(**b**)), which, according to Equations (4) and (5), increase gill resistance. Although a high branchial resistance substantially raises the energetic costs of gill ventilation in most fishes, it appears of less concern to fast oceanic species that breathe through ram ventilation, in which branchial flow is driven by fast, forward swimming rather than the pumping of the buccal and branchial cavities. In these fishes, the high branchial resistance associated with this unique morphometric configuration augmenting gill area helps to slow and streamline a fast and turbulent ram-ventilatory stream to create favorable flow conditions for gas exchange in the interlamellar channels.

In contrast, the large gill areas of lamnid sharks are achieved in the predicted manner: long gill filaments with relatively large lamellae. This likely reflects flow constraints imposed by the elasmobranch gill design in which water passing between the gill lamellae must subsequently flow through specialized channels along the interbranchial septum to exit the gill slits (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy). This additional water-flow pathway increases resistance through the elasmobranch gill and appears to preclude the recruitment of a high lamellar frequency to augment gill area (which would further augment branchial resistance). The relatively large lamellae of lamnid sharks appear to require additional structural support through a slightly thicker water–blood barrier ($\sim 1.2\,\mu m$ in the shortfin mako, in comparison to $0.5\,\mu m$ in tunas).

Marine Fishes of Intermediate Activity

This is largely a heterogeneous group of fishes characterized mainly by gill areas that are smaller than those of highly active oceanic species and larger than those of sluggish fishes. Included in this group are most marine fishes studied to date, including many jack species, mullets (Mugilidae), porgies (Sparidae), seabasses (Serranidae), wrasses (Labridae), butterfishes (Stromateidae), croakers (Sciaenidae), puffers (Tetraodontidae), and sharks from the families Sphyrnidae and Carcharhinidae, including oceanic species such as the blue shark, *Prionace glauca* (**Figure 4**). Often referred to as Gray's intermediates (after IE Gray who conducted the first comprehensive comparative study of gill surface areas in the 1950s), the gills of these fishes are largely normal; the gill filaments are of average length and number, and although many of these species are capable of ram ventilation at faster swimming speeds, the lamellae are generally taller and more traditionally shaped than those of the more highly active species. In teleosts, lamellar frequencies typically range from 15 to 25 mm^{-1}, while in elasmobranchs, frequencies of 10–15 mm^{-1} are more common, likely reflecting flow constraints imposed by the interbranchial septum. The thickness of the water–blood barrier usually ranges from 1.5 to $6\,\mu m$.

Sluggish Marine Species

This group includes relatively inactive species usually associated with the benthos or ocean depths that have small gill areas. Fishes from the deep ocean such as the bristlemouths (Gonostomatidae), barbeled dragonfishes (Stomiidae), deepsea tripod fishes (Ipnopidae), and some cusk eels (Ophidiidae) typically have low total filament lengths resulting from generally short and widely spaced filaments. Lamellar frequencies are also reduced, ranging from 7 to 20 mm^{-1}, which minimizes branchial resistance and the energetic requirements of gill ventilation. In some groups, a direct correlation has been found between ocean depth and gill size, in which the smaller gills of deeper-dwelling species likely reflect reduced metabolic demands. In shallower waters, benthic species including flatfishes (Bothidae and Pleuronectidae), some elasmobranchs (Squalidae, Scyliorhinidae, Triakidae, Rajidae, and Torpedinidae), and toadfishes (Batrachoididae) also have reduced gill areas and, in some cases, the water–blood barrier can be quite thick (e.g., the small-spotted catshark, *Scyliorhinus canicula*, $>11\,\mu m$), although this is not necessarily a distinguishing characteristic (e.g., the common sole, *Solea solea*, $<3\,\mu m$). The well-studied oyster toadfish, *Opsanus tau*, has fairly large lamellae, but a small total filament length (resulting largely from only three gill arches on each side of the head) and low lamellar frequency (10–13 mm^{-1}) leading to a small gill area (**Figure 4**), which, when coupled with a relatively thick lamellar water–blood barrier (5–$6\,\mu m$), results in a gill diffusion capacity 100× less than that of a comparably sized tuna.

Freshwater Fishes

The gill surface areas of these fishes are generally smaller than similar species inhabiting the marine environment. For example, the relatively active rainbow trout, *Oncorhynchus mykiss*, has a gill surface area similar to that of *O. tau* (**Figure 4**). This likely reflects several factors, including the reduced osmotic costs associated with life in freshwater and differences in dissolved oxygen levels (i.e., for a given temperature, air-saturated freshwater contains 15–20% more O_2). Despite an increase in O_2 availability, freshwater systems lack high-energy demand fishes comparable to those of the open ocean, which results in a reduced range in gill surface area. The largest gill areas of freshwater fishes thus approach those of marine species of intermediate activity (**Figure 4**) and are often associated with life in hypoxia (see below) or diadromy (the ability to inhabit both marine and freshwater environments). The smaller gill surface areas of freshwater fishes generally result from fairly small lamellae. The water–blood barrier thickness in freshwater fishes typically ranges from 2 to $10\,\mu m$ which is similar to the combined range of intermediate and sluggish marine species.

Air Breathers

In order to exploit hypoxic habitats (**see also Hypoxia**: The Expanding Hypoxic Environment), many fishes have auxiliary air-breathing organs ranging from respiratory epithelia lining the mouth and digestive tract to gas bladders and lungs (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction and Respiratory Adaptations for

Air-Breathing Fishes). Air offers the distinct advantage of containing much more O_2 per unit volume than water and being a less viscous respiratory medium, thus reducing ventilatory costs. The evolution of air breathing is often associated with a reduction in gill area (**Figure 4**), which minimizes the loss of oxygen acquired through an air-breathing organ to hypoxic water (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes). In many species, such as the lungfishes of the genera *Lepidosiren* and *Protopterus*, the gills have become so reduced that drowning occurs if air access is denied. However, most air-breathing fishes are facultative air breathers, meaning the gills are large enough to sustain aerobic metabolism in normoxia and air breathing is used primarily to supplement aquatic respiration under hypoxic conditions or during heightened O_2 demands associated with exercise. The water–blood barrier in air-breathing fishes is often quite thick, especially in amphibious species such as the climbing perch, *Anabus testudineus*, where it can exceed 10 μm and may help to limit gill desiccation and maintain lamellar structural integrity out of water. In nonamphibious air breathers, a thick water–blood barrier may work in conjunction with a small gill area to reduce oxygen loss to the hypoxic environment via the gills. However, many air-breathing fishes maintain relatively thin barriers (i.e, the spotted snakehead, *Channa punctata*, 2.0 μm) indicating the continued importance of the gills in aquatic respiration.

Hypoxia Dwellers

Fishes living in periodic or chronic hypoxia and lacking the ability to breathe air generally show changes to gill morphology that increase diffusion capacity. Specifically, inhabitants of hypoxic swamps, including some African cichlids (Cichlidae), elephantfishes (Mormyridae), cyprinids (Cyprinidae), livebearers (Poeciliidae), characids (Characidae), and trahiras (Erythrinidae), as well as fishes living in the ocean's oxygen minimum zone (OMZ), such as bristlemouths, pearleyes (Scopelarchidae), and bigscale fishes (Melamphaidae) or hypoxic tidepools, including sculpins (Cottidae), usually have larger gill areas than conspecifics or closely related species living in normoxic waters. Unlike high-energy demand teleosts, gill areas in hypoxia dwellers are generally augmented through relatively large lamellae and long gill filaments, thus maintaining low energetic costs for gill ventilation. Few measures of the water–blood barrier thickness exist for such fishes, although it is hypothesized that they should be fairly thin.

Hypoxia-induced changes to gill morphometrics depend on both the severity and periodicity of low O_2 levels. On evolutionary timescales, selective pressures for the exploitation of nutrient-rich waters in the OMZ have resulted in a number of mesopelagic species specialized for life in chronic hypoxia, such as the pearl eye, *Scopelarchoides nicholsi*, which has such long gill filaments they protrude from the opercular openings (**Figure 5**). In environments with prolonged but periodic hypoxia (e.g., many freshwater swamps), phenotypic plasticity in gill morphology allows for adjustment to changing conditions on shorter timescales. For example, African cichlids reared in the laboratory under hypoxic conditions have longer filaments and higher gill surface areas than those raised in normoxia. Such plasticity in gill morphology is epitomized by the crucian carp, *Carassius carassius*, which, when exposed to hypoxia in ice-covered ponds during the winter, can increase gill area by 7.5× in 7–14 days by exposing lamellae normally embedded in an interlamellar cellular mass (**see also Ventilation and Animal Respiration**: Plasticity in Gill Morphology).

Scaling: Fish Gill Morphometrics in Relation to Fish Growth

Gill surface area and its componential dimensions are often reported in relation to fish body mass using log–log plots (**Figure 4**) and the power-law scaling equation:

$$Y = aM^b \tag{6}$$

or log form

$$\log Y = \log a + b \log M \tag{7}$$

where Y is the particular gill morphometric (i.e., A, L_{fil}, n_{lam}, or A_{lam}), a is the intercept value for a 1-g specimen, M is the fish mass, and b is the species-specific slope or scaling exponent (=regression coefficient). As a fish grows, isometric geometry of the gills (i.e., the length/area/volume relationship assuming gill mass increases at the same rate as body mass, $b = 1.0$) predicts that L_{fil} should scale to the one-third (i.e., length/volume, $b = 0.33$), n_{lam} to the negative one-third (length^{-1}/volume, $b = -0.33$), and A_{lam} to the two-thirds (area/volume, $b = 0.67$), which, when added together, sum to the expected scaling exponent for total gill

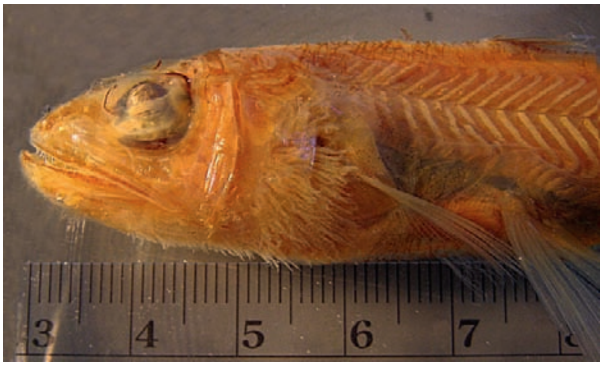

Figure 5 Elongate gill filaments of the pearleye, *Scopelarchoides nicholsi*, extending out the opercular slits. Scale is in cm.

surface area (area/volume, $b = 0.67$). However, in general, measured values do not conform to these geometric predictions, indicating the influence of various physiological processes affecting gill growth. For example, the scaling exponent for gill area ranges from under 0.50 to over 1.00. The mean of this range (0.80) appears to correlate with the mean scaling exponent for fish standard metabolic rate with body mass (0.81), while deviation from the mean may reflect a connection to active metabolic demands (e.g., in continuously swimming fishes which are never at rest) or other variables (**see also Energetics**: Physiological Functions that Scale to Body Mass in Fish). The low scaling exponents of many air-breathing fishes (e.g., *C. punctata*, $b = 0.59$; **Figure 4**) reflect an increased reliance on auxiliary air breathing with growth. At the opposite extreme, the hemoglobin-lacking blackfin icefish, *Chaenocephalus aceratus*, has a scaling exponent of 1.09, which appears to be associated with the increasingly problematic effects of diffusion limitation at larger body sizes.

By incorporating species-specific changes with mass, scaling equations facilitate interspecific comparisons of gill morphometrics and are often extrapolated to compare species of different body size. This has largely replaced methods of early gill studies comparing fishes of different weights through mass-specific gill areas (i.e., gill area/fish mass), which are generally inappropriate because gill area and body mass do not scale isometrically. Although the extrapolation of scaling equations thus provides a more favorable means of comparison, statistically, morphometric relationships can only be compared over a shared (i.e., overlapping) weight range. Errors associated with extrapolating gill area, or other morphometric relationships (especially those established using a limited sample size or weight range), can be seen in **Figure 4** where two independently determined regression lines for *O. mykiss* result in very different scaling equations.

Glossary

Active metabolic rate (AMR) The maximum O_2 consumption rate measured either in a swim tunnel respirometer or following exhaustive exercise.

Cardiac output (V_b) Volume of blood pumped per unit time from the ventricle; the product of heart rate and stroke volume.

Cardiovascular oxygen transport The total amount of oxygen transported through the cardiovascular system ($T_{O_2} = Q \times Ca_{O_2}$).

Critical swimming speed (U_{crit}) The U_{crit} is determined in a swim tunnel where the fish are forced to swim against a current. The current velocity is increased in steps and each step is maintained for a specified time (usually 10 min to 1 h) or until the fish fatigues.

Routine metabolic rate (RMR) The O_2 consumption rate of resting fish is called resting or routine metabolic rate and is usually higher than the SMR.

Standard metabolic rate (SMR) The minimum metabolic rate of survival. Typically, SMR is measured on resting, unstressed adult animals in the post-absorptive state under normothermic conditions. For fish, normothermic is defined as a temperature well within the species tolerance limits for which the animals have had ample time to acclimate.

Metabolic Rate and the Cost of Activity

The locomotion of fish has been broadly classified into three categories depending on the swim intensity. During burst exercise, fish swim at high velocities that can only be maintained for short periods (<20 s) and most of the energy used for the locomotion is generated by anaerobic metabolism. Following these intense bouts of activity, the O_2-consumption rate is temporarily increased, while the fish recover and repay the 'O_2 debt'. A sustained swimming velocity can be maintained for long periods (>200 min) without muscular fatigue and the energy is derived from aerobic metabolism. Between these two extremes is prolonged exercise, which is the swimming velocity that the fish can maintain for 20 s to 200 min. This article reviews cardiac and respiratory function in fish during sustained and prolonged exercise (**Figure 1**).

The energy available for aerobic activity in fish is limited by the scope for activity (SA); the difference between the maximum or active metabolic rate (AMR) and the standard metabolic rate (SMR). Both the SMR and AMR vary with, for example, body mass and ambient temperature, and there are significant differences among species. In general, the SA increases with body mass. The metabolic rate of fish during aerobic activity is usually measured with indirect calorimetry, such as oxygen consumption rate (O_2, **Figure 2**; **see also Ventilation and Animal Respiration**: Techniques in Whole Animal Respiratory Physiology), which can be converted to units of metabolic power output through the oxycalorific coefficient (13.6–14.4 kJ mg^{-1} O_2).

The maximum O_2 consumption rate ($\dot{V}_{O_{2max}}$) is measured while the fish are swimming (**Figure 2**) at or near the critical swimming speed (U_{crit}) or just after they have been chased to exhaustion.

Following feeding, the heat increment (HI; also called the specific dynamic action), which is the metabolic cost of digestion and assimilation, may nearly double the routine metabolic rate (RMR) of fish. The elevation in RMR due to the HI reduces the SA in salmonids, and in less active fish, it may demand most of the metabolic scope. However, in other species, such as sea bass, the $\dot{V}_{O_{2max}}$ is increased postprandially, and the SA is not reduced.

The metabolic cost of swimming increases exponentially as a function of swimming velocity (**Figure 2**). The increase in $\dot{V}_{O_2}$ from rest to maximum varies among fish species, body mass, and ambient temperature. Reported values for the factorial increase in $\dot{V}_{O_2}$ from SMR to $\dot{V}_{O_{2max}}$ range from 5-fold to 20-fold. It is often assumed

Figure 1 Summary of some of the cardirespiratory changes that support the increased metabolic demands of the locomotory muscles.

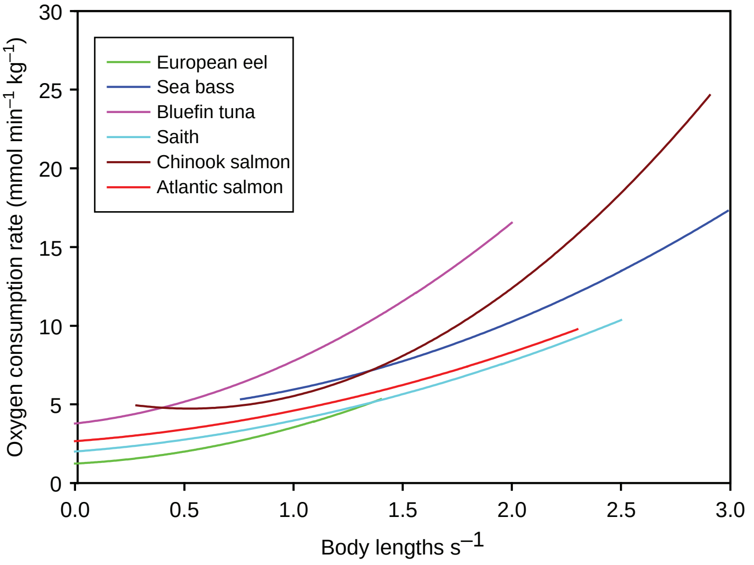

Figure 2 Oxygen consumption rate ($\dot{V}_{O_2}$) of fish swimming at different velocities. The $\dot{V}_{O_2}$ for each species depends on the body mass of the fish and ambient temperature. The $\dot{V}_{O_2}$ (as measured in mmol min^{-1} kg^{-1}) decreases with increased body mass and increases with temperature until the thermal maxima for the species are approached. The body mass of the fish and ambient temperature were as follows: Atlantic salmon (*Salmo salar*), 1 kg 10 °C; European eel (*Anguilla anguilla*), 0.643 kg 18 °C; sea bass (*Dicentrarchus labrax*), 0.325 kg 18 °C; bluefin tuna (*Thunnus thynnus*), 8.3 kg 20 °C; saithe (*Pollachius virens*), 0.485 kg 10 °C; Chinook salmon (*Oncorhynchus tshawytscha*), 0.387 kg 10 °C.

that the increase in $\dot{V}_{O_2}$ above SMR reflects the total energetic cost of activity. However, not all of the increase in $\dot{V}_{O_2}$ with swimming speed reflects the direct cost of locomotion. The energetic cost of the cardiac and the branchial pumps (see below) changes with swimming velocity. Furthermore, other metabolic demands may increase with swimming velocity such as the cost of osmoregulation and protein synthesis. There is also evidence to indicate that SMR is reduced as swimming speed increases due to the redistribution of blood flow. Therefore, the increase in $\dot{V}_{O_2}$ in swimming fish does not necessarily reflect the net cost of locomotion, but instead a combination of factors, some of which will increase the apparent cost of locomotion, such as the increased costs of ventilation and cardiac pumping while others, such as reduced basal metabolic rate, may reduce the apparent cost of locomotion.

Spontaneous routine-swimming activity under natural conditions may demand more energy than suggested by the cost of steady swimming in laboratory swim tunnels. This is mainly because the routine swimming of fish is not steady and rectilinear as in swim tunnels, but interrupted by accelerations and powered turns. The net cost of routine swimming may be three- to fourfold higher than for steady swimming. Therefore, the sustainable swimming speeds estimated in laboratories are likely higher than the routine swimming speed, which can be sustained under natural conditions. The opposite is likely true for burst swimming activity, because swimming tunnels are known to limit the maximum burst swimming capability, and as a result, potentially, the critical swimming speed.

The optimum swimming speed (U_{opt}) is the velocity that maximizes the distance traveled for a unit energy expended. For salmonids, the U_{opt} is close to 1 body length s^{-1}, which appears to coincide with the routine swimming velocity of migrating salmon in the ocean. If foraging success is proportional to the distance covered, there may be substantial gains to be had from swimming at U_{opt} compared with lower velocities. Similarly, during migration, there is a considerable energetic advantage in maintaining U_{opt}.

The O_2 Cascade and Transport of Respiratory Gases

The O_2 consumed by the locomotory muscles is primarily transported to tissues through a sequence of processes that are driven by convection and diffusion (**Figure 1**). The first step is ventilation and then diffusion of O_2 from water across the gill epithelia and into the blood (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). Most of the O_2 transported from the gills to the tissues is bound to the hemoglobin (**Figure 3**; **see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). Finally, O_2 diffuses from the blood to the tissues, where it is consumed in the mitochondria (**see also Tissue Respiration**: Mitochondrial Respiration and Cellular Respiration). This transfer of O_2 is appropriately described as the O_2 cascade drawing an analogy with a cascaded waterfall, where O_2 progressively falls down its partial pressure gradient. Some of the O_2 consumed by fish is not carried by the cardiovascular system, but diffuses directly through the skin or is consumed at the gills. Cutaneous O_2 uptake is particularly important during embryonic and larval stages before the gills are fully developed (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Respiratory Transitions). Adults of water breathing fish may take up 10–20% of the resting O_2 consumption through the skin. However, cutaneous O_2 uptake is not likely to contribute significantly to the increased O_2 demands of exercising muscles.

The respiratory quotient (CO_2 produced/O_2 consumed) is near unity in fish and, therefore, the consumption of O_2 is matched by excretion of CO_2 (**Figure 3**; **see also Tissue Respiration**: Cellular Respiration). The CO_2 diffuses out of muscle cells and into the red blood cells (RBCs), where carbonic anhydrase (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbonic Anhydrase in Gas Transport and Exchange) converts CO_2 to HCO_3^-. Most of the HCO_3^- then leaves the RBCs through Cl^-/HCO_3^- exchange and is carried in the plasma, while smaller fractions are carried as HCO_3^- in the RBCs or as molecular CO_2 dissolved in plasma. When the blood reaches the gills, the process is reversed and HCO_3^- re-enters the RBCs, is dehydrated by carbonic anhydrase, and diffuses as CO_2 down a partial pressure gradient out of the fish (**See also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion) facilitated by the interaction between O_2 and CO_2 exchange (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange).

Ventilation and Diffusion across Gills

In resting fish, the buccal and opercular pumps drive water almost continuously across the gills by pressure differences created by alternate changes in the volume of the buccal and opercular cavities. During exercise, the ventilation volume increases in step with or even disproportionately more than $\dot{V}_{O_2}$. Therefore, the cost of ventilation increases with swimming. As swimming speed increases, the mode of ventilation may shift from active to ram ventilation, where most of the power required for ventilation is generated by the locomotory muscles. Some species are obligate ram ventilators and rely entirely on this form of ventilation. In the ram mode of ventilation, the fish adjust ventilation volume by changing the mouth gape. Ram ventilation is more efficient in terms of ventilatory work than the buccal and opercular pumps and reduces the overall cost of ventilation compared with buccal and opercular pumping.

The secondary lamellae are the main gas exchange surfaces of the gills (**see also Design and Physiology of**

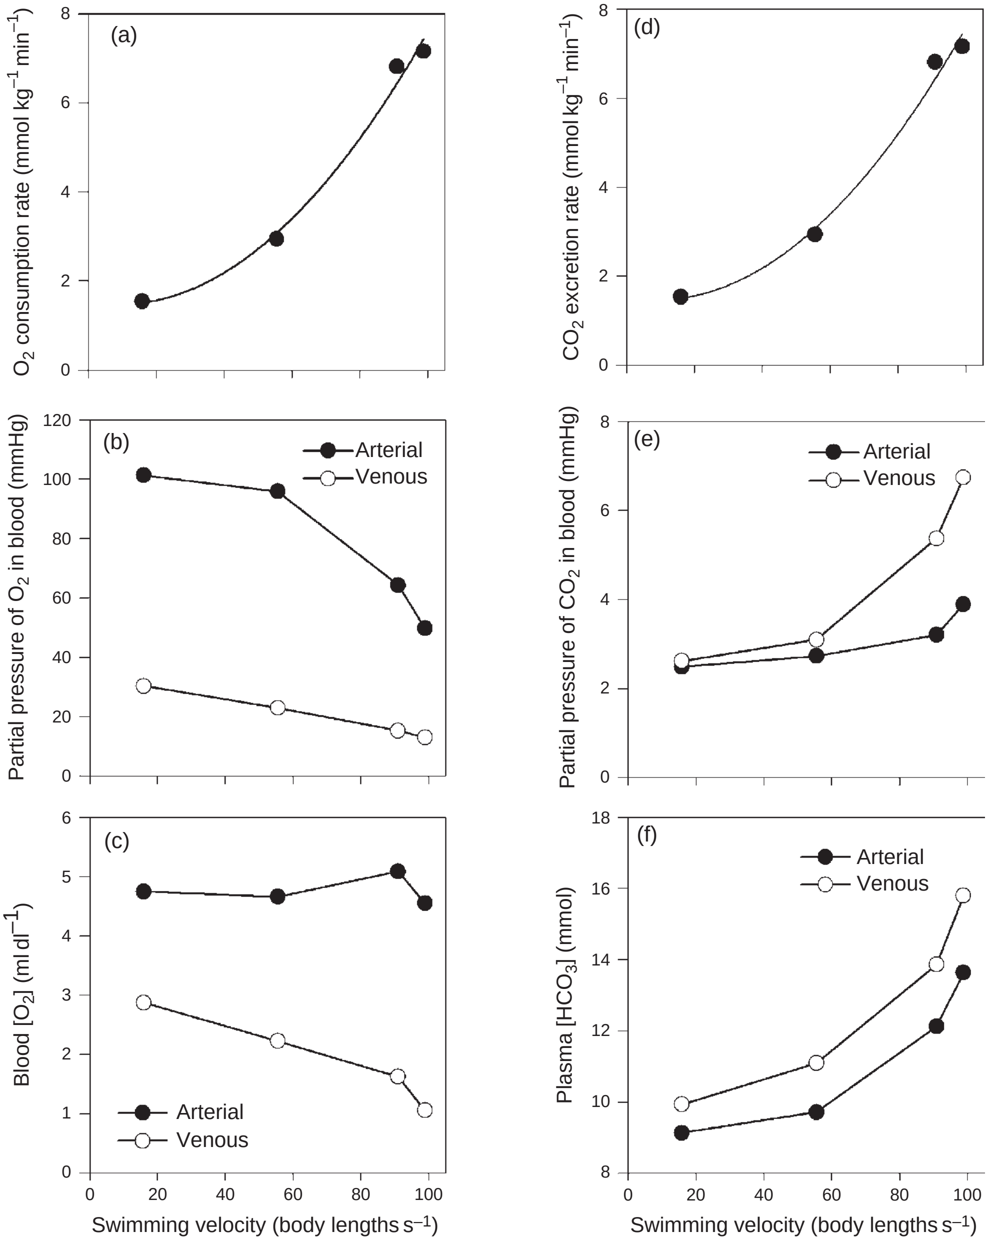

Figure 3 Blood gases in swimming rainbow trout. Oxygen consumption rate (a), partial pressure of O_2 in blood (b), concentration of O_2 in blood (c), CO_2 excretion rate (d), partial pressure of CO_2 in blood (e), and concentration of HCO_3^- in plasma. As swimming velocity increased up to U_{crit}, the cardiac output increased 2.5-fold and the arterial-venous difference in O_2 concentration increased by 1.9-fold. Data replotted from Brauner CJ, Thorarensen H, Gallaugher PE, Farrell AP, and Randall DJ (2000) CO_2 transport and excretion in rainbow trout (*Oncorhynchus mykiss*) during graded sustained exercise. *Respiration Physiology* 119: 69–82 and Brauner CJ, Thorarensen H, Gallaugher PE, Farrell AP, and Randall DJ (2000). The interaction between O_2 and CO_2 in the blood of rainbow trout (*Oncorhynchus mykiss*) during graded sustained exercise. *Respiration Physiology* 119: 83–96.

Arteries and Veins: Branchial Anatomy) for uptake of O_2 and excretion of CO_2. Water flows over the lamellae countercurrent to the direction of internal flow of blood. This allows the partial pressure of O_2 in the dorsal aorta (Pa_{O_2}) to be higher than the P_{O_2} of the expired water (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). The rate of diffusion of O_2 between water and blood is proportional to the partial pressure gradients of the gasses at any location across the lamellae. The total conductance for O_2 between water and blood, termed either transfer factor or diffusing capacity, includes the combined conductance of the external water, a boundary layer of water over the gill epithelium, diffusion over the gill epithelium, through plasma, into the RBCs, and the reaction of O_2 with hemoglobin. Furthermore, shunts of water and blood flow from the respiratory surfaces may decrease the apparent conductance as well as regional inhomogenities in perfusion, ventilation, and conductance of the gills. The exact contribution of each factor to the total conductance is not known.

The total conductance for CO_2 between blood and water is higher than that of O_2 and, therefore, a diffusion limitation is less likely for CO_2 than O_2. However, it has been suggested that the rate-limiting step in the excretion of CO_2 is the HCO_3^-/Cl^- exchange at the RBCs (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion).

During exercise, the pattern of blood flow through the gills changes to increase the effective respiratory surface area (**Figure 1**) as well as to reduce the mean diffusion distances between water and blood. At rest, only two-thirds of the lamellae are perfused, mostly in the basal regions of the filaments. The increase in blood pressure in the ventral aorta during exercise recruits the more distal lamellae on each filament, and thus increases the effective respiratory surface area. Furthermore, the higher blood pressure causes proportionately more blood to flow through the central than through the basal region of each lamellae than at rest, which reduces the mean diffusion distance between blood and water. Catecholamines may also change the blood flow pattern of the gills, as well as increase the permeability of the gill epithelium for O_2 during exercise.

There is a good correlation between total gill surface area and $\dot{V}_{O_{2max}}$ of different species of fish (**see also Hypoxia**: Respiratory Responses to Hypoxia in Fishes). As a result, it has been suggested that total gill surface area is the primary limitation to $\dot{V}_{O_{2max}}$ in fish.

Cardiovascular Gas Transport

The internal O_2 convection is described by the Fick equation:

$$V_{O_2} = Q \times (Ca_{O_2} - Cv_{O_2}) \tag{1}$$

where Q is cardiac output, and Ca_{O_2} and Cv_{O_2} are arterial and venous blood O_2 contents, respectively.

Cardiac Output

The resting Q (Q_{rest}) of fish has been measured in many species of fish and reports range from 6.2 to 132 ml min^{-1} kg^{-1} (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping). Most of the variability in Q_{rest} is caused by temperature differences, with higher Q_{rest} occurring at increased temperatures (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature). At temperatures between 8 and 12 °C, the Q_{rest} in teleost fish ranges between 9 and 40 ml min^{-1} kg^{-1}. More active fishes tend to have higher Q_{rest}.

During exercise, Q is increased because of both increased heart rate (HR) and stroke volume (SV) (**see also Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming). Many species, for example, salmonids, appear to modulate Q primarily through changes in SV, while changes in HR appear to be less important. However, other species, such as sea bass, modulate Q primarily through changes in HR.

The maximum Q (Q_{max}) of fish during prolonged exercise increases with temperature as does Q_{rest}. Furthermore, active fish also have a higher Q_{max} than sluggish fish. The reported values for the relative increase in Q (Q_{max}/Q_{rest}) during exercise range from no change to about threefold increases. However, there is no clear difference in the relative increase in Q between active fish and sluggish fish during exercise.

The hearts of active fish are larger than the the hearts of less active fish (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping and Cardiac Anatomy in Fishes). Moreover, there is considerable plasticity in the heart size of fish and the heart size may increase, for example, in response to exercise training, temperature, and maturation.

Blood O_2/CO_2 Content

The O_2 content of blood depends on hemoglobin concentration, the P_{O_2} of the blood, and the affinity of hemoglobin for O_2. The hemoglobin concentration is generally proportional to hematocrit (Hct, which is the RBC fraction in the blood) and the mean corpuscular hemoglobin concentration. In blood, most of the O_2 is carried bound to hemoglobin and only 4–6% of the total O_2 content is dissolved in the plasma. Because the affinity of hemoglobin for O_2 varies depending on the number of O_2 molecules bound to the hemoglobin, the curve for O_2 saturation of hemoglobin as a function of P_{O_2} is nonlinear (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). The affinity of fish hemoglobin for O_2 is affected by pH, CO_2, nucleotide triphosphate levels, and temperature (**see also Transport and Exchange of Respiratory Gases in the Blood**: O_2 Uptake and Transport: The Optimal P50). Reduced pH causes a right shift of the O_2 saturation curve (Bohr shift), and can decrease the O_2 capacity of Hb (Root shift) (**see also** Root **Transport and Exchange of Respiratory Gases in the Blood**: Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). Furthermore, adrenaline can affect intracellular pH and nucleotide triphosphate levels of RBCs and thus modulate the O_2 affinity of hemoglobin (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin).

When fish approach U_{crit}, the Pa_{O_2} may decrease (**Figure 3(b)**), while the Ca_{O_2} remains fairly constant during aerobic exercise (**Figure 3(c)**). By contrast, Cv_{O_2} may decrease by more than 50% (**Figure 3(c)**). The Hct may increase slightly as swimming speed increases both because RBCs are released from the spleen and plasma volume is reduced (**see also Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming). However, even if the Hct is increased, the Ca_{O_2} does not change appreciably from resting values.

During aerobic exercise, the delivery of CO_2 from the tissues to the gills increases. The P_{CO_2} and concentrations of CO_2 and HCO_3^- in blood increase, more so in the venous blood (**Figures 3(d)–3(f)**). Although P_{CO_2} increases, blood pH remains unchanged indicating that fish can elevate plasma HCO_3^- either through acid excretion (coupled with HCO_3^- retention) at the gills or kidney, or through direct HCO_3^- uptake across the gills.

Blood-Flow Distribution

As swimming velocity increases, the gas transfer between the gills and the locomotory muscles is elevated both because Q increases and blood flow is redistributed from the intestines and other organs to the muscles (**Figure 1**). The largest shift in blood flow is from the intestines. Little is known about blood-flow redistribution from other tissues such as the skin, but their contribution is likely much less than that from the intestines.

The intestinal blood flow in resting fasted fish is 30–40% of Q_{rest}, although values as low as 10% of Q_{rest} have been reported (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion). As swimming speed increases, gut blood flow is progressively reduced by 30–70%. By contrast, gut blood flow may nearly double in resting fed fish (reported values range from 40% to 155% increase) to support the blood flow and O_2 demands during digestion (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion). The increase in gut-blood flow in fed fish may reduce the blood flow available to exercising muscles, for example, in salmonids, where the cardiovascular system cannot perfuse maximally both muscles and intestines simultaneously. Interestingly, the U_{crit} of some other species, such as sea bass, is not reduced following feeding and their cardiovascular system appears to support simultaneously the O_2 demands of locomotion and the HI.

In addition to providing more O_2 to exercising muscles, the reduced gut-blood flow may also be important for cardiovascular function in swimming fish. There is a significant volume of blood contained in the intestinal veins. The volume of blood in the veins depends on passive distension of the venous walls by blood pressure and/or active changes in venous compliance. Reduced blood pressure or compliance in the intestinal veins could shift blood volume from the gut into the central circulation. This shift in blood volume may be important to increase or maintain central venous pressure in exercising fish and thus the filling pressure of the heart, which, in turn, is important for supporting maximum cardiac output (**see also Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels).

The systemic blood pressure of fish increases during exercise and this may be important for ensuring maximum perfusion of the gills. The increased resistance in the gut circulation in exercising fish may be important to counteract the reduced resistance to blood flow to the locomotory muscles and thus aid in maintaining arterial blood pressure in swimming fish (**see also Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming).

Limitations to Maximum Oxygen Consumption

The maximum O_2 consumption rate in fish could, in principle, be limited by any step in the O_2 cascade or mitochondrial oxidative phosphorylation pathway (**Figure 1**). Furthermore, substrate availability or transport of ATP to the sites of utilization could also limit $\dot{V}_{O_{2max}}$. Therefore, the limitations of $\dot{V}_{O_{2max}}$ may be a result of the interplay of numerous factors.

There are several lines of evidence that suggest that the primary limitation to $\dot{V}_{O_{2max}}$ in fish resides in the convective transport of O_2 from the gills to the tissues ($T_{O_2} = Q \times Ca_{O_2}$). Both Q_{max} and Ca_{O_2} can directly affect $\dot{V}_{O_{2max}}$. When the Ca_{O_2} in fish is reduced through anemia, reduced hemoglobin O_2 affinity, or exposure to hypoxia, then $\dot{V}_{O_{2max}}$ and swimming performance of fish are decreased. There is a near proportional change in $\dot{V}_{O_{2max}}$ of rainbow trout when the $T_{O_{2max}}$ is varied by experimentally changing the Hct above or below normal values. There is also evidence to indicate that rainbow trout with high Q_{max} have higher $\dot{V}_{O_{2max}}$ and U_{crit} than fish with lower Q_{max}.

When comparing different species of fish, the available data suggest that there is a close correlation between the $T_{O_{2max}}$ and $\dot{V}_{O_{2max}}$. This supports the hypothesis that $\dot{V}_{O_{2max}}$ of fish is primarily limited by $T_{O_{2max}}$. However, the $T_{O_{2max}}$ is clearly not the sole determinant of $\dot{V}_{O_{2max}}$ in fish, and there is ample evidence to suggest that other levels in the O_2 cascade can also affect $\dot{V}_{O_{2max}}$. Some of these are discussed below.

There may be a diffusion limitation in tissues. The Cv_{O_2} is reduced in swimming fish (**Figure 3(c)**), although there is always residual O_2 in venous blood, which suggests that there may be some form of diffusion limitation in tissues. Thus $\dot{V}_{O_{2max}}$ may increase independent of $T_{O_{2max}}$ by increasing the conductance of O_2 from blood to tissues, for example, through increased capillarization.

Another factor that can affect $\dot{V}_{O_{2max}}$ in fish is the size of the gas-exchange area of the gills. Certainly, more-active fish have a larger gill surface area than do less-active fish. Furthermore, experimental reduction in gill surface area will affect gas transfer. At maximum swimming speed, the Pa_{O_2} is reduced (**Figure 3(b)**) and Pa_{CO_2} is increased (**Figure 3(e)**) in some species of fish. These changes in partial pressure can be caused either by insufficient ventilation volume or by diffusion limitations at the gills. Because ventilation volume increases in step with $\dot{V}_{O_2}$ it is unlikely to cause a reduction in Pa_{O_2}. However, the total conductivity for O_2 at the gills may not increase in step with $\dot{V}_{O_2}$, and that would cause a reduction in Pa_{O_2} and an increase in Pa_{CO_2}. This suggests that a diffusion limitation for O_2 and CO_2 may exist across the gills as gas diffusion rates increase with exercise.

It may be useful to draw an analogy between O_2 transfer in fish from water to tissues and an electrical circuit with resistors arranged in series. Each of the factors mentioned above are potential limitations to $\dot{V}_{O_{2max}}$. However, to take the analogy one step further, the relative contribution of each of the 'resistors' to the total resistance to flow of O_2 through the system varies. Therefore, a unit change in any of the larger 'resistors' has a greater effect on O_2 flux than a proportional change in the smaller resistors. Because changes in $T_{O_{2max}}$ of trout can have a substantial effect on $\dot{V}_{O_{2max}}$, T_{O_2} must be one of the larger resistors of the system and possibly the largest, while diffusion limitations for O_2 across the gills and from blood to tissues are significantly smaller. The $\dot{V}_{O_{2max}}$ in mammals also appears to be primarily limited by $T_{O_{2max}}$.

Although the available information points to $T_{O_{2max}}$ as being the primary limitation to $\dot{V}_{O_{2max}}$ in fish, comprehensive studies have only been performed on few species. Considering the great number and diversity of fish species, it is difficult to make generalizations. Furthermore, the concept of symmorphosis states that "functional design (of the respiratory system) is commensurate with functional demand" such that all structures within the respiratory system are approximately matched with the aerobic capacity of an animal. Thus, the gas-exchange area of the gills, heart size, and T_{O_2} are all correlated with $\dot{V}_{O_{2max}}$. Increases in the capacity of a single step in the O_2 cascade can have only limited effects on $\dot{V}_{O_{2max}}$, because other steps in the O_2 cascade will take over as primary limitations for O_2 transport.

Glossary

Capacitance coefficient Formally defined as $\Delta C/\Delta P$, where C is concentration and P is the partial pressure of a gas. If the gas is present exclusively in physical solution, this is identical to the solubility of the gas.

Convection Bulk movement of a medium, e.g., gas, water, or blood.

Gas partial pressure in a liquid The partial pressure of a gas in blood or water is the partial pressure that a gas phase should have in order to be in equilibrium with that liquid. Thus, it is not a physical partial pressure as defined in a gas mixture.

Parallel inhomogeneity Inhomogeneity in some property, e.g., ventilation or perfusion among the structurally identical units of a gas-exchange organ.

Gas Exchangers

The primary job of the gas-exchange organ is to acquire oxygen from and deliver carbon dioxide to the environment. Therefore, it has a crucial role in the overall transport of gases between the environment and the metabolizing tissues. As outlined in **Figure 1**, this transport has four steps:

1. convective transport of the respiratory medium over the respiratory surface,
2. diffusion across the respiratory surface from medium to blood,
3. convective transport by blood between the respiratory surface and the metabolizing tissues, and
4. diffusion from the capillaries to the mitochondria in the surrounding tissues (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Respiratory Transitions).

While this overall transport layout is universal among vertebrates, the specific design of the gas-exchange organs is not. Thus, the way blood and media are arranged and flow relative to each other differ considerably among the various groups (**Figure 2**). In terrestrial vertebrates, the lungs are of two main types: the avian, or parabronchial type of lung, and the mammalian lung type. In the former, blood and medium (air) flow in a crosscurrent-like fashion, whereas in the latter, blood perfuses a ventilated pool of air with no specific orientation. Although the latter type differs greatly in sophistication between mammals and reptiles and amphibians, the basic design is the same. This also holds for the air-breathing organs of air-breathing fishes even though these may be of different anatomical origin. Among fishes, a countercurrent arrangement of the blood and water flows is universally found in the gill, although in some air-breathing species this may have been reduced and lost its quantitative importance (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

Water versus Air as Respiratory Media

There are a number of important differences between water and air as respiratory media that have consequences for gas exchange (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Respiratory Transitions):

1. The density of water is greater than that of air by a factor ~800.
2. The viscosity of water is greater than that of air by a factor ~50.
3. Diffusion coefficients for gases in water are smaller than those in air by a factor ~8000.
4. The capacitance coefficient (solubility) of CO_2 in water is ~30 times greater than that of O_2, whereas in air they are identical.

The density of the medium has importance for the work of breathing in the event that the hydraulic driving pressure (in water-breathing fishes that would be the pressure difference between the buccal and opercular cavities) and the flow are both pulsatile. In this case, the repeated acceleration of the much denser water with each breath

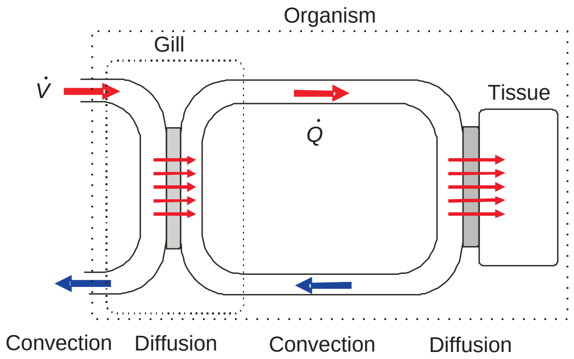

Figure 1 Gas-transport system in a hypothetical organism, illustrating how gas is transported, from the environment to the respiring tissues, by convection and diffusion in an alternating fashion.

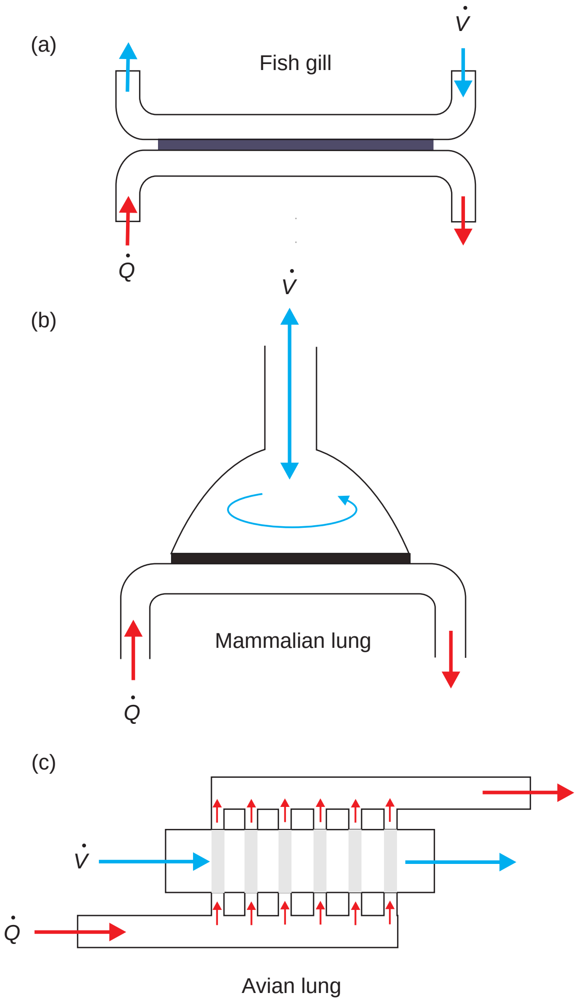

Figure 2 Models of vertebrate gas exchangers. In the fish gill (a), water and blood flow in a countercurrent fashion. In the mammalian lung (b), the blood exchanges gases with a pool of alveolar air that in turn is ventilated with ambient air in a tidal fashion. In the avian lung (c), air flows unidirectionally through the parabronchi and blood flows perpendicular to air flow, termed crosscurrent flow. This system is termed 'ventilated pool' or 'dynamic pool'.

would add to the cost of breathing in fishes. Indeed, the driving pressure is pulsatile in these fishes, and model studies of the pressure/flow relations in the interlamellar space of fish gills indicate that this is the case for flow as well.

The viscosity determines the frictional force that has to be overcome when fluid flows and therefore directly affects the work of breathing. This is independent of the degree of pulsatility of either pressure or flow.

The diffusion coefficients for respiratory gases in the respiratory media might, at first, seem irrelevant since gases are transported from the environment to the respiratory surface by convective transport as outlined in **Figure 1**. However, the risk of buildup of partial-pressure gradients of respiratory gases within the medium close to the respiratory surface is much greater in water than in air. Such gradients will reduce the efficiency of the exchange process. Thus, in fishes, it has been estimated that up to ~25% of the total resistance to diffusion resides in the respiratory water itself.

The capacitance coefficients of O_2, CO_2, and N_2 in water and air are given at 20 °C in **Table 1**. It is apparent that the capacitance coefficient for oxygen is much less in water than in air, which implies that air-saturated water contains correspondingly less oxygen than air contains. Therefore, in order to present the same amount of oxygen at the respiratory surface, much more water has to be moved. To express this quantitatively Fick's principle is applied to the respiratory medium:

$$\dot{M}_{O_2} = \dot{V}\beta_{O_2}(PI_{O_2} - PE_{O_2}) = \dot{V}(CI_{O_2} - CE_{O_2}) \qquad (1)$$

Here $\dot{V}$ is the ventilation rate and β_{O_2} the capacitance coefficient. By introducing the extraction coefficient (the fractional removal of oxygen from the ventilated water, often also referred to as the utilization) $E_{O_2} = (CI_{O_2} - CE_{O_2})/CI_{O_2}$ and rearranging, the following equation is obtained:

$$\frac{\dot{V}}{\dot{M}_{O_2}} = \frac{1}{E_{O_2}\beta_{O_2}PI_{O_2}} = \frac{1}{E_{O_2}CI_{O_2}} \qquad (2)$$

The left-hand side of the equation is termed the convection requirement, which represents the amount of

Table 1 Capacitance coefficients for O_2, CO_2, and N_2 at 20 °C

	O_2	CO_2	N_2
Water	1.82	51.7	0.931
Air	54.7	54.7	54.7

The tabulated values are in μmol·L^{-1}·mmHg^{-1}.
Values for air are calculated as 1/(*RT*), where *T* is the absolute temperature and *R* is the gas constant in L·mmHg·K^{-1}·μmol^{-1} (6.24×10^{-5})
Values for water are taken from *Handbook of Chemistry and Physics*, 73rd edition.

medium required to be moved over the respiratory surface per unit of oxygen taken up. The convection requirement is inversely proportional to the product of the extraction coefficient, the capacitance coefficient, and the inspired oxygen partial pressure. The product of the latter two represents the inspired oxygen concentration. In **Figure 3**, the convection requirement has been plotted as a function of CI_{O_2}, and the approximate value in humans, rainbow trout (*Oncorhynchus mykiss*), and common carp (*Cyprinus carpio*) have been included. An additional value has been included representing rainbow trout and common carp, assuming they have the same low extraction coefficient as humans (and most air breathers). This illustrates the important fact that water breathers tend to have higher extraction coefficients than do air breathers, which to some extent compensates for a high ventilation requirement.

From **Table 1** it is also evident that, while the respiratory gases have identical capacitance coefficients in air, this is not so in water where CO_2 is ~30 times more soluble than O_2. Comparison with the inert gas N_2 shows that this is due to an unusually high capacitance coefficient of CO_2 in water. This fact dictates an important difference between water and air breathers: while the O_2 partial pressures in the blood of air- and water-breathing animals are often similar, water breathers have much lower partial pressures of CO_2 in their blood than air breathers. This can be demonstrated by applying the Fick's principle simultaneously to CO_2 and O_2 transport by the respiratory media:

$$\dot{M}_{O_2} = \dot{V}\beta_{O_2}(PI_{O_2} - PE_{O_2}) \quad (3a)$$

$$\dot{M}_{CO_2} = \dot{V}\beta_{CO_2}(PE_{CO_2} - PI_{CO_2}) \quad (3b)$$

Dividing the CO_2 equation by the O_2 equation, recalling that $\dot{M}_{CO_2}/\dot{M}_{O_2} = RQ$ (respiratory quotient), and rearranging yields

$$PE_{CO_2} - PI_{CO_2} = RQ\frac{\beta_{O_2}}{\beta_{CO_2}}(PI_{O_2} - PE_{O_2}) \quad (4)$$

Thus, the increase in the CO_2 partial pressure of the respiratory medium as it passes over the respiratory surface equals the corresponding fall in O_2 partial pressure times the ratio of the O_2 to CO_2 capacitance coefficient times the *RQ*. The latter is always close to 1.0 (usually between 0.7 and 1.0), so the ratio of capacitance coefficients is crucial. In air, this ratio is 1.0, whereas in water it is ~1/30. This is illustrated in **Figure 4**, which shows the expired CO_2 partial pressure as a function of the expired O_2 partial pressure at an *RQ* of 1.0. It is clear that even if a water breather were able to extract all the oxygen, the expired partial pressure of CO_2 would not exceed 5–6 mmHg. This means that in water breathers the CO_2 partial pressure of blood will be very much lower than in air breathers (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Respiratory Transitions). **Figure 4** also indicates the approximate ranges of air breathers and water breathers on the lines along with the hypothetical range that would have been observed in air breathers if the oxygen extraction coefficient had been in the same range as that of water breathers.

The differences between air breathers and water breathers, discussed so far, are all due to the different properties of the respiratory media and are completely independent of the nature of the gas-exchange organ.

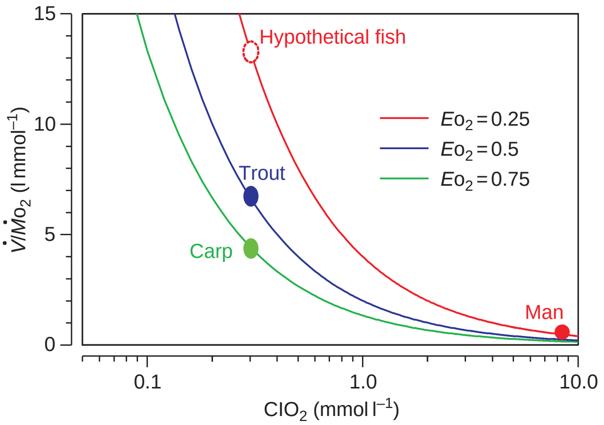

Figure 3 The convection requirement ($\dot{V}/\dot{M}$) as a function of the inspired oxygen concentration. Due to the much lower oxygen-capacitance coefficient of water (here a temperature of 15 °C was assumed) compared to air, the inspired oxygen concentration of air-equilibrated water is much lower than that in air and the convection requirement is correspondingly higher.

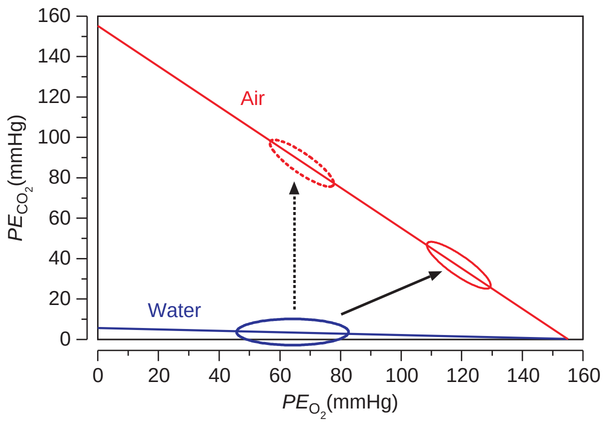

Figure 4 The PE_{CO_2} vs. PE_{O_2} diagram. In air breathers the slope is in the range −0.7 to −1.0 (depending on the respiratory quotient, *RQ*) whereas in water breathers it is only approximately −1/30 due to the very high CO_2 relative to O_2 capacitance coefficient of water. The approximate range of values *in vivo* are indicated by solid circles on the lines for water and air breathers. The dotted circle indicates theoretical values in air breathers with an oxygen-extraction coefficient equal to that of water breathers.

The Efficiencies of Gas Exchange

For the whole organism, the extraction coefficient, as defined earlier, is the appropriate measure of gas-exchange efficiency. This is, however, not a measure of the performance of the gill although it clearly depends on it. There are two measures of the efficiency of the gill as a gas exchanger which can be derived by starting with Fick's principle for water and blood, respectively:

Here, $\dot{V}w$ denotes gill ventilation rate and $\dot{Q}$ cardiac output and βw_{O_2} and βb_{O_2} are the capacitance coefficients of water and blood, respectively. While the relationship

$$\dot{M}_{O_2} = \dot{V}W(CI_{O_2} - CE_{O_2}) = \dot{V}W\beta W_{O_2}(PI_{O_2} - PE_{O_2}) \qquad (5a)$$

$$\dot{M}_{O_2} = \dot{Q}(Ca_{O_2} - C\bar{v}_{O_2}) = \dot{Q}\beta b_{O_2}(Pa_{O_2} - P\bar{v}_{O_2}) \qquad (5b)$$

between concentration and partial pressure in water is linear, in blood it is nonlinear, as described by the oxygen-equilibrium curve. Therefore, βb_{O_2} should be thought of as the slope of the straight line connecting the venous and arterial point on the oxygen-equilibrium curve (**Figure 5**); however, this slope is not constant and depends upon the outcome of the gas-exchange process. Nevertheless, it is a useful way to proceed as seen below. To simplify, conductances for ventilation ($Gv = \dot{V}w\beta_{O_2}$) and perfusion ($Gp = \dot{Q}\beta_{O_2}$) can be included such that the oxygen flux can be described as the product of a conductance and a driving partial-pressure difference:

$$\dot{M}_{O_2} = Gv(PI_{O_2} - PE_{O_2}) \qquad (6a)$$

$$\dot{M}_{O_2} = Gp(Pa_{O_2} - P\bar{v}_{O_2}) \qquad (6b)$$

If we simplify the above equations by multiplying and dividing with the total partial pressure difference available to the gill, we obtain

$$\dot{M} = Gv\frac{(PI - PE)}{(PI - P\bar{v})}(PI - P\bar{v}) = Gv\varepsilon w(PI - P\bar{v}) \qquad (7a)$$

$$\dot{M} = Gp\frac{(Pa - P\bar{v})}{(PI - P\bar{v})}(PI - P\bar{v}) = Gp\varepsilon b(PI - P\bar{v}) \qquad (7b)$$

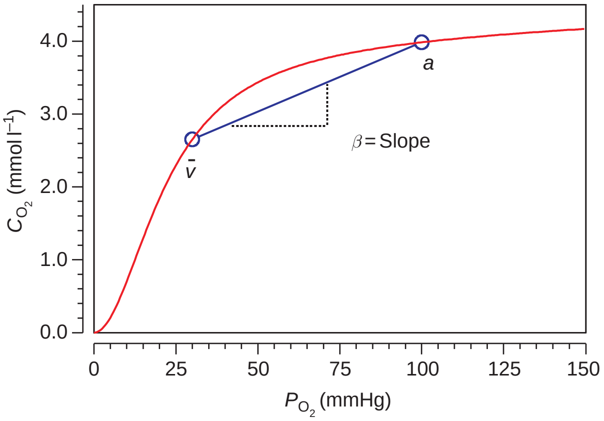

Figure 5 The oxygen-capacitance coefficient of blood βbo_2 can be calculated as the average slope of the oxygen-equilibrium curve between the venous and arterial values, that is, the slope of the secant line connecting them.

Now $\varepsilon w = (PI - PE)/(PI - P\bar{v})$ is the efficiency of the gill seen from the waterside. It expresses how well the ventilated water is deoxygenated by the gill. But, as opposed to the extraction coefficient, it takes into account the fact that PE can never go below $P\bar{v}$. Thus, if PE reaches $P\bar{v}$, the efficiency is 1, and if PE stays at PI, the efficiency is 0. Likewise, $\varepsilon b = (Pa - P\bar{v})/(PI - P\bar{v})$ is the efficiency of the gill seen from the blood side, and it expresses how well the blood is oxygenated by the gill. Obviously, the efficiency, ε_b, attains a value of 1 if $Pa = PI$ and a value of 0 if $Pa = P\bar{v}$. The efficiencies can also, appropriately, be termed the relative partial-pressure differences, because they represent the difference in partial pressure between the input and output on either of the sides viewed relative to the total difference available to the exchanger. From the above equations, it is apparent that the two efficiencies are not independent, that is, $Gv/Gp = \varepsilon b/\varepsilon w$. Thus, if $Gv > Gp$ then $\varepsilon b > \varepsilon w$ and vice versa. In the case where $Gv = Gp$, and therefore $\varepsilon b = \varepsilon w$, the exchanger is said to be matched (discussed in greater detail below).

One can derive an interesting connection between the extraction coefficient and the efficiency of the gill from the waterside:

$$\begin{aligned} E &= \frac{PI - PE}{PI} = \frac{PI - PE}{PI}\frac{PI - P\bar{v}}{PI - P\bar{v}} = \frac{PI - PE}{PI - P\bar{v}}\frac{PI - P\bar{v}}{PI} \\ &= \varepsilon w\frac{PI - P\bar{v}}{PI} = \varepsilon w(1 - P\bar{v}/PI) \end{aligned} \qquad (8)$$

Therefore, the extraction of oxygen from the water certainly depends not only on the performance of the gill as a gas exchanger, but also on the factor (1-Pv/PI), which is independent of the performance of the gill. The mixed-venous oxygen partial pressure, Pv, in the resting condition is species dependent and largely determined by the oxygen affinity of the blood. The higher the oxygen affinity, the lower the $P\bar{v}$ and thus the higher the extraction coefficient of oxygen.

The Efficiency of the Ideal Countercurrent Exchanger

The real fish gill is very complex, and a completely realistic model of gas exchange correspondingly so, with loss of generality as a consequence. A simple model that provides information about the performance, that is, the efficiencies of gas exchange, requires quite a few simplifications:

1. The blood and water flows are perfectly countercurrent and steady (no pulsatility).

2. Blood and water are separated by a uniform diffusion barrier.
3. In the water, as well as in the blood, there are only longitudinal gradients (i.e., no stratification).
4. The blood-gas-equilibrium curves are linear, and there is instantaneous equilibrium between the partial pressures and the concentrations (i.e., no reaction limitation).
5. All respiratory units (secondary lamellae and interlamellar water spaces) are ventilated and perfused at the same rate and have the same diffusion conductance (no $\dot{V}/\dot{Q}$ inequality).

Figure 6 is a graphical representation of such an idealized view of the gill. Performing a mass balance for any respiratory gas on a fine scale, as indicated in the figure, results in two, coupled first-order differential equations:

$$\frac{\mathrm{d}Pw}{\mathrm{d}l} = \frac{Gd}{Gv}(Pw - Pb) \tag{9a}$$

$$\frac{\mathrm{d}Pb}{\mathrm{d}l} = \frac{Gd}{Gp}(Pw - Pb) \tag{9b}$$

Table 2 How to calculate the efficiencies of countercurrent gas exchange

If Gv/Gp ≠ 1

$$\varepsilon b - \frac{Pa - Pv}{PI - P\bar{v}} = \frac{\frac{Gv}{Gp}\left(1 - e^{-\frac{Gd}{Gp}\left(1 - \frac{1}{Gv/Gp}\right)}\right)}{\frac{Gv}{Gp} - e^{\frac{-Gd}{Gp}\left(1 - \frac{1}{Gv/Gp}\right)}}$$

$$\varepsilon w - \frac{PI - PE}{PI - P\bar{v}} = \frac{1 - e^{-\frac{Gd}{Gp}\left(1 - \frac{1}{Gv/Gp}\right)}}{\frac{Gv}{Gp} - e^{\frac{-Gd}{Gp}\left(1 - \frac{1}{Gv/Gp}\right)}}$$

If Gv/Gp = 1

$$\varepsilon b = \varepsilon w = \frac{\frac{Gd}{Gp}}{1 + \frac{Gd}{Gp}}$$

These are obtained by simultaneously solving the two differential equations (9a) and (9b).
Note that at *Gv/Gp* = 1 the general expressions are undefined because both numerator and denominator are then zero.
The solution for the special case *Gv/Gp* = 1 can be obtained from any of the general expressions by applying L'Hospital's rule.

Solving this system of equations yields the partial pressures as a function of length (*l*) along the exchange surface (i.e., *Pw* = *Pw(l)* and *Pb* = *Pb(l)*) and once these (and thereby also the arterial and expired partial pressures, *Pa* and *PE*) are known, the efficiencies, can be calculated. These are listed in **Table 2** Also listed is the solution applicable in the special case of $Gv/Gp = 1$ where the general solutions are undefined. It is noteworthy that although there are three conductances involved (namely the convective, *Gv*, the perfusive, *Gp*, and the diffusive, *Gd*), the efficiencies are completely described by any two ratios of conductances that can be formed from these. As is customary, the solutions given in **Table 2** use the ratios Gd/Gp and Gv/Gp. It is, however, easy to replace one set of ratios with another, since, for example, $Gv/Gp = (Gd/Gp)/(Gd/Gv)$. As evident from **Figures** 7(**a**) and 7(**b**) an increase in the Gd/Gp ratio will increase either efficiency and thus generally improve the conditions for gas exchange. *Gd* for the gill as a whole is given by

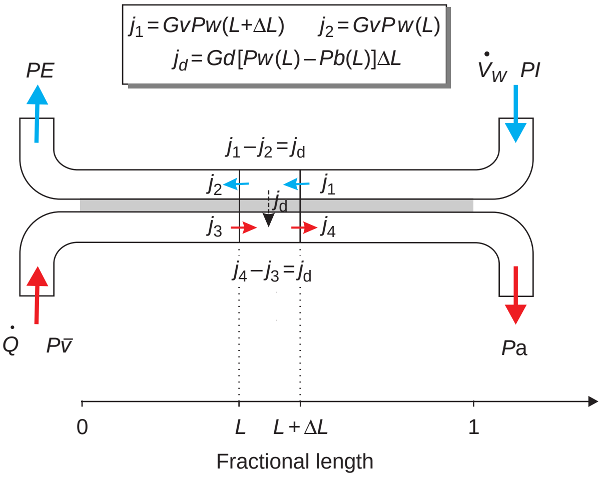

Figure 6 Model view of the gill, illustrating the fundamental mass balance on a small element. On the waterside, the equations of the mass balance have been indicated and letting the length of the element, Δ*L*, tend to zero, will lead to the differential equations (9a) and (9b).

$$Gd = \frac{KA}{t} \tag{10}$$

where *K* is Krogh's diffusion constant, *A* the area of the gill surface, and *t* the thickness of the diffusion barrier. Therefore, it makes perfect sense that an increase in *Gd* (e.g., by increasing area) relative to *Gp* (proportional to blood flow) will increase the performance of the gill as a gas exchanger. Note, however, that a decrease in *Gp* works equally well with respect to increasing efficiencies.

The dilemma of gas exchange in the gill (and any other gas-exchange organ) becomes immediately apparent when comparing how the efficiencies are controlled by the ventilatory to perfusive conductance ratio, Gv/Gp. When this ratio increases, the efficiency on the blood side goes up while that on the water side goes down and vice versa. So, increasing ventilation and thereby *Gv* will

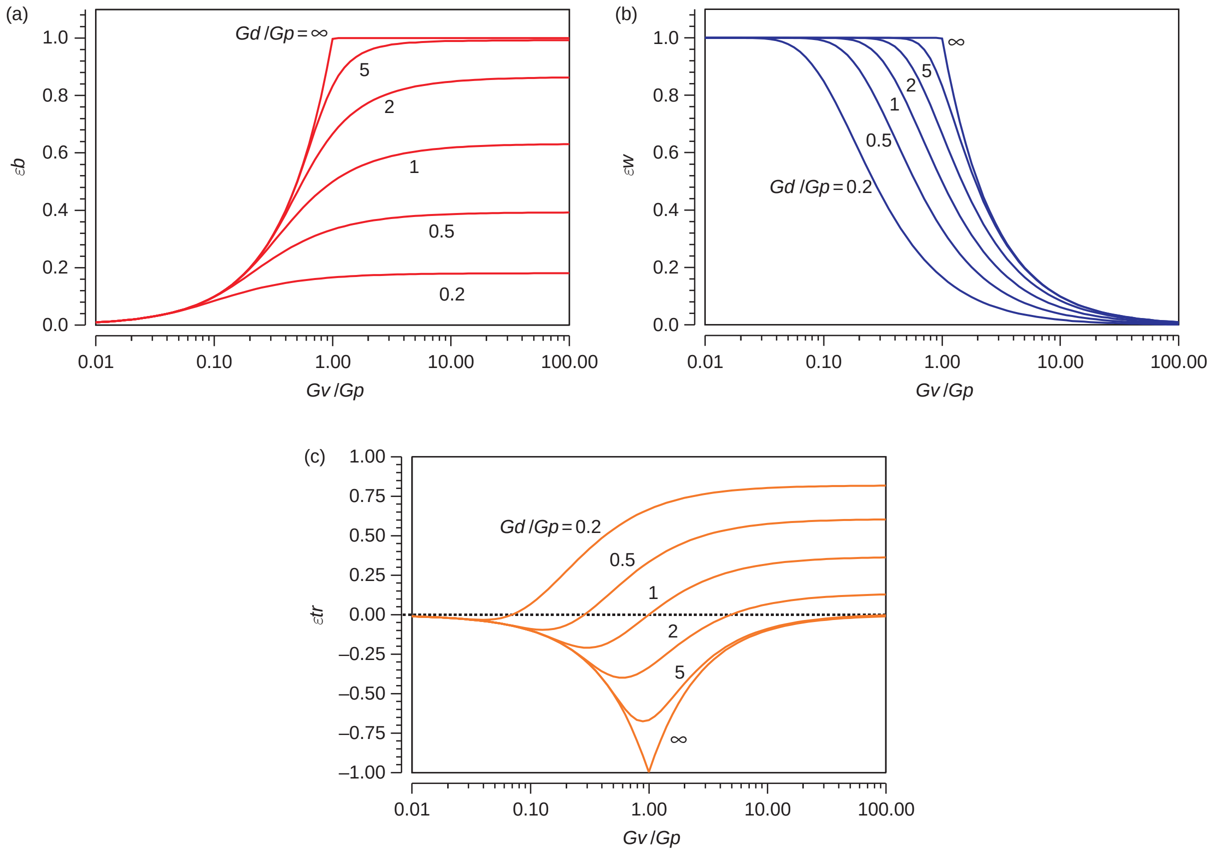

Figure 7 The efficiencies of gill gas exchange as a function of the two dimensionless conductance ratios *Gd/Gp* and *Gv/Gp*. At *Gv/Gp* = 1, the exchanger is matched and an increase in *Gd/Gp* at this point will eventually make the gill a perfect gas exchanger with maximal efficiency on both sides simultaneously. (a) The efficiency or relative partial pressure difference on the blood side, εb. (b) The efficiency or relative partial pressure on the waterside, εw. (c) The total transfer efficiency or partial pressure overlap, εtr. Note that an efficiency of 1 means 100% efficiency.

increase oxygenation of the blood but at the expense of the efficiency of exploitation of the ventilated water.

Inspection of the two figures, however, reveals that there exists one – and only one – perfect compromise where it is possible to have high efficiencies on both sides of the exchanger simultaneously. This compromise is at $Gv/Gp = 1$, and the exchanger is said to be matched at this point. In fact, as Gd/Gp tends toward infinity both efficiencies tend toward 1.0, and the perfect exchange is approached (i.e., the water gives up all its oxygen, and at the same time the blood comes into equilibrium with the inspired water). This situation is better appreciated in **Figure** 7(**c**), which shows $1-\varepsilon w-\varepsilon b$ a function of the conductance ratios. This is termed the total-transfer efficiency. From the definition of the efficiencies, it is given by

$$\varepsilon tr = 1 - \frac{PI - PE}{PI - P\bar{v}} - \frac{Pa - P\bar{v}}{PI - P\bar{v}} = \frac{PE - Pa}{PI - P\bar{v}} \qquad (11)$$

This can take on values from 1 to −1, and when the gill is matched and the diffusion to perfusion conductance ratio tends to infinity, a value of −1 is reached, which is total partial pressure overlap, that is, $Pa = PI$ and $PE = P\bar{v}$. This means that the gill, in theory, is a perfect gas exchanger, provided its ventilation and perfusion are properly matched. This situation comes about entirely due to the countercurrent-exchange principle, which is the only exchange principle that allows for perfect exchange. Thus, even though the bird lung, with its crosscurrent exchange, is very efficient, and may be an important component that allows the bar-headed goose to fly over the Himalayas, it still lags behind the fish gill.

Efficiency versus total exchange

High efficiency of gas exchange is important to minimize the costs of the ventilatory and circulatory pumps. However, there are many situations where total exchange is more important than efficiency, and often the adjustments necessary to increase or to maintain exchange will actually decrease efficiency. The total exchange can be expressed as the product of a total conductance and the total partial pressure difference available to the gill:

$$\dot{M} = G\mathrm{tot}(PI - P\bar{v}) \qquad (12)$$

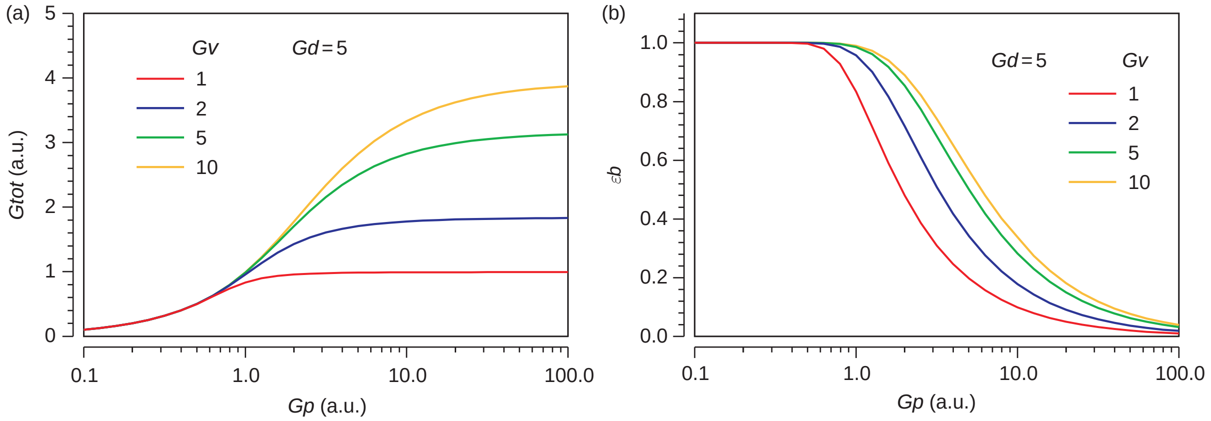

Figure 8 The simultaneous changes in the total conductance (a) and in the efficiency on the blood side (b) resulting from varying the perfusion conductance (G_p) while keeping the diffusion (G_d) and ventilation (G_v) conductances constant.

From eqns (7a) and (7b), it can be seen that the total conductance can be expressed in either of two ways:

$$\mathrm{Gtot} = Gv\varepsilon w = Gp\varepsilon b \qquad (13)$$

As evident, the total conductance depends on the efficiency as well as directly on a conductance in itself. **Figures 8(a)** and **8(b)** illustrate the difference between the total conductance and the efficiency. In **Figure 8(a)**, the total conductance increases as *Gp* increases at four values of *Gv* and one value of *Gd* (all in arbitrary units). At the same time, the efficiency on the blood side of the exchanger actually decreases. Thus, it is possible to increase oxygen uptake over the gill while the exchange efficiency on the blood side decreases. In this particular example, we varied *Gp* which is proportional to cardiac output, but this applies in general and it is important to realize

1. An increase in any of the three conductances alone, or in any combination with any of the other conductances, will always lead to an increase in the total conductance and thereby exchange.
2. This may, at the same time, lead to increases, decreases, or maintenance of the status quo in the efficiencies.

These statements are even more fundamental than it first might seem, because they will apply to any exchange system provided that the blood-gas-equilibrium curves are thermodynamically possible. Thus, in any organism, regardless of the exchange system or oxygen-equilibrium curve and in terms of total exchange between the organism and the surroundings, it never can be advantageous to decrease blood flow, even though this may increase the efficiency.

The effect of the nonlinear nature of the blood-gas-equilibrium curve

The gas-equilibrium curves of blood are nonlinear, and more so for oxygen than for carbon dioxide (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). Thereby *Gp* (for CO_2 as well as for O_2) is no longer a constant, but depends on *Pb*, that is, $Gp(Pb) = \dot{Q}(\partial Cb/\partial Pb)$, where $Cb = Cb(Pb)$ is a function describing the oxygen-equilibrium curve. This generally makes it impossible to solve the differential equations given in eqns 9(a) and 9(b). They may, however, be solved numerically. The nonlinear nature of the oxygen-equilibrium curve has the consequence that, for the same overall (or average) capacitance coefficient, it is more efficient than a linear relationship. This is because the concave shape of the oxygen-equilibrium curve increases the overall partial-pressure difference between water and blood. This is illustrated in **Figure 9(a)**, which shows the calculated oxygen-partial-pressure profiles along the exchange surface in the linear and the nonlinear cases with an identical average capacitance coefficient for oxygen. Along most of the surface, the oxygen partial pressure is kept lower in the nonlinear case, but eventually it exceeds that of the linear case. The greater exchange is, of course, reflected on the waterside of the exchanger where Po_2 falls more steeply and ends at a lower expired Po_2. **Figure 9(b)** shows how this is translated to a Cbo_2 versus Pbo_2 plot. Starting from the same venous point, and with the same average oxygen capacitance coefficient, the arterial oxygen concentration as well as the partial pressure ends at a lower value. The greater the concaveness of the oxygen-equilibrium curve followed during exchange, the greater the benefits. This concaveness, in turn, is determined by the sigmoidicity (the degree of S-shape) of the oxygen-equilibrium curve.

While, in this way, the shape of the oxygen-equilibrium curve affects the efficiency of exchange in the gill, its position, usually defined by the P_{50} (the partial pressure at which the hemoglobin is 50% saturated with O_2), is also very important. The P_{50} affects the overall efficiency of oxygen removal from the water (i.e., the extraction

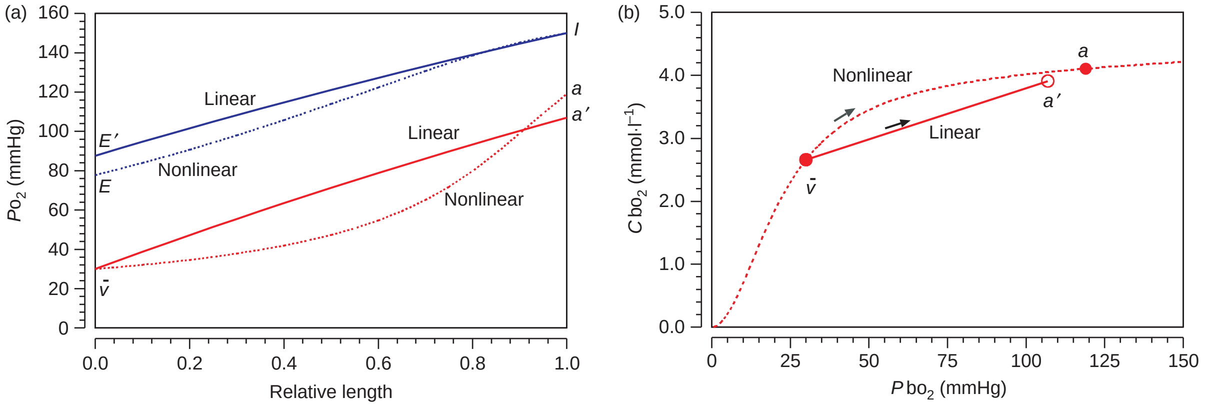

Figure 9 Comparison of oxygen exchange in the gill with linear vs. nonlinear oxygen-equilibrium curves. (a) Oxygen partial pressure profiles in water (blue) and blood (red) along the length of the exchange surface in the event of a linear (fully drawn lines) or nonlinear (broken lines) oxygen-equilibrium curve. The mixed-venous and inspired points are input parameters in the calculation, whereas the arterial and expired points are the results. (b) The nonlinear oxygen-equilibrium curve used in the calculation of the profiles of this example (P_{50} = 22 mmHg, n_H = 2.0) with the mixed-venous and arterial points plotted in. When exchanging oxygen along a linear curve connecting the mixed-venous and arterial points, the resulting arterial point, a′, is at a lower partial pressure and a lower concentration.

coefficient). The higher the hemoglobin-oxygen affinity (the lower the P_{50}), the lower the mixed-venous Po_2 will tend to be, as is evident from eqn (8), and this will tend to increase the extraction coefficient. Thus, common carp, which has a high blood-oxygen affinity relative to that of rainbow trout, has a much higher oxygen-extraction coefficient. This has been shown to be entirely attributed to the differences in the oxygen-equilibrium curves.

For CO_2, the same analysis applies but, because its blood equilibrium curve is much closer to a straight line than that for oxygen, the nonlinearity is of much less significance. In fact, a linear relationship is quite predictive for CO_2.

The effects of pulsatile flow

The gill ventilation by the buccal and opercular pumps as well as cardiac pumping are cyclic processes and the driving pressure differences across the gill for both water and blood are pulsatile as a result. Detailed analyses of the relation between pressure and flow on the waterside as well as on the blood side of the gill indicate that if pressure is highly pulsatile, then so is flow. Everything else being equal, this is expected to decrease the efficiency of gas exchange in the gill, which is also what one finds when modeling this. The degree to which efficiency is reduced is, however, surprisingly small in most fishes including the salmonids and the cyprinids. Only in tunas and mackerels, which have very thin water–blood diffusion barriers and narrow interlamellar water spaces, does this seem to be of significance. In fact, calculations indicate that, for these groups, pulsatility could have a serious impact on the efficiency of gas exchange. Interestingly, these species tend to ram-ventilate (eliminating pulsatility of the water flow but not blood flow), which more or less eliminates the problem.

The effect of parallel imhomogeneities

The gill consists of an immense number of gas-exchange units and, as in mammals, an uneven distribution of the ventilation, perfusion, and diffusion conductances among the units will decrease efficiency compared to the situation with the same overall conductances evenly distributed among the respiratory units. Theoretically, this effect can be serious and more so for oxygen exchange than carbon dioxide, which is due to the greater concaveness of the oxygen-equilibrium curve over the range of exchange. In practice, nothing is known about the degree of inequality in living fishes, but it is probably not as important as in mammals, where gravity effects make it much more difficult to achieve homogeneity.

Glossary

Aerobic metabolism The generation of metabolic energy where oxygen acts as the final electron acceptor.

Ammonotelic Organisms in which ammonia is the dominant form of nitrogen excretion.

Anaerobic metabolism The generation of metabolic energy by processes that do not require oxygen.

Anoxia The complete absence of dissolved oxygen in water.

Carbonic anhydrase A family of enzymes that reversibly catalyze the conversion of carbon dioxide to carbonic acid.

Conductance The measure of the ease with which a gas moves from one compartment to another. G_x in the gas transfer equation $G_x = M_x/\Delta P_x$, where M_x is the rate of transfer and ΔP_x the partial pressure gradient.

Convection Bulk movement of a medium, e.g., gas, water, or blood.

Diapause A period of quiescence in animals, characterized by cessation of growth and reduction in metabolic activity.

Diffusion Net movement of a solute from an area of higher concentration to an area of lower concentration.

Diffusive boundary layer The layer of semi-stagnant water adjacent to the surface of a gas exchanger in which substances (e.g., dissolved gases) either become depleted or accumulate depending on the direction of net flux.

Egg capsule The nonliving shell encapsulating the eggs of oviparous fish species. It is also called the zona radiata or chorion (although not homologous with the chorion of amniotes).

Forced convection Convection brought about by the action of some external agent (e.g., hydraulic pressure and mechanical energy).

Gas exchanger A structure or region of the body surface heavily involved in and often specialized for respiratory gas exchange.

Metabolic intensity The rate of energy utilization per unit mass (also called mass-specific metabolic rate).

Metabolic rate Energy utilization per unit time.

Natural convection Convection due to density differences in the medium (also called free convection).

Partial pressure The pressure exerted by a particular gas in a mixture of gases.

Perfusion The internal circulation of body fluids.

Perivitelline fluid The fluid in the perivitelline space between the egg capsule and the egg proper (which initially is bounded by the vitelline membrane, hence the name).

Proton trapping The conversion of a lipid-soluble compound (e.g., NH_3) into a water-soluble compound (e.g., NH_4^+) by the addition of a proton. This prevents the water-soluble compound from crossing the plasma membrane by simple diffusion, effectively trapping it on that side of the membrane.

Resistance The sum of the impediments to fluid flow, resistance is increased by vessel length, fluid viscosity, and decreased by increased vessel radius.

Respiratory cascade A model of gas exchange in which gas is viewed as flowing through a series of resistances from the environment to the tissues or vice versa. The model is based on the analogy of water flowing down a series of cascades with the difference being that gas flow is driven by differences in partial pressure rather than gravity.

Rhesus (Rh) glycoproteins Membrane protein that facilitates ammonia transfer.

Temperature–oxygen squeeze The progressive decrease in the effective availability of O_2 experienced by aquatic organisms when faced with rising temperatures. This squeeze occurs because metabolic demand for O_2 increases but O_2 solubility in water decreases as temperature rises.

Ventilation The movement of the respiratory medium (air or water) over the surface of the gas exchanger.

Ventilation–perfusion ratio The flow rate of the respiratory medium through or over the gas exchanger divided by the flow rate of the blood perfusing the gas exchanger.

Respiratory Gases

Developing fish, like adults, depend primarily on aerobic metabolism to support cellular processes. Aerobic metabolism requires a steady supply of oxygen from the environment to the tissues where it serves as the final electron acceptor in the mitochondrial electron-transport chain (**see also Tissue Respiration**: Mitochondrial Respiration). Two gases, carbon dioxide and ammonia, are produced in the tissues as waste products of fuel catabolism. Both gases are toxic and must be removed from the body. In terms of quantity, oxygen exchange is greatest, followed by carbon dioxide and then ammonia. Molar exchange ratios vary depending on species, stage, and diet but for most developing fish they fall in the range of 1.0 for O_2, 0.8–0.9 for CO_2, and 0.05–0.15 for NH_3.

The absolute rate of oxygen consumption typically increases by several orders of magnitude during the course of embryonic and larval development as a direct consequence of the increasing size of the tissue mass (**Figure 1**). Consequently, rates of O_2 consumption are frequently expressed on a mass-specific basis by dividing total O_2 consumption by tissue mass. This measure, termed mass-specific metabolic rate or metabolic intensity, allows the investigator to compare rates of O_2 consumption across different developmental stages. Even so, metabolic intensity typically varies three- to fivefold during the course of embryonic and larval development. This variation appears to be associated with specific developmental events. For example, metabolic intensities are particularly high during epiboly, low just before hatch, and high again toward the end of endogenous feeding. In most species, there does not appear to be any significant trend with respect to age or its covariate, body mass.

Ontogenetic patterns of CO_2 and NH_3 production would be expected to mirror that for O_2 consumption, but with some minor differences reflecting stage-specific differences in energy sources (that would affect molar exchange ratios) and the relative importance of urea versus ammonia as an excretory product for nitrogenous wastes (see below). To date, no one has actually measured CO_2 production throughout the course of development. NH_3 production has been determined in very few cases compared with O_2 consumption, and behaves more or less as expected.

Fish have some capacity for anaerobic metabolism during embryonic and larval development, but the capacity is severely limited by a small carbohydrate reserve (typically <3% of total yolk energy). Carbohydrates are the major fuel during anaerobic metabolism. Some species appear to be able to catabolize amino acids anaerobically, but this ability is probably not widespread. Embryos of some species can tolerate extended periods in complete anoxia, but they do so by entering a hypometabolic state that precludes further development until O_2 is available again. Anoxic tolerance of species that do not normally enter diapause tends to decrease as development proceeds.

Properties of Respiratory Gases in Aqueous Solutions

The concentration of dissolved gas in an aqueous medium is described by Henry's law:

$$C = \alpha P \tag{1}$$

where C is the molar concentration, P the partial pressure, and α the solubility coefficient. Ammonia is the most water soluble of the three major respiratory gases, followed by CO_2 then O_2. Relative solubilities at 20 °C are 22 783 for NH_3, 27.8 for CO_2, and 1.0 for O_2. Gas solubility decreases with increasing temperature, with the effect being somewhat greater for CO_2 than O_2. The magnitude of the temperature effect is relatively large. Water can only hold

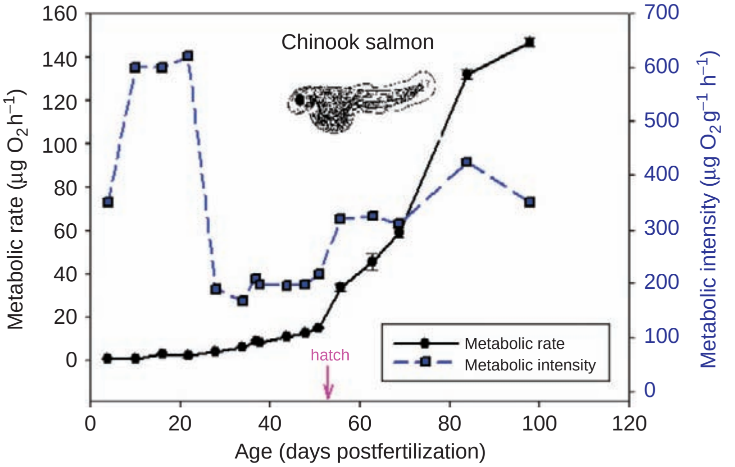

Figure 1 Changes in metabolic rate and metabolic intensity (mass-specific metabolic rate) with age for embryos and endogenous feeding larvae of Chinook salmon at 10 °C. Data from Rombough PJ (1994) Energy partitioning during fish development: additive or compensatory allocation of energy to support growth? *Functional Ecology* 8: 178–186.

~53% as much O_2 and ~38% as much CO_2 at 30 °C as at 0 °C. The lower solubility of O_2 at higher temperatures, in particular, has important physiological consequences. A rise in temperature increases metabolic demand for O_2, but reduces its availability in the environment. It has been proposed that the resulting temperature-oxygen squeeze is what ultimately sets the upper limit of thermal tolerance in fish (**see also Temperature**: Effects of Climate Change and **Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature.

The capacity of developing fish to extract O_2 from the environment is generally less than that of adults, which may partially explain their lower thermal tolerance (other factors such as limited capacities for homeoviscous adaptation (**see also Temperature**: Membranes and Temperature: Homeoviscous Adaptation) and isozyme switching are also important).

Gas solubility normally decreases with increasing salinity. The solubility of O_2 in seawater (35 ppt) is ~81% of that in pure water at 20 °C. This means that marine fish have access to less O_2 than freshwater fish, under air-saturation conditions. It also means that blood plasma (osmolarity ~300–350 mOsm) can hold somewhat less dissolved gas than pure water (~90% for O_2 at 20 °C). Ammonia is somewhat unusual for gases in that its solubility increases slightly with increasing salinity. The solubility of NH_3 in plasma is ~3.4% greater than that in pure water.

The behavior of CO_2 and NH_3 in an aqueous medium is more complex than O_2. In the absence of a specific carrier molecule such as hemoglobin, O_2 is present only in its dissolved form, $O_2(g)$, and is subject to Henry's law. CO_2 and NH_3, in contrast, can combine with water to form ionic compounds that are not subject to Henry's law. When $CO_2(g)$ combines with water, it forms carbonic acid which then dissociates into the bicarbonate ion and a proton: $CO_2(g) + H_2O \Leftrightarrow H_2CO_3 \Leftrightarrow HCO_3^- + H^+$. At high pH, the bicarbonate ion can further dissociate into the carbonate ion and another proton: $HCO_3^- \Leftrightarrow CO_3^{2-} + H^+$. The relative concentrations of the various forms depend on the pH of the solution and the presence of various buffers and carrier molecules. At physiologic pH, the dominant form is HCO_3^- (80–90% of total CO_2). Dissolved CO_2 typically represents only a small fraction of the total amount of CO_2 in solution (<5% in plasma) (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion). Ammonia can bind with protons in water to form the ammonium ion: $NH_3 + H_3O^+ \Leftrightarrow NH_4^+$. At physiologic pH, the ionized form (NH_4^+) is dominant (>98% total). This is fortuitous because the NH_4^+ is much less toxic than NH_3 (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia and Ureotelism).

The Respiratory Cascade

The underlying principles governing gas exchange during development are the same as those that apply to juveniles and adults (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). The concept of a respiratory cascade is often used to describe the flow of gases between the environment and the tissues (**Figure 2**). This concept breaks overall gas exchange into a series of steps involving diffusive or convective

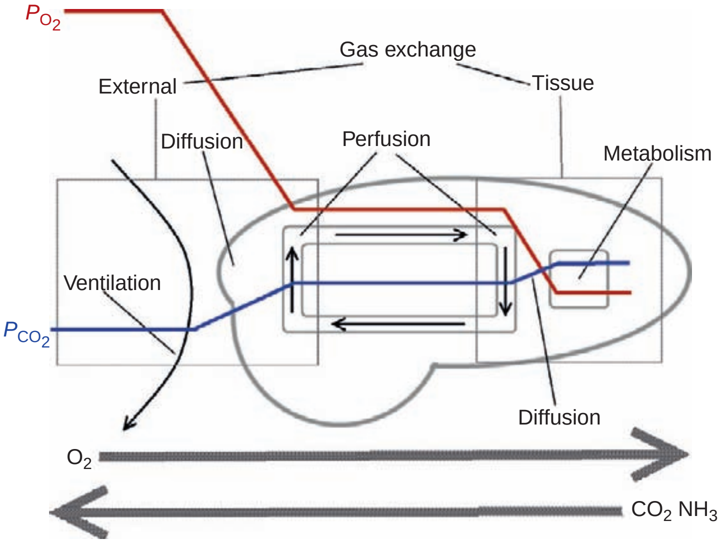

Figure 2 Schematic diagram showing the respiratory cascade for a fish larva. Gas transport is by diffusion and convection. Diffusion takes place externally at the level of the gas exchanger and internally at the tissues. Convection in the external medium is termed ventilation, while movement of the blood is termed perfusion. Diffusion is driven by differences in partial pressure with the direction of the gradient depending on the gas (shown by the large arrows). Representative partial-pressure gradients are shown for O_2 and CO_2. Gradients illustrate general trends and are not to scale (see text for representative ΔP's). Modified from Piiper J (1982) Respiratory gas exchange at lungs, gills and tissues: Mechanisms and adjustments. *Journal of Experimental Biology* 100: 5–22.

transport. In well-developed actively-ventilating larvae, as in adult fish, there are generally considered to be four steps in the respiratory cascade. For O_2 these steps would be: (1) bulk fluid to surface of gas exchanger (skin or gill); (2) surface of gas exchanger to blood in gas exchanger; (3) blood in gas exchanger to blood in tissue; and (4) blood in the tissue to the mitochondrion. Flows of CO_2 and NH_3 would be in the opposite direction. Steps 1 and 3 involve convective transport, while steps 2 and 4 involve diffusive exchange. Gas flux through the system is driven by differences in partial pressure (ΔPx). The total partial pressure difference across the whole system varies depending on the gas, stage of development, and activity (among other things) but generally would be expected to fall in the range of ~100–150 torr (= mmHg) for ΔP_{O2}, ~2 torr for ΔP_{CO2}, and $\sim 20 - 50\,\mu$torr for ΔP_{NH3}.

Dissecting the respiratory cascade is somewhat more complicated for embryos because of the presence of the egg capsule (also called the chorion or zona radiata) and the fact that for about the first one-third of embryonic development there is no blood circulation. The space between the egg capsule and embryo is filled with perivitelline fluid (PVF) that is not stirred generally for the first one-third or so of embryonic development. The extent to which the PVF is stirred during later embryonic stages is variable, depending on factors such as species, temperature, dissolved-O_2 level, and pH. If the PVF is unstirred and there is no blood circulation, the respiratory cascade is essentially reduced to two steps: (1) convective exchange in the bulk fluid and (2) diffusion from the egg capsule through to the mitochondrion. If PVF is stirred and blood is circulated, the respiratory cascade consists of up to six steps: (1) external convection in the bulk medium, (2) diffusion through the egg capsule, (3) convection in the PVF, (4) diffusion through the gas exchanger, (5) internal convection in the blood, and (6) diffusion through the tissues.

Respiratory cascades can be further subdivided if the investigator wishes to look at what is happening in finer detail. One such subdivision that is particularly important during development is the diffusive boundary layer (DBL). The DBL is a layer of semi-stagnant fluid immediately adjacent to a surface such as the skin, gill, or egg capsule. Depending on the direction of flux, gases accumulate or become depleted in this layer. For example, O_2 levels in the DBL adjacent to the skin of a fish larvae would tend to be lower than the free-stream value (**Figure 3**), while CO_2 and NH_3 levels would tend to be

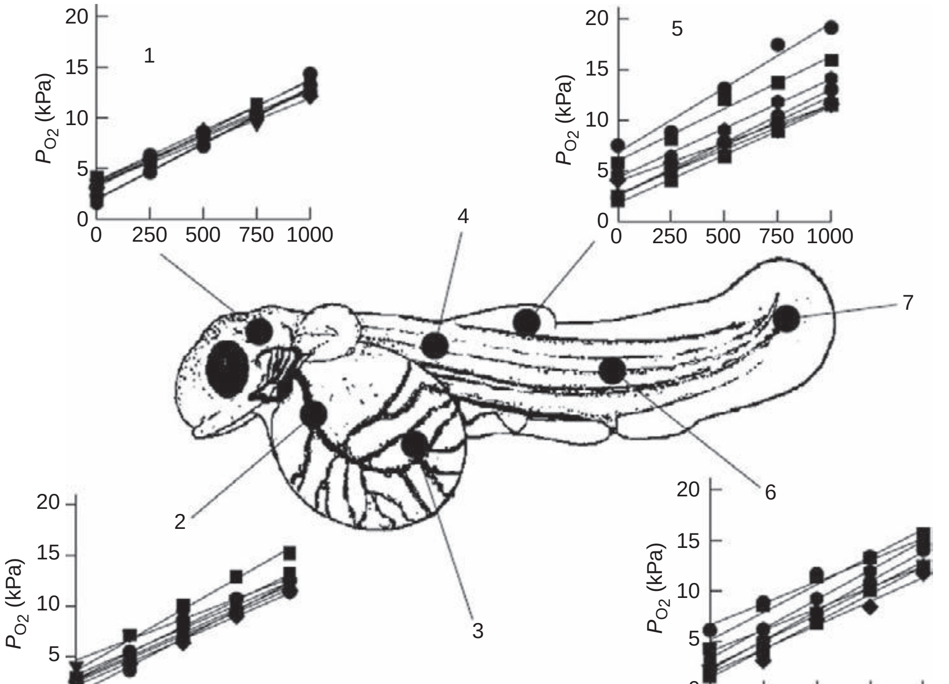

Figure 3 Oxygen partial pressure (P_{O2}) in the DBL surrounding a newly hatched rainbow trout larva in still water. Graphs show values at various distances from the skin surface for seven to eight individuals at locations 1, 2, 5, and 6. Results were similar at locations 3, 4, and 7. The free-stream value >1 cm from the body surface was 20.9 kPa (157 torr). Data from Rombough PJ (1998) Partitioning of oxygen uptake between the gills and skin in fish larvae: A novel method for estimating cutaneous oxygen uptake. *Journal of Experimental Biology* 201: 1763–1769.

higher. Boundary-layer thickness is usually defined as the distance from the boundary surface to where velocity is 99% of the free-stream value. The thickness (*d*) of this layer is proportional to $v^{-1/2}$, where v is the bulk velocity of the fluid flowing past the surface. The exception is where the bulk flow of fluid is constrained by channeling or some similar process, in which case the thickness of the boundary layer cannot exceed half the channel width (e.g., between adjacent gill lamellae). DBLs are present on both sides of a barrier. The thickness of the layer on a given side will depend on the bulk flow rate on that side and the degree of channeling. In the case of most external gas exchange surfaces (e.g., skin or gills), the thickness of the boundary layer at the outer surface is very much greater than at the inner surface. In these cases, the resistance to flux imparted by the inner layer is usually included with the resistance of the gas exchanger. An exception to this would be the egg capsule when both the bulk medium and the PVF are stirred. In this case, there could be a substantial DBL adjacent to the inner as well as outer surface of the capsule. External boundary layers can have a substantial impact on diffusive gas exchange (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs and Respiratory Gas Exchange During Development: Respiratory Transitions).

Diffusion

The planar diffusion of a gas is described by the Fick equation

$$\mathcal{J} = KA(\Delta P/\delta) \qquad (2)$$

where $\mathcal{J}$ is the rate of gas transfer, K the Krogh constant of diffusion, A the area, ΔP the partial pressure gradient, and δ the diffusion distance. Krogh's constant of diffusion is the product of the diffusion coefficient (D) and the Bunsen capacitance coefficient (α).

The diffusion of each gas in a mixture of gases is independent of other gases when it is in the gaseous or dissolved form. However in an aqueous medium, the dominant forms of CO_2 and NH_3 are not as dissolved gas, but in the form of ions (i.e., as HCO_3^- and H^+ or NH_4^+). This makes it possible for the diffusion of these gases to be linked indirectly via chemical reactions between the various ions and/or charge coupling. At this juncture, it is worth pointing out that the movement of ionic compounds such as HCO_3^- and NH_4^+ depends on the electrical as well as the concentration gradient (i.e., the electrochemical gradient). This complication is usually ignored when considering the bulk transfer of respiratory gases but becomes important when considering the implications of gas movement on acid–base balance and ion exchange.

Diffusion in Aqueous Media

Values for D, α, and K for O_2 and CO_2 in pure water at 20 °C are given in **Table 1**. The rate of diffusion in water is inversely proportional to the size of the molecule, which explains the lower diffusion constant for CO_2. The aqueous diffusion coefficient for NH_3 in water is similar to that for CO_2. Values for D of both O_2 and CO_2 increase $\sim 2\%\ °C^{-1}$ due to increased kinetic energy. As mentioned, CO_2 is more soluble in water than O_2 (i.e., $\alpha_{CO2} > \alpha_{O2}$) and displays greater temperature sensitivity. Krogh's constant of diffusion increases with increasing temperature at a rate of $\sim 1\%\ °C^{-1}$ for O_2 but decreases at approximately the same rate for CO_2. K for CO_2 at 0 °C is ~25 times that for O_2; the difference at 30 °C is ~18-fold. The higher K value for CO_2 has important physiological consequences. Given the same partial pressure gradient and resistance, CO_2 will diffuse 18–25 times as fast as O_2. This keeps internal P_{CO2} low (typically 2–5 torr in adult fish; values for developing fish have not been determined) and means that O_2 uptake is far more likely to become limiting than CO_2 excretion (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). The extremely high solubility of NH_3 keeps internal P_{NH3} very low, in the range of 50 μtorr in adult fish (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia). P_{NH3} values in the yolk of rainbow trout *Oncorhynchus mykiss* embryos have been reported to be in the range of 10–25 μtorr.

Table 1 Physicochemical parameters for oxygen and carbon dioxide in pure water at 20 °C

Gas	*D (10^{-5} cm^{2}s^{-1})*	*α (nmol cm^{-3} torr^{-1})*	*K (10^{-5} nmol cm^{-1} s^{-1} torr^{-1})*
O_2	2.5	1.82	4.6
CO_2	1.82	51.4	93
CO_2/O_2	0.73	28.2	20.2

D is the diffusion constant, α the Bunsen solubility coefficient, and *K* the Krogh's constant of diffusion.

Diffusion through Membranes

The basic principles governing the diffusion of gases through biological membranes are the same as those for diffusion in an aqueous medium. However, rates of diffusion can be quite different in the two media because of differences in the solubility of gases in the lipid (membrane) and aqueous (water) phases. This is reflected in different values for Krogh's coefficient in the two media. Transport of CO_2 and NH_3 across membranes is potentially problematic because the dominant forms of both gases are ionic: HCO_3^- for CO_2 and NH_4^+ for NH_3. Ions are strongly hydrophilic and, as a result, have low intrinsic membrane permeabilities. Rapid transport of these compounds across membranes requires that they be converted to a more lipid-soluble form or have their movement facilitated by a specific transport carrier.

Oxygen

As far as we know, O_2 only moves across cell membranes by diffusion. Empirically determined values for K_{O2} for tissues of adults of lower vertebrates are typically about one-third the value for K_{O2} in pure water. This value is generally what has been applied to developing fish. However, a recent estimate based on measurements in zebrafish *Danio rerio* embryos suggests that the K_{O2} for embryonic tissue may actually be quite close to the K_{O2} for water. Interestingly, there have been a couple of reports that the K_{O2} for yolk is higher than that for water. The reason for this is unclear. One potential explanation has to do with the high lipid content of yolk. O_2 is considerably more soluble in lipid than in water. A higher K_{O2} for yolk, if confirmed, would mean that the yolk lipids may actually facilitate O_2 transport to embryonic tissues. This could be particularly important prior to the onset of blood circulation.

Carbon Dioxide

Like O_2, CO_2 is highly soluble in lipid and should cross plasma membranes readily. The problem is that most of the CO_2 in internal fluids is in the form of dissociated H_2CO_3. Neither HCO_3^- nor H^+ can cross membranes readily (at least not without the aid of specific transporters). To cross membranes fast enough to keep up with the rate of production, H_2CO_3 must be dehydrated to dissolved CO_2 which can then diffuse across the membrane (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion). This process requires the presence of the enzyme carbonic anhydrase (CA; **see also Transport and Exchange of Respiratory Gases in the Blood**: Carbonic Anhydrase in Gas Transport and Exchange), which catalyzes the reaction $CO_2(g) + H_2O \Leftrightarrow H_2CO_3$. Fish express multiple isoforms of CA (at least 16 in zebrafish). The precise roles of the various isoforms are not well understood, but some appear to be involved primarily in CO_2 transport and excretion, some in acid–base balance and ion exchange, and some in other specific processes. The situation is complicated by the fact that CO_2 excretion, acid–base balance, and ion exchange are all intimately interconnected.

In adult fish, CO_2 diffuses out of the tissues into the blood stream where most of it enters red blood cells (RBCs) (**Figure 4**; **see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). Inside the RBC, CA catalyzes the hydration of CO_2 to H_2CO_3, which then dissociates into HCO_3^- and H^+. The H^+ ions are buffered by hemoglobin, while the HCO_3^- ions leave the RBC through electroneutral Cl^-/HCO_3^- exchangers. A small amount of CO_2 also appears to be hydrated under the influence of CA in the interstitial fluid. HCO_3^- dissolved in the blood plasma is transported to the gas exchanger, where the process is reversed. HCO_3^- re-enters the RBC and combines with H^+ to form H_2CO_3, which is then dehydrated to CO_2 in the same CA-catalyzed reaction. The CO_2 diffuses down its partial-pressure gradient out of the RBC and across the respiratory epithelium. Some of the CO_2 that enters the external boundary layer is hydrated to HCO_3^- and H^+, where the H^+ may play a role in proton trapping of NH_3. CA activity has been reported in the boundary layer of some species.

It generally has been assumed that the process of CO_2 excretion is similar for developing and adult fish. This is probably true once fish begin to produce hemoglobin. As noted above, hemoglobin inside RBCs plays a central role in adult fish. The problem is that some fish do not start to produce appreciable amounts of hemoglobin until near the end of the larval stage. Even with species such as zebrafish that begin hemoglobin production at a relatively early age (~24 h postfertilization, hpf), there is still a period when neither hemoglobin nor red cells are present. How CO_2 is transported from the tissues to the gas exchanger during this period is unknown. A clue might reside in the apparent high buffering capacity of embryonic tissue, approximately twice that of adult muscle in the case of early zebrafish embryos. Another possibility is that tissue or extracellular CA plays a larger role. Developing fish appear to initiate CA production at an early age. In zebrafish, at least four CA isoforms are expressed by the time the blood begins to circulate. One of these, CAb, which is involved in catalyzing CO_2 hydration/dehydration reactions in RBCs of adult fish, is present as early as 8 hpf (i.e., well before the differentiation of RBCs). Precisely how or even if CAb is involved in CO_2 excretion at such an early age is not known. Based on changes in the respiratory exchange ratio for O_2 and CO_2, CA appears to begin to play an important role in CO_2 excretion in zebrafish between 24 and 48 hpf. Blocking CA activity with various inhibitors at 48 hpf resulted in an approximately 50% reduction in the rate of CO_2 excretion.

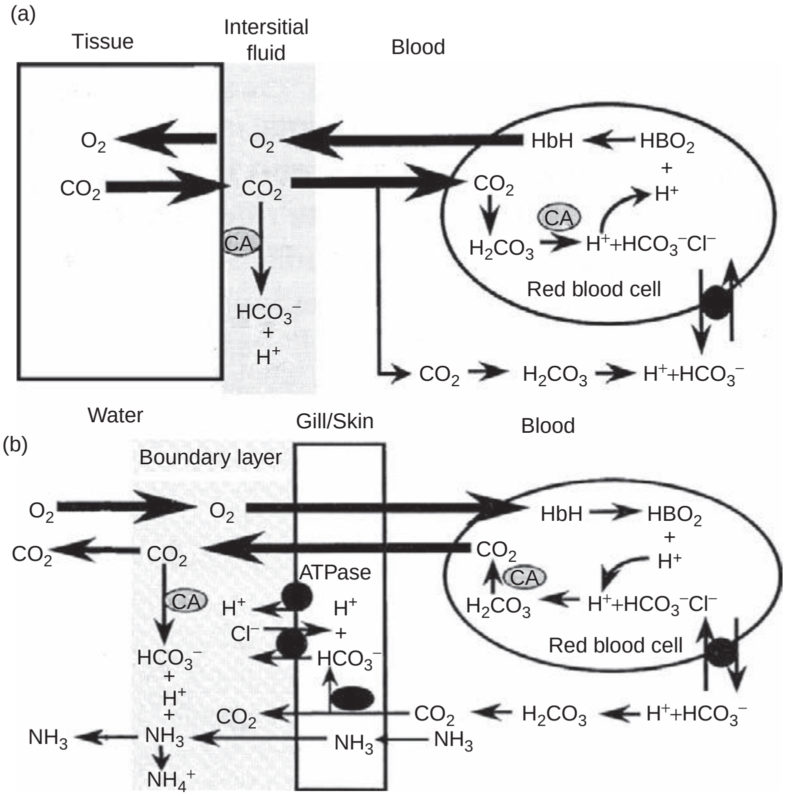

Figure 4 CO_2 excretion in adult fish. (a) Exchange at the tissues. (b) Exchange at the gills or skin. HbH and HBO_2 are deoxygenated and oxygenated hemoglobin, respectively. The enzyme CA catalyzes the hydration/dehydration of CO_2. CO_2 and O_2 transport by Hb are linked by the reciprocal Bohr and Haldane effects. Proton trapping of NH_4^+ in the external boundary layer is a potential linkage between CO_2 and NH_3 transport. Processes are thought to be similar during early life. Modified from Tufts B and Perry SF (1998) Carbon dioxide and acid–base balance. In: Perry SF and Tufts BL (eds.) *Fish Respiration*, pp. 229–281. San Diego, CA: Academic Press.

There has been some speculation in the literature that transport proteins/channels similar to those involved in ammonia transport (see below) may facilitate the transmembrane transport of CO_2. However, recent empirical studies of artificial and natural membranes indicate that simple diffusion through the phospholipid bilayer can fully account for observed CO_2 membrane permeabilities. These studies have shown that the rate-limiting step in transmembrane transport is the near-membrane boundary layer, not the membrane itself.

Ammonia

Dissolved NH_3 can cross membranes by simple diffusion through the lipid bilayer. Ammonia, however, is not particularly soluble in lipid (the oil/water partition coefficient for NH_3 is ~ 1/750 that for CO_2). The impact of this low lipid solubility can be ameliorated to some extent by acid trapping in the external boundary layer, where NH_3 picks up a proton and is converted to NH_4^+. This helps maintain the NH_3 partial pressure gradient across the membrane. Another means of circumventing low lipid solubility is the use of specific membrane transporters (**Figure 5**). This appears to be the major role of the Rhesus (Rh) glycoproteins. Rh proteins are widely distributed in aquatic organisms, including fish, where they appear to facilitate NH_3 transport in a manner similar to the way aquaporins facilitate water transport. Finally, ammonia may be excreted as the ammonium ion either directly as appears to be the case in some marine fishes or coupled to Na^+ uptake, which appears to be more widespread. In general, direct diffusion of NH_3 and Rh-facilitated transport appears to account for the bulk of total ammonia transport in adult fish.

Fish begin to express ammonia transporter (Rh protein) genes relatively early in development. Rh expression has been reported in zebrafish embryos as early as ~1 dpf, the stage blood starts to circulate. Rainbow trout already express relatively high levels of mRNA for several Rh proteins by the eyed stage, nearly half way to hatch. Knock-down of Rh proteins results in about a 50% decrease in the rate of NH_3 excretion in newly hatched zebrafish (3 dpf) demonstrating that even at this early age facilitated NH_3 transport is important. Ammonia excretion across the skin of larval zebrafish appears to be tightly linked to acid secretion illustrating the potential importance of proton trapping of NH_4^+ in maintaining the transepithelial NH_3 gradient.

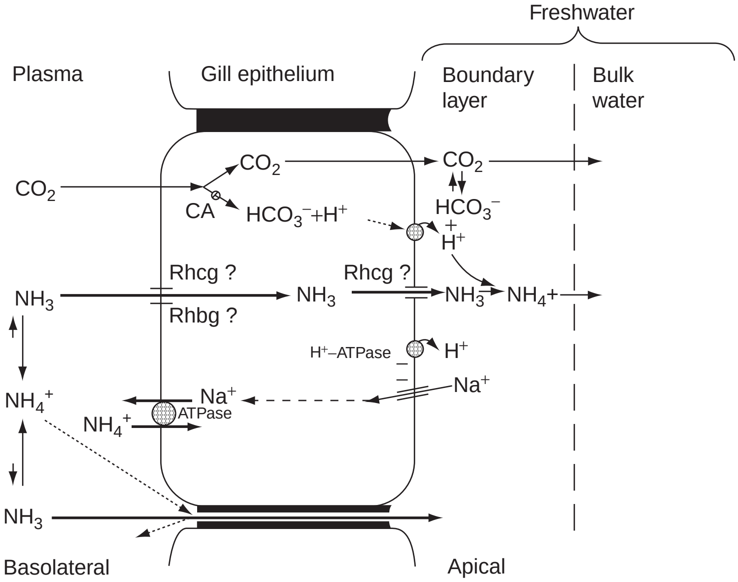

Figure 5 Model of ammonia excretion in freshwater fish. Rhcg and Rhbg are putative Rhesus NH_3 transporters. Note the potential linkage between NH_3 and CO_2 transport via proton trapping of NH_4^+ in the external boundary layer. Modified from Weihrauch D, Wilkie MP, and Walsh PJ (2009) Ammonia and urea transporters in gills of fish and aquatic crustaceans. *Journal of Experimental Biology* 212: 1716–1730.

At this juncture, it is worth pointing out that at least some fish species employ an alternate/complementary strategy to deal with the potential toxicity of NH_3 during development, namely to convert it to urea (**see also Nitrogenous-Waste Balance**: Ureotelism). Urea is less toxic than ammonia, and also is less energetically favorable because its synthesis requires a net input of energy (~4 ATP equivalents/urea). Embryonic urea production occurs even in species that would be considered ammonotelic as adults. In general, urea represents a greater fraction of total N excretion earlier in development. Excretion of a high-energy N-compound during early development suggests that the capacity for direct NH_3 excretion initially may be limited. Two factors, the diffusive resistance imparted by the presence of the egg capsule and a lack of ammonia transporters, have been advanced as reasons for this apparent limitation.

Time

Time is also an important factor when considering diffusion. Diffusion time (t) is $\sim\delta^2$. If the distance is small, diffusion is rapid (e.g., O_2 takes ~0.1 ms to diffuse 1 μm in water), but if the distance is greater than about 1 mm, diffusion is generally too slow to satisfy metabolic demand ($t_{O2} \sim 100$ ms at 1 mm). This means that if gas has to be transported over longer distances, an alternate method must be used.

Convection

Convection is the method used to transport gases over longer distances. Convection can be natural or forced. Natural convection depends on density differences to move the bulk fluid the gas is dissolved in (**Figure 6**). Forced convection requires energy input, usually provided by the organism. Convective transport can be quantified using the equation

$$J = F\beta(\Delta P) \tag{3}$$

where J is the rate of gas transfer, F the flow rate, β the gas capacitance of the medium, and ΔP the difference in partial pressure in the medium entering and leaving the site where gas is exchanged. Flow in

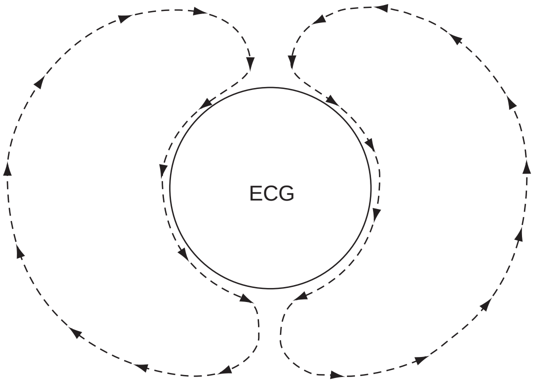

Figure 6 Natural convection of water surrounding a salmon egg. The respiring embryo removes O_2 and adds CO_2 to the DBL. This increases the density of the water in the boundary layer, which falls away from the egg generating toroidal water currents. Modified from O'Brien RN, Visaisouk S, Raine R, and Alderdice DF (1978) Natural convection: A mechanism for transporting oxygen to incubating salmon eggs. *Journal of the Fisheries Research Board of Canada* 35: 1316–1321.

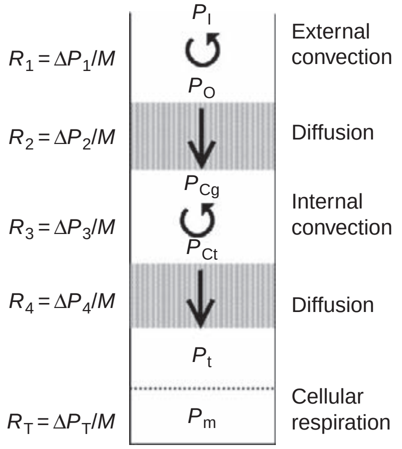

Figure 7 The respiratory-cascade model depicted as a series of convective and diffusive resistances. Partial pressure differences (ΔP) between successive regions are determined by resistance (R) and the rate of production or consumption of the gas (M). Faster stirring of conductive elements reduces ΔP for those elements. Total resistance (R_T) is the sum of all the individual resistances. P_I = free-stream partial pressure, P_O = partial pressure of medium leaving gas exchanger, P_{Cg} = partial pressure in capillary at gas exchanger, P_{Ct} = partial pressure in capillary at tissue, P_t = partial pressure in tissue, and P_m = partial pressure at the level of the mitochondrion. Modified from Otis AB (1987) An overview of gas exchange. In: Farhi LE and Tenney SM (eds.) *Handbook of Physiology: The Respiratory System*, pp. 1–11. Bethesda MD: American Physiological Society.

the external medium (water for most fish) is referred to as ventilation and abbreviated as V. Flow of the internal medium (blood in vertebrates) is referred to as perfusion and abbreviated as Q. For external convection, β is the capacitance of water (βw) which is generally close to the value of the Bunsen coefficient (α). β for internal convection (βb) includes dissolved gas and any gas that is dissociated or chemically bound to carrier molecules in the blood (e.g., hemoglobin). In general, $\beta b > \beta w$, the precise extent depending on the gas, hemoglobin concentration, and buffering capacity of the blood (for details concerning determination of βb, **see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs).

For efficient gas exchange, the ventilation–perfusion ratio ($\dot{V}$: Q) should be balanced so all the gas brought to one side of a gas exchanger can be carried away at the other side. Because β's are different for O_2 and CO_2, $\dot{V}$: Q cannot be optimized for both gases simultaneously. In adult fish, $\dot{V}$: Q is generally close to the optimum for O_2 implying that O_2 transport is most likely to become limiting. There is little information on $\dot{V}$: Q ratios during early life because of the practical difficulty of measuring $\dot{V}$ and Q in very small organisms. Measuring $\dot{V}$ is particularly problematic because there is often not a clear ventilatory flow.

Resistance

The total flux of gas from the medium to the tissues or vice versa (M_x) can be described by the mass transfer equation, usually written as

$$M_x = G_x \Delta P_x \text{ or } M_x = \Delta P_x / R_x \qquad (4)$$

where ΔP_x is the partial pressure gradient, G_x the total conductance, and R_x the total resistance ($R_x = 1/G_x$). Similar equations can be written for each step in the respiratory cascade (**Figure 7**). The overall resistance to gas exchange is the sum of all the individual diffusive or convective resistances in the pathway (i.e., $R_t = R_1 + R_2 + R_3 + \ldots$). The ratio of the resistance of an individual component to total resistance (e.g., R_1/R_t) is a useful indicator of the relative impact of that particular component of the pathway.

Glossary

Aerobic metabolism The generation of metabolic energy where O_2 acts as the final electron acceptor.

Branchial respiration Exchange of respiratory gases across the gill.

Cutaneous respiration Exchange of respiratory gases across the skin.

Diffusive boundary layer The layer of semi-stagnant water adjacent to the surface of a gas exchanger in which substances (e.g., dissolved gases) either become depleted or accumulate depending on the direction of net flux.

Egg capsule The nonliving shell encapsulating the eggs of oviparous fish species, which is also called the zona radiata or chorion (although not homologous with the chorion of amniotes).

Gastrulation Migration and rearrangement of cells after the embryo undergoes cell proliferation to increase cell number (cleavage stage) to create three primary germ layers during early development.

Organogenesis The process whereby the primary germ layers develop into rudimentary organs. Organogenesis continues until the definitive characteristics of the organ are achieved.

Oviparous Laying eggs that develop and hatch externally.

Ovoviviparous Eggs hatch within the mother. Nutrients are from the yolk and the mother provides for gas exchange.

Perivitelline fluid Fluid found in the perivitelline space between the egg membrane or embryonic skin and the egg capsule. Similar, but not identical, to the ambient medium in terms of chemical composition.

Viviparous Giving birth to live young. Mother contributes nutrients as well as providing for gas exchange.

Introduction

Fish, like all animals, begin life as a single cell. This cell ultimately gives rise to all the cells in the body as the developmental program progressively unfolds. Developmental processes post-gastrulation (i.e., for most of development) are powered almost entirely by aerobic metabolism. This means that the embryo needs a continuous supply of O_2. It also has to get rid of the waste products of metabolism, in particular carbon dioxide and ammonia. In adult fish, uptake and removal of these gases is the task of the respiratory system. Developing fish, however, initially do not possess a respiratory system or, indeed, any kind of specialized structure for gas exchange. This article focuses on how fish embryos and larvae obtain O_2 and get rid of CO_2 and NH_3 as well as how the sites and mechanisms by which this is accomplished change as development proceeds.

Fishes comprise the largest group of vertebrates with more than 30 000 extant species in three classes: Agnatha (jawless fishes), Chondrichthyes (cartilaginous fishes), and Osteichthyes (bony fishes). As might be expected, they display great diversity in terms of habitat, life history, morphology, and how they handle various physiological problems. This diversity extends to development of the respiratory system. Some of the more unusual respiratory adaptations include the development of temporary external gills by embryos of some cartilaginous (e.g., little skate *Raja erinacea*) and bony fishes (e.g., spined loach *Cobitis taenia*). Viviparous and ovoviviparous fishes develop complex placenta-like structures where gases are exchanged between the embryo and the mother. Air-breathing bony fishes have formed various types of accessory respiratory structures (e.g., labyrinth organs, swimbladders, and lungs) in addition to internal gills (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes). For the vast majority of fishes, which are oviparous and water breathing, respiratory development is more straightforward. Early in development, gas exchange takes place solely by diffusion across nonspecialized body surfaces. Later in development, internal gills begin to form and eventually supplant the skin as the major site of gas exchange. The focus of this article is on this transition from cutaneous to predominantly branchial respiration. Emphasis is on O_2 uptake. O_2 is the gas that is most likely to become limiting during development and it is also the gas we know most about. It is assumed that, aside from the direction of flux, exchange patterns for CO_2 and NH_3 are essentially the same as those for O_2 but more research is required to confirm this.

Resistance to Respiratory Gas Exchange

As pointed out in **Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Models and Mechanisms (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs), the flux of gases between an organism and its environment can be viewed as passing through a series of diffusive and convective resistances. For most of embryonic and larval development, diffusive resistances dominate. The diffusive resistance imparted by the boundary layer, the egg capsule, the perivitelline fluid (PVF), body surfaces, notably the skin and gills, and the tissues themselves is particularly important. One of the major trends observed in the ontogeny of the respiratory system is a shift toward greater reliance on convection as a means of transporting gases. This shift is driven by tissue growth, greater diffusion distances, and a relatively reduced surface area for exchange. Tissue growth results in increased metabolic demand for O_2 and concomitant increases in the need to get rid of CO_2 (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion) and NH_3 (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia) as well as increases in the distances over which gases must be transported.

Diffusive flux is described by the Fick equation (see eqn (2) in **Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Models and Mechanisms and Efficiency of Gas Exchange Organs). According to this equation, the major determinants of the quantity of gas exchanged per unit time are Krogh's constant (K), the area of the exchange surface (A), the partial pressure gradient (ΔP), and the diffusion distance (δ). Organisms can do little about K, but they can adjust the value of the other variables to suit their needs. If the intent is to maximize exchange, this can be achieved by having a large surface area, a small diffusive distance, and a large ΔP. It should be pointed out at this juncture that developing fish do not always maximize diffusive flux. Fish not only need to ensure that sufficient O_2 is supplied to the tissues to support aerobic metabolism during embryonic and larval development, but also need to keep tissue P_{O_2} relatively low to minimize the production of oxygen free radicals. Design characteristics of the developing respiratory system that appear to be inefficient in terms of maximizing diffusive fluxes are probably a reflection of this trade-off.

Diffusive Boundary Layer

The diffusive boundary layer (DBL) is the single most important barrier to diffusive gas exchange for much of larval development. The thickness of the boundary layer adjacent to the skin of rainbow trout (*Oncorhynchus mykiss*) in slow-moving water ($\leq 0.01\,\mathrm{cm\ s^{-1}}$) is in the order of $1000\,\mu\mathrm{m}$ during the first half of larval development and represents 60–90% of the total resistance to O_2 flux (**Figure 1**). Increasing water velocity (v) reduces the thickness (d) of the boundary layer ($d \sim v^{-0.5}$), but even at a velocity of $2\,\mathrm{cm\ s^{-1}}$ the boundary layer is still $\approx 300\,\mu\mathrm{m}$ thick and accounts for $\approx$40% of total resistance. A velocity of $2\,\mathrm{cm\ s^{-1}}$ is equivalent to that of water flowing over the gill of a resting adult trout and is much higher than is likely to be encountered by larvae of most species in nature. The thickness of the boundary layer and its impact on O_2 flux in rainbow trout larvae appear to be relatively uniform over the whole surface of the body in slow-moving water ($\leq 0.08\,\mathrm{cm\ s^{-1}}$). This uniformity begins to break down at higher velocities with the boundary layer becoming relatively thinner above more anterior surfaces and relatively thicker in more sheltered regions (this assumes water flow is anterior to posterior, which is normally the case because most larvae are positively rheotactic). Regional differences in the thickness of the boundary layer can also be induced by the movement of the pectoral fins. In 1975, Peterson showed that the rhythmic flutter of the pectoral fins displaced water from behind the opercula of Atlantic salmon (*Salmo salar*). This tended to draw water through the buccal and opercular cavities. Routine swimming reduces the overall thickness of the boundary layer, but probably produces little regional variation because the boundary layer tends to be dragged along with the larvae at the low speeds characteristic of routine swimming. This may not be the case during the startle response (C-starts) when velocities are briefly high enough to move the larvae out of the viscous hydrodynamic regime.

The external boundary layer is also a significant resistance to diffusive gas exchange during embryonic development. Its relative impact, however, does not appear to be as great as for larvae. There are two reasons for this. At the same water velocity, the DBL adjacent to the external surface of the egg capsule tends to be thinner than it is adjacent to the skin of a hatched larva. For example, at a water velocity of $0.01\,\mathrm{cm\ s^{-1}}$, the boundary

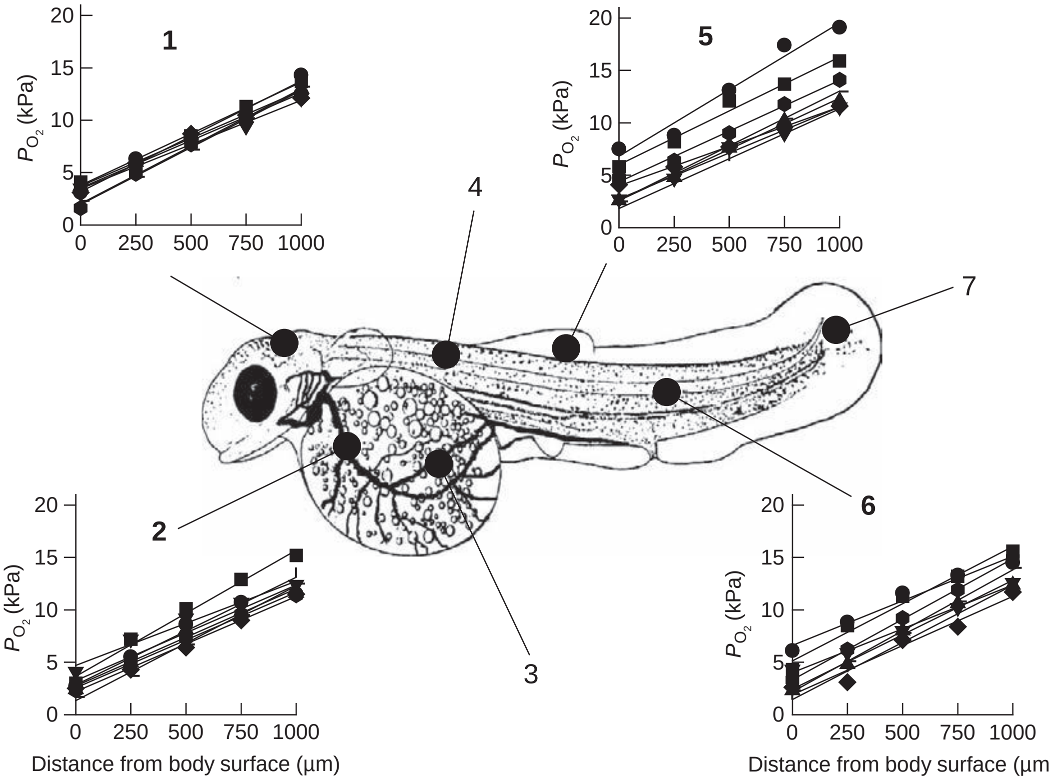

Figure 1 Oxygen profiles at various locations in the diffusive boundary layer surrounding newly hatched rainbow trout larvae in still water. Regression lines represent different individuals. From Rombough PJ (1998) Partitioning of oxygen uptake between the gills and skin in fish larvae: A novel method for estimating cutaneous oxygen uptake. *Journal of Experimental Biology* 201: 1763–1769.

layer external to the egg capsule just prior to hatch is ≈350 µm thick in rainbow trout, while that surrounding the newly hatched larvae only a few days later is >1000 µm thick. This difference probably has something to do with shape because it persists if one compares the thickness of the boundary layer surrounding an artificially decapsulated embryo with that for an intact egg at the same stage of development. The other reason for a lower relative impact prior to hatch has to do with the fact that embryos face an additional resistance to gas exchange not experienced by larvae, namely that imparted by the egg capsule and PVF. Although the absolute resistance of the boundary layer per unit thickness is the same for eggs and larvae, the relative resistance is less in eggs because of these added barriers. That being said, the boundary layer still represents a major fraction of total resistance during the egg stage. In rainbow trout, it accounts for 25–40% of the total resistance of O_2 flux, depending on the stage of development and water velocity. The relative impact of the boundary layer in embryos tends to increase with age but is unaffected by hypoxia. The increase with age is a reflection of increasing metabolic demand for O_2.

The DBL has a significant impact on CO_2 and NH_3 exchange by virtue of the resistance it provides to their excretion. Its negative impact on NH_3 excretion appears to be mitigated to some extent by acting as a site for proton trapping of the NH_4^+ ion (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia). The boundary layer surrounding rainbow trout larvae has been shown to be significantly more acidic than the bulk medium as a consequence of the accumulation of CO_2 and its hydration to carbonic acid. This favors the conversion of NH_3 to NH_4^+, which in turn helps maintain the NH_3 partial pressure gradient for diffusive efflux from the body. Dissociation and proton trapping in the boundary layer could potentially impact CO_2 excretion; however, this has not been investigated.

Egg Capsule and PVF

The egg capsule and the PVF together represent a substantial resistance to diffusive gas exchange. Their precise impact is difficult to quantify and would be expected to vary with species and stage of development, but based on the little that is known, their combined resistance would appear to be about the same magnitude as for the external boundary layer (i.e., ≈20–40% of total resistance). Measurements of P_{O_2} gradients in the PVF indicate that the combined resistance of the egg capsule and PVF was equivalent to ≈30–75% of the resistance from the body surface to the mitochondria during cleavage and early gastrulation in loach *Misgurnus fossilis*. In eyed embryos of rainbow trout, the drop in P_{O_2} across the capsule and PVF was about the same as that across the external boundary layer (i.e., ≈40% total resistance). Removing the egg capsule (which also eliminates the PVF) surrounding chinook *Oncorhynchus tshawytscha* embryos shortly before normal hatch decreased total resistance to ≈50%.

The PVF appears to represent more of a barrier to diffusive gas exchange than does the egg capsule. Krogh's constant of diffusion for O_2 (K_{O_2}) is essentially the same for PVF as for water. Estimates for K_{O_2} of egg capsules of different species range from 13% to 87% (mean = 22%) of that for pure water. This means that on a per-unit thickness basis, the capsule has a greater impact than the PVF. The PVF, however, is much thicker than the capsule. Egg capsule thickness varies among species but is generally in the range of 20–60 μm. The thickness of the PVF also varies depending on species but is typically at least several hundred microns thick (e.g., ~200 μm in Atlantic salmon and ~400 μm in loach). Precise estimates of the relative impacts of the two layers are difficult to determine because, unlike the egg capsule, the thickness of the PVF is not uniform around the embryo. Generally, the PVF is thicker adjacent to the ventral surface of the embryo and thinner on the dorsal surface. Ignoring this complication, one would expect the impact of the PVF to be about twice that of the capsule if the PVF is not stirred. This is the situation for about the first one-third of embryonic development. Older embryos stir the PVF. This decreases the overall resistance of the PVF and facilitates gas exchange. Unfortunately, there are no empirical estimates of the magnitude of this effect, and we know too little about the dynamics of PVF flow to model it with any accuracy.

In general, embryos employ two types of movements to stir the PVF: flexing of the trunk musculature and oscillation of the pectoral fins. There is some controversy as to the efficacy of trunk movements, but oscillation of the pectoral fins almost certainly facilitates gas exchange. In Atlantic salmon, fairly high-frequency trunk movements (>100 h^{-1}) begin abruptly during early organogenesis. The frequency of trunk movement declines as development proceeds to reach levels in the range of only 1–2 h^{-1} by late organogenesis. About midway through organogenesis, embryos begin to use their pectoral fins to stir the PVF. The frequency of pectoral fin movements is much greater than trunk movements, in the range of 60–130 min^{-1}. The frequency of pectoral fin movement increases with both increasing temperature and decreasing O_2 level as would be expected if their primary role were to enhance O_2 exchange. Unfortunately, the impact of these ventilatory movements on gas exchange has not been quantified (**Figure 2**).

Skin

In most species, the skin is the only significant site of gas exchange between the organism and its environment during embryonic development. During the earliest stages, gases are exchanged across the vitelline membrane but this is soon replaced by the skin once the primary germ

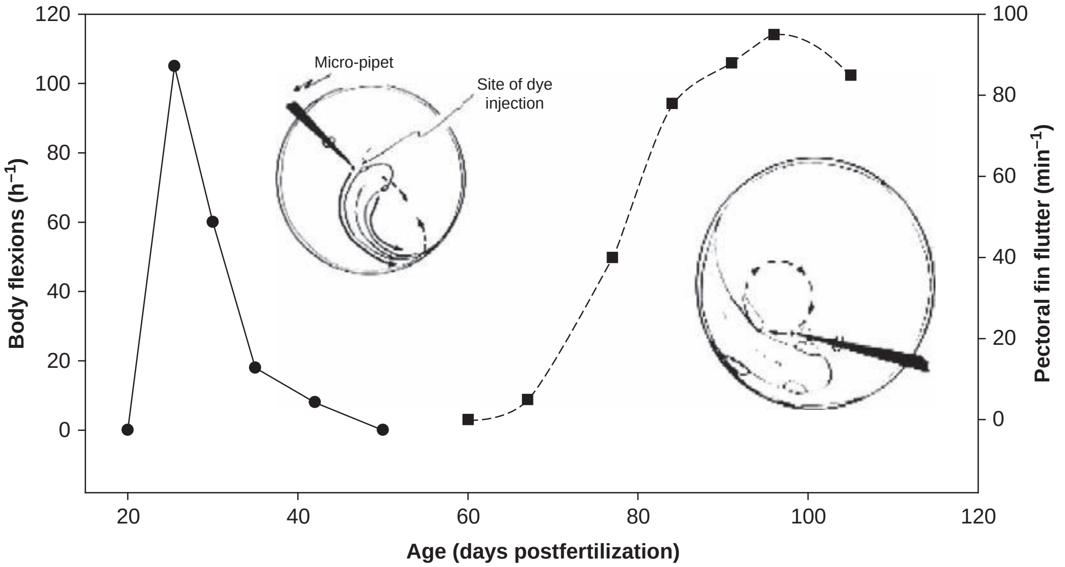

Figure 2 Frequency of body flexions and pectoral fin movements by Atlantic salmon embryos. Body flexions are indicated by the circles and solid line; pectoral fin movements are indicated by the squares and dashed line. Note the difference in frequency timescales (i.e., h^{-1} vs. min^{-1}). The inset drawings indicate the trajectories (indicated by arrows) taken by injected dye in response to body flexion (left) and pectoral fin movements (right). From Peterson RH and Martin–Robichaud DJ (1983) Embryo movements of Atlantic salmon (*Salmo salar*) as influenced by pH, temperature, and state of development. *Canadian Journal of Fisheries and Aquatic Sciences* 40: 777–782.

layers begin to differentiate. As mentioned, embryos of a few species develop temporary external gills while still in the egg capsule, but this is exceptional. The vast majority of species continues to rely on the skin as their sole means of exchanging gases until the internal gills come on line. The stage at which this occurs varies considerably among species. On the one hand, salmon and trout, for example, begin to develop gills before hatch, well before use in gas exchange after hatch. Many marine species, on the other hand, do not initiate gill formation until well into the larval stage, perhaps many weeks after hatch. The transition from cutaneous respiration to primarily branchial (gill) respiration is a gradual process (**Figure 3**). In salmon and trout, for example, it takes several weeks for the transition to occur and even at the end of the transition period, the skin still accounts for a considerable fraction of total O_2 uptake ($\approx$20–30%). In this regard, it is worth noting that the skin in most species remains a significant site of gas exchange (5–30% of total O_2 uptake) even for adults.

The primary reason most developing fish are able to manage without any specialized respiratory structures has to do with their small size. Surface area is a major determinant of exchange capacity of a gas exchanger. The surface area of the skin of an embryo is large in relation to the mass of tissue it has to support. This is because for geometrically similar objects, surface area (A) is proportional to the relevant linear dimension squared, while mass (M) is proportional to the linear dimension cubed. The net result is that the surface-to-mass ratio of an organism tends to decrease with increasing size (i.e., $A \sim M^{2/3}$). In other words, smaller organisms have larger $A{:}M$ ratios than larger organisms. For example, the mass-specific surface area (A/M) of the skin of a newly hatched walleye *Stizostedion vitreum* weighing 2.5 mg is 38-times greater than the mass-specific surface area of the gill of a 1-kg adult. Larvae tend to have higher mass-specific metabolic rates ($\dot{M}_{\mathrm{O}_2}/M$) than adult fish (8.5-times greater in walleye); however, even taking this into account, the effective surface area per unit O_2 uptake of a newly hatched walleye larvae is still 4.5-times larger than for the adult fish.

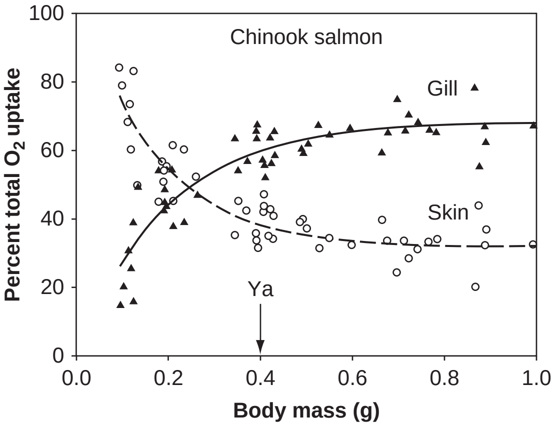

Figure 3 Changes during the course of larval development in the relative amounts of O_2 taken up across the skin and gills of chinook salmon (*Oncorhynchus tshawytscha*). The arrow marked 'Ya' indicates size at yolk absorption. From Rombough PJ and Ure D (1991) Partitioning of oxygen uptake between cutaneous and branchial surfaces in larval and young juvenile chinook salmon *Oncorhynchus tshawytscha*. *Physiological Zoology* 64: 717–727.

Another factor that facilitates cutaneous gas exchange during development is the thinness of the skin. According to the Fick equation, flux is inversely proportional to membrane thickness. The skin of fish embryos and larvae is typically in the order of 10–20 μm thick, although values in the range of 2–3 μm have been reported (e.g., herring (*Clupea harengus*)). These lower values are less than the thickness of the gill blood–water barrier of many adult fish.

The skin is generally well vascularized during late-embryonic and early-larval development. This is particularly true for the yolk-sac epithelium, but this probably has more to do with nutrient mobilization than gas exchange. Regional differences in the degree of vascularization do not appear to translate into differences in O_2 uptake rate. Indeed, the net rate of O_2 uptake across the yolk-sac epithelium, the most densely vascularized region of the skin, was actually slightly lower than the average rate for the rest of the body in Atlantic salmon larvae. In rainbow trout larvae, no significant regional differences in rates of transcutaneous O_2 uptake were recorded in still or slow-moving water. The most likely explanation for the apparent lack of correlation between uptake rates and blood-vessel density is that perfusion and blood gas transport are not limiting in normoxia. This is probably also true for moderate levels of hypoxia. This interpretation is supported by observations that reducing the O_2-carrying capacity of the blood by eliminating hemoglobin has little or no impact on the overall rate of O_2 consumption by zebrafish (*Danio rerio*) larvae under most conditions. It is not until O_2 falls to very low levels that one sees any advantage of having hemoglobin in terms of meeting larval metabolic O_2 demand.

Rates of O_2 uptake across the skin of fish larvae have been determined for only a few species, but they do not appear to be strikingly different from rates of uptake across the skin of adult fish. Area-specific rates of cutaneous O_2 uptake in adult fish are generally in the range of 6–10 μg-O_2 h^{-1} cm^{-2}; reports of transcutaneous uptake rates in salmonid larvae fall in the range of 3–9 μg-O_2 h^{-1} cm^{-2}. This is despite the fact the skin of larvae is considerably thinner (<1/5th) than the skin of adults. The most likely explanation for the relatively low rates of area-specific O_2 uptake that have been reported for larvae is that transcutaneous O_2 uptake is not the limiting step in the O_2 cascade under the conditions in which it has been measured (i.e., in normoxia and relatively early in larval development). Estimates of the effective surface area available per unit O_2 uptake support this contention. A morphometric study of five species indicated that newly hatched larvae had 2.5–6.0 times the cutaneous surface needed to meet their metabolic demand for O_2 in normoxia, assuming that the efficiency of transcutaneous uptake was the same in larvae as it was in adults. This is a conservative estimate because there are reasons to believe that the exchange potential of the skin is actually greater for larvae than for adults (e.g., shorter diffusion distances). One situation in which cutaneous exchange capacity might not be sufficient during early larval development is in profound hypoxia, but the dynamics of this situation have not been investigated. It is possible that in extreme hypoxia some other step in the O_2 cascade (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Models and Mechanisms) might become limiting before skin surface area.

While cutaneous gas exchange capacity initially may not be limiting, it will eventually become so as the larva continues to grow and mature. There are two major reasons for this: a gradual increase in skin thickness and a gradual decrease in $A:M$ ratios. The larval skin initially is only a few cells thick, but thickens considerably toward the end of the larval period. For example, the skin thickness of Atlantic salmon increases from ≈20 μm at hatch to ≈70 μm by the early fry stage. The skin also tends to mineralize which further decreases its exchange capacity. As discussed previously, $A:M$ ratios tend to decrease with increasing body size. The cutaneous surface area of fish larvae typically expands with increases in body mass at a rate proportional to $\approx M^{0.6}$. The metabolic demand for O_2, in contrast, typically expands at a rate $\approx M^{0.9}$. The net result is a gradual decrease in skin surface area per unit O_2 uptake. At some point, the available surface area on the skin simply becomes too small to keep up with the rate of metabolic expansion. The size at which this occurs varies among species and is also strongly dependent on temperature. Different species have different body shapes and growth trajectories for various parts of the body. The result can be a considerable variation in the species-specific rate of skin expansion. There are also species-specific differences in the rate of metabolic expansion. Temperature has a pronounced impact on larval metabolic rate, both within (mean $Q_{10} \approx 3.0$) and among species (mean $Q_{10} \approx 2.0$), but little or no impact on surface area. As a result, cutaneous respiration tends to become limiting at a smaller size for larvae of warm-water species than for cold-water species. For example, cutaneous O_2 uptake is estimated to become limiting for zebrafish larvae incubated at 28 °C at a body mass of ≈300 μg. Cutaneous uptake in salmonid larvae incubated at 10 °C is not projected to become limiting until they reach a body mass of ≈100 mg. Interestingly, in both groups the size at which cutaneous O_2 uptake is projected to become limiting coincides fairly closely to the size at which gill surface area begins to expand.

Gills

The gills of teleost fishes are anatomically complex structures consisting of, in order of formation, gill arches, gill filaments, and gill lamellae (**see also Ventilation and Animal Respiration:** Gill Respiratory Morphometrics). Gill lamellae are considered the definitive site of gas exchange, but some exchange also occurs across the filaments and arches. The gills are also functionally complex. Functions associated with the adult gill include gas exchange, acid–base balance, iono-regulation, ammonia excretion, hormone production, immune defense, and metabolism of various circulating metabolites. There has been some controversy concerning the order in which the developing gill assumes these various functions. Recent physiological evidence suggests that ion exchange shifts to the gill before gas exchange. This supports the morphological evidence showing that the cells involved in ion exchange (mitochondria-rich cells) appear on the arches and filaments well before lamellae, the definitive site of gas exchange, start to form. Since ion exchange and some components of NH_3 and CO_2 excretion are functionally linked, this raises the possibility that the gill may initially play a more important role in the excretion of these two gases than it does in O_2 uptake.

The stage at which definitive gill development, defined as the appearance of filamental buds, is initiated varies considerably among species (branchial-arch formation is a poor indicator as they are associated with the aortic arches which form early in organogenesis in all species). For example, gill filaments begin to form in rainbow trout several days before hatch. Gill filaments are first observed in zebrafish about 1 day after hatch (**Figure 4**). In Atlantic

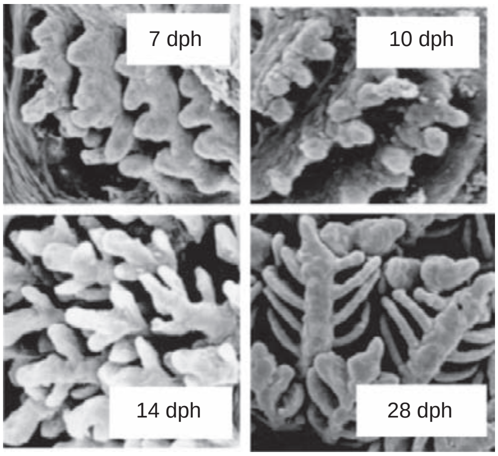

Figure 4 Development of the gills of zebrafish larvae. At 7 days posthatch (dph), filament buds can be seen forming on the gill arches. Lamellar buds first appear at about 10 dph. By 14 dph, 1–3 basal (closest to the gill arch) lamellae have formed. Aside from being smaller, the gill of a 28-dph larva is similar to that seen in juvenile and adult fish.

halibut (*Hippoglossus hippoglossus*), gill filaments do not appear until near metamorphosis, >1 month after hatching. The speed at which gill development proceeds, once initiated, also varies. In some species, the gill assumes its definitive adult appearance within a few weeks, while in other species it may take several months to reach this stage.

The transition from cutaneous to primarily branchial respiration is mainly a result of rapid expansion of the diffusing capacity of the gill rather than a decrease in the diffusing capacity of the skin. Diffusing capacity (*D*) is a measure of gas conductance (the reciprocal of resistance) and can be quantified as K^*A/d, where A is the surface area, d is the diffusion distance, and K is the Krogh's coefficient of diffusion. The absolute diffusing capacity of the skin increases throughout larval development but does so at a slower rate than the rate of metabolic expansion. The net result is that skin surface area per unit O_2 uptake gradually decreases. Gill diffusing capacity, in contrast, increases in both absolute and relative (compared to metabolism) terms. During the initial stages of gill development, there is a very rapid increase in surface area and a smaller, but still significant, decrease in diffusion distance. Allometric mass exponents for gill surface area during the initial period of expansion average about 3.0 across species (i.e., $A \approx M^{3.0}$), but values as high as 7.1 are reported.

Rates of gill expansion gradually diminish as development proceeds and by the end of the larval period they stabilize at levels typical of juvenile and adult fish (i.e., $SA \approx M^{0.8\text{–}0.9}$). Gill surface area per unit body mass is maximal (i.e., higher than at any other life stage, including juvenile and adult) at about this time. The thickness of both gill filaments and lamellae decreases as development proceeds. The magnitudes of these decreases, however, are relatively small. For example, in Atlantic salmon, mean filament diffusion distance decreased from 14 μm at hatch to 11 μm by the early juvenile stage; the corresponding decrease in lamellar diffusion distance was from 3.7 to 2.4 μm.

More important is the shift in the site of branchial gas exchange from the filaments to the lamellae. Whereas filaments accounted for ≈88% of gill surface area in newly hatched Atlantic salmon, they represented <30% of total gill area in young juveniles. The net result was about a 70% decrease in the average thickness of the blood–water barrier, from about 13 to 4.0 μm. Diffusing capacity, which takes into account both *SA* and *d*, has been shown to be a fairly accurate indicator of the fraction of O_2 actually taken up across the gill and skin for most of larval development (**Figure 5**). The exception is very early in larval development where *D* tends to underestimate gill uptake (and overestimate skin uptake). This discrepancy probably reflects differences in how the skin and gills are ventilated.

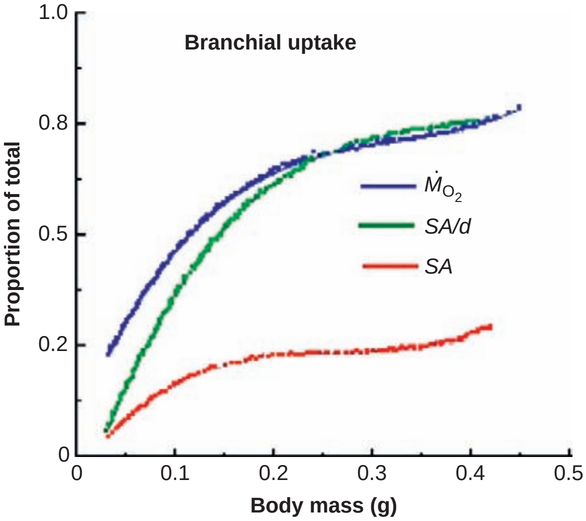

Figure 5 Actual ($\dot{M}_{O_2}$, blue line) vs. estimated fractions of total O_2 taken up across the gill of young Atlantic salmon based solely on relative surface area (*SA*, red) and a combination of surface area and diffusion distance (*SA/d*, green). Surface area alone is a poor predictor of O_2 uptake. The anatomical diffusing factor, *SA/d*, provides a much better estimate, particularly for larger fish. From Wells PR and Pinder AW (1996) The respiratory development of Atlantic salmon. 2. Partitioning of oxygen uptake among gills, yolk sac and body surfaces. *Journal of Experimental Biology* 199: 2737–2744.

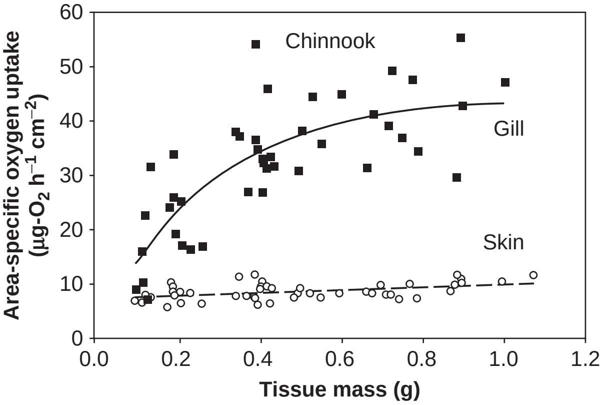

Figure 6 Changes in area-specific O_2 uptake across the skin and gills during the course of larval development in chinook salmon. Area-specific uptakes are initially similar for skin and gills, but by the end of the larval period about 4-times as much O_2 per unit surface area is taken up across the gill as across the skin. From Rombough PJ and Ure D (1991) Partitioning of oxygen uptake between cutaneous and branchial surfaces in larval and young juvenile chinook salmon *Oncorhynchus tshawytscha*. *Physiological Zoology* 64: 717–727.

Branchial gas exchange potentially is more effective than cutaneous gas exchange. In chinook salmon, for example, 4–5 times as much O_2 per unit surface area was taken up across the larval gill once it began to be well ventilated than across the skin (**Figure 6**). Part of this difference is due to shorter blood–water diffusion distances in the gill. More important, however, are differences in how the two surfaces are ventilated. In particular, water in the gill is forced to flow through relatively narrow channels between adjacent filaments or lamellae. This effectively reduces the thickness of the branchial boundary layer to about 30% of channel width. As a result, the effective thickness of the boundary layer adjacent to the gill lamellae of a rainbow trout larvae is only about 1/20th the thickness of the boundary layer adjacent to its skin at the same flow rate (the relative impact on filamental exchange is not as great because of larger interfilamental distances). A thinner boundary layer has the effect of increasing ΔP_{O_2} at the gill surface and, thereby, enhancing flux rates. Channeling has the added advantage of ensuring that water flow in the gill is unidirectional and largely countercurrent to the flow of blood. At low flow rates, countercurrent flow has been shown to result in higher exchange efficiencies than if blood flow and water flow are at some other angle to each other. There is some evidence that fish larvae can direct water flow over portions of their skin surfaces so it is approximately countercurrent to blood flow, but this appears to be limited to relatively small regions of the body and only occurs intermittently.

Gill ventilation initially tends to be intermittent. This does not appear to reflect an inability to detect changes in ambient O_2 levels (the primary driver of gill ventilation in adult fish) or a lack of neuromuscular control. Studies of zebrafish indicate that they possess functional O_2-sensitive neuroepithelial cells on their gills as early as 1-day post-hatch. When newly hatched Arctic char larvae are exposed to hypoxia, they quickly shift from an intermittent to continuous ventilatory pattern. The most likely explanation for early discontinuous breathing is that it is energetically less expensive than regular breathing. The surface area of the skin of newly hatched larvae, which does not need to be ventilated, typically is more than sufficient to meet the metabolic demand in normoxia. Under these circumstances, energy that otherwise would be used to ventilate the gills can be freed up for other purposes. This raises the question of why the gills are ventilated even intermittently in normoxia. A possible explanation has to do with the other functions of the larval gill, in particular its role in ion exchange. Ion exchange is an energetically expensive process supported by aerobic metabolism. For this process to continue, some O_2 must be supplied to the gill. This explanation fits with the observation that although the gill of newly hatched trout larvae is responsible for about 20% of total O_2 uptake, very little, if any, of that O_2 appears to make it into the systemic circulation.

One of the major functional advantages of gill respiration over cutaneous respiration is a better ability to extract O_2 under hypoxic conditions. The initial stages of lamellar expansion, in particular, are associated with decreases in critical O_2 levels (P_c). P_c is the minimum O_2 level at which fish are able to maintain a normal metabolic rate when faced with declining P_{O_2}. The reasons the gill is more effective in hypoxia are twofold. The channeling of water between adjacent filaments and/or lamellae results in a significant reduction in the thickness of the DBL. This effectively increases the P_{O_2} at the exchange surface, which is particularly important at low ambient P_{O_2}. Gill ventilation also provides the fish with more control over how much water can be passed over the exchange surface. Larvae can alter water flow over the skin (e.g., by swimming or pectoral fin movements) but this is relatively ineffective because of the much greater thickness of the DBL and the resulting greater mass of water that needs to be moved. In some (but not all) species, the shift to primarily gill ventilation translates into improved hypoxic tolerance (i.e., survival at low P_{O_2}). The reason not all species respond this way is not that their gills are less efficient. There is a general trend during larval development for tissues to become less tolerant of anoxia and hypoxia. Whereas enhanced O_2 uptake at the gill more than compensates for this increased sensitivity to low P_{O_2} in some species, it does not in other species.

Glossary

Active metabolism The maximum aerobic metabolic rate associated with swimming at the greatest sustainable velocity.

Aerobic scope The capacity of an animal to increase its level of aerobic metabolism beyond that which is required for maintenance alone and thereby support activities such as muscular exercise, growth or reproduction; it sets the capacity for oxygen-consuming physiological processes that an animal may perform at a given time. Aerobic scope is the difference between minimal and maximal oxygen consumption rate.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

Respirometer An apparatus used to measure respiratory metabolic rates via indirect calorimetry (e.g., via oxygen consumption or carbon dioxide excretion).

Resting-routine metabolism The metabolic rate for quiescent fish, but not necessarily the lowest rate during the 24-h cycle.

Routine metabolism The metabolic rate including spontaneous movements.

Standard metabolism In ectotherms, this term describes the minimal level of aerobic metabolism (per unit time) required for maintenance functions to sustain life. In this sense, it is analogous to basal metabolism in endotherms, although SMR is strongly influenced by environmental temperature and so it is not always constant within an individual.

Swimming metabolism The metabolic rate measured at some voluntary or forced level of swimming.

Ventilation The movement of the respiratory medium (air or water) over the surface of the gas exchanger.

Ventilation volume The total amount of water pumped over the gills in a period of time (usually 1 min); the product of the rate of breathing multiplied by the volume of water pumped with each breath.

Ventilatory frequency The frequency of buccal or opercular movements.

Ventilatory stroke volume The volume of water pumped per buccal–opercular stroke or movement.

Introduction

Measurements of fish respiratory metabolism and gill ventilation can inform us concerning a fish's physiological state, by providing a quantitative measure of how rapidly energy and oxygen are being converted/used. Data on respiratory metabolic rates are important in the construction of bioenergetic models, and changes in respiratory metabolic and gill ventilatory rhythms can be sensitive indicators of altered environmental conditions or physiological states, and thus can reveal much about a fish's recent and current activity, acclimation, and level of stress. The scope of this article is limited to measurements of respiratory (aerobic) metabolism and gill ventilation.

Respiratory Metabolism Measurement Methods

Metabolic rates can be measured using either direct or indirect calorimetry. Direct calorimetry, the measurement of heat production, is rarely used for fishes because their metabolic and heat production rates are generally low (e.g., compared with those of mammals or birds) and the heat capacity of water is high, which together result in limited measurement sensitivity. Indirect calorimetry, through measurement of oxygen consumption rate ($\dot{M}_{O_2}$), has become the conventional measure for fishes because changes in dissolved oxygen levels over time in water can be determined with relative ease and reliability. The iodometric or Winkler method of measuring O_2 concentrations (mg or mL O_2 L^{-1} H_2O) is highly accurate when fresh reagents are available to fix and titrate water samples and is very useful in the field. Clark-type polarographic electrodes and fiber-optic O_2 sensors (see below) measure O_2 tensions (i.e., partial pressures, P_{O_2}) and are easier and faster to use in the laboratory than the Winkler method. The wide availability and precision of these electrodes have resulted in the rapid expansion of the field of respiration physiology over the past 30 years. Oxygen consumption rate is only an accurate measure of overall metabolism when anaerobic contributions are insignificant. During high-speed sustained and burst swimming or during exposure to hypoxia, metabolic requirements cannot be met aerobically and any deficit is met anaerobically, as indicated by either lactate appearance in the blood or tissues, or an O_2 debt that is repaid during recovery.

In addition to oxygen consumption rate, carbon dioxide (CO_2) production rate can be measured by indirect calorimetry. However, the high solubility of CO_2 in water makes it difficult to measure changes in the partial pressure of CO_2 (P_{CO_2}) accurately with available electrodes, and changes in total CO_2 of the water over time are often difficult to measure against the background CO_2 bound as carbonates and bicarbonates, especially in hard water and saltwater.

Respiratory Metabolism Levels

Aerobic metabolism in fishes can be categorized as standard, resting routine, routine, swimming, and active. Standard metabolism is the minimum metabolic rate for intact fish. Resting-routine metabolism is the rate for quiescent fish, but not necessarily the lowest rate during the 24-h cycle. Routine metabolism is the rate including spontaneous movements. Swimming metabolism rates are measured at some voluntary or forced level of swimming. Active metabolism is the maximum aerobic rate associated with swimming at the greatest sustainable velocity. Aerobic scope is calculated as the difference between active and standard metabolic rates and reflects the aerobic capacity available for everything beyond maintenance, such as growth, reproduction, exercise, and digestion/absorption of food.

The standard (i.e., basal, maintenance, or resting) metabolic rate is the minimum required to sustain life. It should be measured when fish are absolutely quiescent – that is, when they are expending no energy for activity (even random activity), food digestion, reproductive development, growth, or stress responses. Fish should be carefully shielded from changes in water temperature and chemistry and from all disturbances, and they should be given adequate time to habituate to the respirometer. Metabolic rates should be recorded throughout the diel cycle to determine the minimum rate. The innate restlessness of pelagic fishes such as salmon or tuna makes it much more difficult to determine standard metabolism for these species than for demersal or sedentary forms such as flatfishes. Some workers have calculated standard metabolism from data on swimming fish from relationships between swimming velocity and the logarithm of metabolic rate via extrapolation to zero velocity. Besides the statistical problem (i.e., widening confidence limits) associated with extrapolation, the physiology (e.g., via hormone secretions) of active and quiescent fish may be quite different.

The resting-routine metabolic level falls between standard and routine metabolism. Measurements of resting-routine metabolism require a quiescent fish without food in its gut, a respirometer with dimensions that constrain swimming but are not overly confining, and isolation of the fish from laboratory stimuli. However, these measurements do not account for the diel activity cycles that fish normally undergo.

Most metabolic values reported for fishes are routine rates, which represent generally quiescent to moderately active fish. Routine metabolic rates include spontaneous activity, possibly due to daily activity cycles, and they may include swimming at a velocity of up to 1 body length s^{-1}.

Swimming metabolic rates are measured during various voluntary or forced levels of swimming. Active metabolic rates are generally defined as those attained while a fish is swimming at the greatest sustainable velocity for a particular period of time, such as 1 h.

Gill Ventilation

Oxygen uptake across the respiratory surfaces is driven by diffusion. The rate of O_2 diffusion is directly proportional to the partial-pressure gradient (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs and Respiratory Gas Exchange During Development: Models and Mechanisms). Because the movement of ventilation water over the gills replaces the boundary layer of water next to the lamellar epithelium (where O_2 is diffusing inward), thus maintaining the P_{O_2} gradient between water and blood, gill ventilation is an essential respiratory process in most fishes (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). Ventilation volume is the total volume of water forced over the gills. Ventilatory frequency is the frequency of buccal or opercular movements, and ventilatory stroke volume is the volume of water pumped per buccal–opercular stroke or movement. Percentage utilization of oxygen is the percentage of available oxygen removed by respiration from the inspired water.

Apparatus and Techniques

Oxygen Measurements

Oxygen dissolved in water is usually measured electrometrically or titrimetrically (e.g., with Winkler titrations). One common electrometric measurement system uses the Clark-type oxygen electrode. This electrode consists of an anode (e.g., silver–silver chloride) and a cathode (e.g., platinum), which are bathed in an electrolytic solution in the electrode body. An O_2-permeable membrane is stretched across the electrode tip. When a small polarizing voltage is applied across the anode and cathode, O_2 diffusing across the membrane is reduced at the cathode, producing a small electrical current through the electrode. This current is proportional to the P_{O_2} in the water. The current is amplified and displayed on a meter or digital readout; the display equipment varies from battery-powered portable units to bench-top units with computer interfaces. Because of possible drifting, calibration of Clark-type O_2 electrodes should be checked frequently. Some dissolved oxygen meters use fiber-optic oxygen sensors, which may require less-frequent calibration and maintenance and, unlike the Clark-type oxygen electrode, do not consume O_2. Whereas some meter and electrode systems for dissolved oxygen automatically calculate O_2 concentrations (e.g., mg O_2 L^{-1}) from detected O_2 tensions if water temperature and salinity values are known, other units display P_{O_2} (e.g., in millimeters of mercury (=torr) or kilopascals). These can be converted to O_2 concentration (usually mL O_2 L^{-1}) with the aid of a nomogram or oxygen solubility tables and the formula

$$C_{O_2}(\mathrm{ws}) = P_{O_2}(\mathrm{ws})C_{O_2}(\mathrm{AS}) / P_{O_2}(\mathrm{AS}) \tag{1}$$

where $C_{O_2}(\mathrm{ws})$ is the O_2 concentration (mL O_2 L^{-1}) in the water sample, $P_{O_2}(\mathrm{ws})$ the O_2 tension (mmHg) in the water sample, $C_{O_2}(\mathrm{AS})$ the O_2 concentration in water at air saturation (from nomogram or tables), and $P_{O_2}(\mathrm{AS})$ the O_2 tension at air saturation (from eqn (2)). Oxygen concentrations in mL O_2 L^{-1} can be converted to mg O_2 L^{-1}, assuming 1.428 mg O_2 mL^{-1} O_2.

The oxygen tension at air saturation is

$$P_{O_2}(\mathrm{AS}) = 0.2094(P_B - P_{WV}) \tag{2}$$

where 0.2094 is the mole fraction or volumetric fraction of O_2 in the atmosphere, P_B the total barometric pressure (mmHg), and P_{WV} the water vapor pressure at the experimental temperature (mmHg).

Overall, it is imperative that water samples from respirometers be taken with the minimum possible exposure to the atmosphere. Where continuous monitoring of water O_2 tension is desired, fiber-optic oxygen sensors may be placed directly in the respirometer, provided the water volume is adequately mixed. Fiber-optic oxygen sensors or Clark-type electrodes can be housed outside the respirometer in a thermostatically controlled chamber where water is drawn from the respirometer, forced past the electrode, and returned to the respirometer in a closed loop driven by a peristaltic pump.

Body Mass Considerations

Large fish generally consume more O_2 than small fish. However, on a unit-mass basis, small fish consume more O_2 than large fish. This allometric relationship can be described as

$$Y = aX^b \tag{3}$$

or

$$\log_{10} Y = \log_{10} a + b \log_{10} X \tag{4}$$

where Y is the O_2 consumption rate (mg O_2 min^{-1}), a the mass coefficient, X the body mass (g or kg), and b the mass exponent (**see also Energetics**: Physiological Functions that Scale to Body Mass in Fish and **Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Respiratory Transitions).

The log–log plot of X and Y (eqn (4)) is a linear one, but with a slope (b) that usually is less than 1.0. Consequently, to compare metabolic rates of different-sized fish, O_2 consumption rate cannot simply be divided by fish mass (i.e., mg O_2 g^{-1} h^{-1}), and both intra- and interspecific comparisons of respiratory metabolic rates must be conducted carefully. For intraspecific comparisons, it is best if the mean body masses of the two groups are statistically indistinguishable and the ranges around those means are small. If the two groups of fish have significantly different mean masses, one of two other analyses might be appropriate. The first is an analysis of covariance with mass as the covariate, and the other is to determine the actual mass exponent (e.g., $b = 0.81$) for the particular group of fish and divide the raw data by (mass^b). This last technique yields mass-independent metabolic rates that are most correctly analyzed in $\log_{10}$-transformed form. These two analyses are also appropriate when different species of fish are compared, although their regression intercepts (mass coefficients, a; eqns (3) and (4)) may vary (**see also Energetics**: General Energy Metabolism). Finally, mass exponents should be determined over as wide a size range (e.g., one to two orders of magnitude) of homomorphic (i.e., of same body proportions) individuals as possible.

Respiratory Metabolism

A respirometer incorporates a chamber for the fish and a surrounding respiratory medium (usually water, though air or access to air may be appropriate). There are essentially two types of respirometers: closed respirometers, in which the same volume of respiratory medium is continuously used with little replacement, and open respirometers, in which the medium is continuously replaced. Closed respirometers are of two types: static respirometers and swimming respirometers. In static respirometers, the medium is not moved in directed currents, though it may be kept well mixed by gentle stirrers and the fish itself. In swimming respirometers, water flows within the vessel, forcing the fish to swim against a directed current. In contrast, fresh water continually flows into and out of open (or flow-through) respirometers, the object being to maintain water quality. In general, static and open respirometers are used to measure similar aspects of fish respiration, though the measurements are made differently. Swimming respirometers can be quite elaborate and expensive. Whatever system is chosen, the study will progress most efficiently if several replicate setups can be used simultaneously.

Static Respirometers

A static respirometer contains a circulating, fixed volume of water at constant temperature. It may be as simple as a glass jar or flask and a tight-fitting stopper to which water-sampling and water-flushing tubes have been fitted (**Figure 1**), or a probe that has been inserted directly. The jar or other container should be impermeable to gases and at least partially transparent to allow detection of bubbles. Because air contains up to 30 times more O_2 per unit volume than water, bubbles, as potentially a great source of respirometry error, must be removed. A transparent chamber may also help the enclosed fish to visually orient to the environment (e.g., experimental tank or stream bottom) in which the respirometer is placed, and thereby to acclimate to the confines of the respirometer. Some species (e.g., gobies (Gobiidae) and toadfish (Batrachoididae), which have secretive habits), however, acclimate more readily if the vessel is nearly opaque.

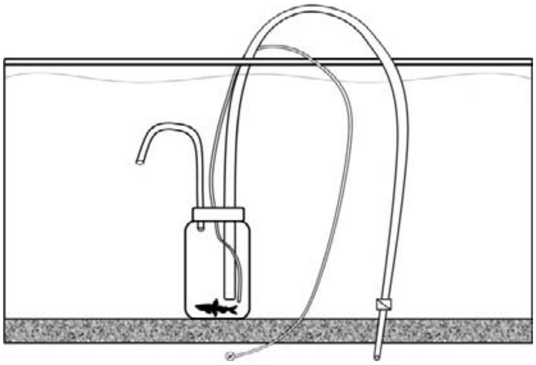

Figure 1 Static, closed respirometer (situated in an aquarium), consisting of a glass jar with rubber stopper through which siphon tubes can flush aquarium water through the respirometer during fish acclimation to the respirometer. The outflow siphon tube is equipped with a tubing clamp (depicted by a rectangle surrounding a diagonal line) to shut off the flushing flow during an experiment. Initial and final water samples are collected in a syringe (not shown) via the small-diameter water-sampling tube and attached stopcock (depicted by a circle surrounding an 'x'). The fish's small movements and gill ventilation circulates the water inside the respirometer. Redrawn by R. Coulter from Cech JJ (1990) Respirometry. In: Schreck CB and Moyle PB (eds.) *Methods for Fish Biology*, pp. 335–363. Bethesda, MD: American Fisheries Society.

Measurements of O_2 consumption are calculated from changes in dissolved O_2 concentration over time, taking into account the respirometer volume:

$$\dot{M}_{O_2} = (C_{O_2}(A) - C_{O_2}(B))V/T \qquad (5)$$

where $\dot{M}_{O_2}$ is the O_2 consumption rate (mg O_2 h^{-1}), $C_{O_2}(A)$ the O_2 concentration in water (mg O_2 L^{-1}) at the start of the measurement period, $C_{O_2}(B)$ the O_2 concentration in water (mg O_2 L^{-1}) at the end of the measurement period, V the volume of respirometer (L), and T the time elapsed during measurement period (h).

Corrections for microbial O_2 consumption or production can be made by accounting for the O_2 consumed from a blank (fishless) respirometer with dimensions and tubing lengths similar to those of respirometers containing fish. Some investigators measure microbial O_2 consumption rates in the fish's respirometer after the fish is removed, a correction technique that is especially recommended for extended metabolic studies because microbial dynamics may differ between experimental and blank vessels.

The volume of the respirometer should generally be 30–50 times that of the fish. A respirometer that is smaller than this may stress the test fish and elevate respiratory metabolic rates. In one that is larger, the time required to measure $\dot{M}_{O_2}$ may be prohibitively long and the fish's ventilatory and fin movements will not keep the water mixed well enough to assure the investigator of representative samples in which case additional stirring mechanisms may be required. Submersible pumps add heat energy to the system, which could affect metabolic rates.

Considerable effort should be made to minimize stress. When fish must be moved, they should be transferred quickly from one tank to another using a vessel (e.g., beaker or bucket) that will prevent air exposure. If possible, the water source and quality should be the same in the respirometers' water bath as it is in the fishes' holding tank. The tank containing the respirometers should be at least partially covered to shield test fish from the glare of lights and the movement of people. Fish should be guided carefully into the respirometer opening. The respirometers can be slowly flushed with water from the respirometer tank (e.g., with a siphon, **Figure 1**) while the fish is initially settling down and between experiments. When the measurement period begins, the outflow tubing normally is clamped off and either the decline in O_2 levels within the system is continuously monitored, or initial and final water samples are taken for O_2 analysis. The outflow tube may be used for this purpose, especially if large samples are needed for Winkler titrations, but a small-diameter, heavy-walled sampling tube is recommended if only a few milliliters are needed. The dead-space water filling the sampling tube is easily removed with syringes and a three-way stopcock (**Figure 1**). Small water samples insure that replacement water drawn into the respirometer from the water bath has minimal effect on the final O_2 measurement. Spontaneous activity from fish in routine metabolic states can be quantified using video recordings of fish, especially if the respirometers have grid marks on the walls.

Special static respirometers can be used to isolate the respiratory contributions from different gas-exchange sites. For example, some respirometers may incorporate a rubber sleeve to separate branchial from cutaneous compartments. In each compartment, the water is circulated past an oxygen electrode by a pump, allowing O_2 consumption rates from each gas-exchange site to be measured separately. Special (e.g., L-shaped, with a gas space at the top of its vertical arm) static respirometers that incorporate an air phase can be used to study respiration by fishes with air-breathing organs (e.g., lung and swimbladder). Changes in volume and O_2 content in the gas space allow calculation of instantaneous O_2 consumption rates.

Because fish eventually deplete the O_2 in the enclosed volume of water, the main limitations of the static respirometer concern long-term experiments, especially those in which fish are to be exposed to prolonged stable levels of hypoxia. For metabolic studies under normoxic conditions, measurements must be made before chamber P_{O_2} declines to a critical level. Flushing the respirometer with hypoxic water permits $\dot{M}_{O_2}$ measurements at predetermined hypoxic P_{O_2} ranges.

Dissolved metabolic wastes (CO_2 and ammonia) also increase during static experiments. Automated systems that incorporate intermittent flows have solved some of the problems inherent in long experiments with static respirometers.

Open (Flow-Through) Respirometers

Open respirometers (**Figure 2**) solve many of the problems that arise during long-term studies with static systems. Continuous flows of water over the fish eliminate the need for periodic flushing flows; wastes do not accumulate, and desired characteristics such as oxygen concentration are maintained.

Under stable environmental conditions, oxygen consumption rates are calculated by the equation

$$\dot{M}_{O_2} = (C_{O_2}(I) - C_{O_2}(O))FR \qquad (6)$$

where $\dot{M}_{O_2}$ is the O_2 consumption rate (mg O_2 min^{-1}), $C_{O_2}(I)$ the O_2 concentration in inflowing water (mg O_2 L^{-1}), $C_{O_2}(O)$ the O_2 concentration in outflowing water (mg O_2 L^{-1}), and FR the water flow rate through the respirometer (L min^{-1}).

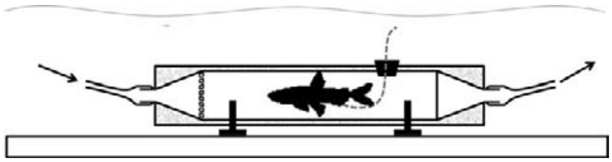

Figure 2 Open (i.e., flow-through) respirometer (situated in a tank of water), consisting of clear acrylic pipe with tapered ends to smooth the slow, continuous flow of water through the respirometer. Note that the inflowing water tube (shown cutoff in this diagram) would be attached (e.g., via a manifold with a port to measure dissolved oxygen) to a constant-head reservoir. The inflowing water would pass through the baffle plate (shown upstream of the fish) in which the perforating holes are drilled at angles to minimize eddy creation in the respirometer. The outflowing water tube (also shown cutoff) would lead to a rack where water could be sampled for dissolved oxygen and captured over a fixed time to measure flow rate. The rubber stopper and dashed line show a possible arrangement for leading an indwelling cannula (e.g., for blood-gas measurements) from the fish out of the respirometer. Not shown is the hatch or removable (rear) end cap through which the fish is inserted and removed from the respirometer. Redrawn by R. Coulter from Cech JJ (1990) Respirometry. In: Schreck CB and Moyle PB (eds.) *Methods for Fish Biology*, pp. 335–363. Bethesda, MD: American Fisheries Society.

To avoid using a time-lag correction factor, fish should be quiescent and water conditions should not change quickly in the flow-through respirometer. To check that the desired slug of water moves through the respirometer without mixing or creating major eddies, flow properties can be checked by injecting dye into the inflow water and observing its pattern through the chamber.

Automated designs incorporate computers or timers (e.g., with solenoid valves) to divert water past a calibrated O_2 electrode.

Generally, water flow rates are set so that the difference in oxygen concentration between inflowing and outflowing water is 0.5–1.0 mg L^{-1}. Water flows are typically measured as the weight (1 g = 1 mL) or volume of outflowing water collected per unit time. Water flowmeters may also be used, but they usually are not precise enough for metabolic calculations.

Flow-through respirometers are generally constructed of clear, thick-walled acrylic plastic such as Plexiglas®. Some kind of inert, virtually gas-impermeable tubing (e.g., a heavy-walled transparent vinyl such as Tygon®) directs the inflowing water to this chamber. This tubing should be as short as possible to minimize the buildup of attached organisms, and should be of the same length on multiple respirometers if these are used. It is important to spread the flow from the small-diameter tubing across the larger diameter of the chamber without creating eddies or dead spaces. Smooth-walled cones connecting the two and a baffle plate usually serve this function (**Figure 2**).

Swimming Respirometers

Swimming respirometers usually contain a closed volume of water that is circulated past a fish, inducing the fish to swim. As in static systems, changes in dissolved oxygen concentration through time in the enclosed volume reflect the rate of respiratory metabolism, in this case at a particular swimming velocity. Two basic designs of swimming respirometers are in current use. The most common is the water tunnel or Brett-type respirometer, which consists of a closed loop of pipe containing a centrifugal pump or propeller connected to an electric motor (**Figure 3**). A variable-speed drive on the motor changes the water velocity past the fish. The fish is restricted to its chamber by screens, flow-straightening tubes, or an electrifiable grid at the rear of the chamber. Gradual turns of custom-bent polyvinyl chloride pipe in the tunnel loop and gradual tapers (<25°) in sections connecting the swimming chamber with other pipes minimize turbulence and temperature increases. Alternatively, a closed loop of pipe of constant diameter allows faster water velocities to be achieved with the same-size motor. However, the somewhat larger volume of the constant diameter system will result in longer experiments, due to the slower change in water P_{O_2} because of metabolism.

Water velocity through the swimming chamber is proportional to pump speed, measured in revolutions of the pump shaft per minute. Water velocity should be measured with an electronic flowmeter, and then compared with speed settings on the motor or pump shaft. After this calibration, water velocity can be determined by measuring pump speed with a tachometer. A correction factor for solid blocking effect must be applied if the test fish occupies more than 10% of the cross-sectional area of the swimming chamber. Automated versions of the Brett-type respirometer may incorporate a computer-controlled system that re-oxygenates respirometer water via an artificial lung perfused with O_2 gas between bouts of oxygen-consumption rate measurements.

The second basic swimming respirometer (Blazka) design is based on concentric (coaxial) tubes; the swimming chamber is in the inner tube and water returns between the inner and outer tubes (**Figure 4**). A propeller, driven by a variable-speed electric motor, or a submersible water pump pulls or pushes water past the fish and returns it to the front of the swimming chamber via the outer tube after it is deflected by a domed cap. The spiraling movement imparted to the water by the rotating propeller can be minimized by replacing the conventional propeller with a jet outboard impeller and by incorporating flow-straightening vanes in the outer tube and small-diameter tubes at the ends of the inner tube. The small-diameter tubes, which may vary in diameter from thin-walled 1.25-cm polyvinyl chloride pipe in larger Blazka respirometers to 3-mm plastic soda straws in small ones, also confine the fish to the swimming chamber. The respirometer may also have an electrified wire grid (8–10 V AC) behind the fish to encourage it to swim if required. The relatively small water volume of the Blazka design minimizes the time needed to measure oxygen consumption rates at a particular temperature and swimming velocity.

Metabolic rates of swimming fish have also been estimated from heartbeat, ventilation, and swimming muscle contraction frequencies by telemetry. These telemetric techniques point the way to improved *in situ* metabolic measurements, although activities that require different muscles (i.e., without inserted electrodes) may not yield accurate metabolic estimates.

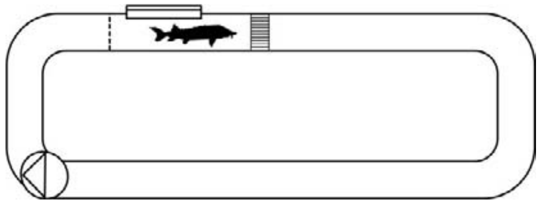

Figure 3 Brett-type, swimming closed respirometer is a loop of pipe (e.g., PVC, with a clear acrylic section for the fish), which incorporates either a propeller or a pump (shown as a circle surrounding a triangle) powered by a variable-speed motor (not shown) to push water past the fish. Flow-straighteners are shown upstream and a screen (dashed line) is shown downstream of the fish. The hatch above the fish, for insertion and removal of the fish, is shown as an acrylic saddle and rubber gasket over the top of the acrylic pipe (not intruding into the smooth, constant diameter of this respirometer). Not shown are sampling tubes for dissolved oxygen measurements. Redrawn by R. Coulter from Cech JJ (1990) Respirometry. In: Schreck CB and Moyle PB (eds.) *Methods for Fish Biology*, pp. 335–363. Bethesda, MD: American Fisheries Society.

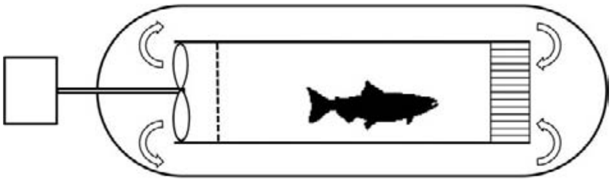

Figure 4 Blazka-type, swimming closed respirometer is an acrylic tube within a larger acrylic tube. A variable-speed motor (rectangle) turns a propeller, drawing water past the fish. The end caps recirculate the water (depicted by the arrows) between the outer and inner tubes, through the flow straighteners (upstream of the fish) and the screen (depicted by the dashed line downstream of the fish). Not shown are the hatches or removable end caps to insert and remove the fish, or the sampling tubes for dissolved-oxygen measurements. Redrawn by R. Coulter from Cech JJ (1990) Respirometry. In: Schreck CB and Moyle PB (eds.) *Methods for Fish Biology*, pp. 335–363. Bethesda, MD: American Fisheries Society.

Gill Ventilation

Gill ventilation is accomplished in two ways: water is actively pumped by the buccal–opercular apparatus, or it is passively forced over the gills as fish swim, called ram ventilation. Ram ventilation requires only that a fish maintains a buccal–opercular gape while it swims at or above a threshold velocity, which is thought to conserve energy. Active pumping of gill ventilation water is commonly measured in a respirometer that directs ventilatory water flows into a container or past a flow probe. Respirometers designed for water collection usually incorporate a thin rubber membrane or mask fitted to the fish's head to separate inspired from expired water for measurements of ventilation volume. The fish is situated in a two-chamber (van Dam-type) respirometer with the membrane sealing the barrier between the two chambers except for the fish's head (**Figure 5**). The water levels in both chambers are set to the same height by adjustment of surface drains so that hydrostatic pressure does not aid or inhibit gill ventilation. Water continuously flows into the anterior chamber (any excess flows out through the surface drain) and is moved from the anterior to the posterior chamber only by the fish's active ventilation. As the fish ventilates its gills, water equal to the ventilation volume is displaced from the posterior chamber via the posterior surface drain. This water is collected for a time as a measure of ventilation volume. Ventilatory movements of the buccal or opercular apparatus can be counted visually or detected with immersed electrodes sutured to the external opercula and connected to an amplifier and computer. Measured simultaneously over a specified time period, the frequency of ventilation (F_G, movements min^{-1}) and the volumetric rate of ventilation ($\dot{V}_G$, mL min^{-1}) allow calculation of ventilatory stroke volume (V_S, mL/movement: $V_S = \dot{V}_G/F_G$). Simultaneous measurements of oxygen concentrations in inspired and expired water, sampled near the mouth and gills, permit estimation of the oxygen consumption rate by the Fick equation:

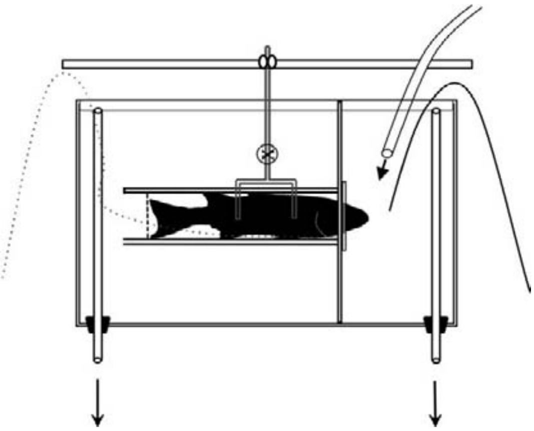

Figure 5 Two-chamber (van Dam-type) respirometer is a clear box (e.g., aquarium), incorporating a clear wall separating the two chambers. The fish is suspended in an acrylic box, so that its head partially protrudes through a hole in a light-gauge latex sheet, which is stretched over a large hole in the separating wall. Thus, the fish acts as a pump to move water from the anterior to the posterior chamber. A constant flow in inflowing water (top, right) enters the anterior chamber, and water not pumped by the fish escapes through the anterior chamber's surface drain (bottom, right). The water displaced by the fish's ventilatory pumping escapes through the posterior chamber's surface drain (bottom left). This flow is collected for a fixed time for the ventilation volume measurement. Note that the two surface drains are adjusted so that the water depths in the anterior and posterior chambers are equal. The solid and dashed lines represent water-sampling tubes for dissolved-oxygen measurements of inspired and expired water, respectively. Redrawn by R. Coulter from Cech JJ (1990) Respirometry. In: Schreck CB and Moyle PB (eds.) *Methods for Fish Biology*, pp. 335–363. Bethesda, MD: American Fisheries Society.

$$\dot{M}_{O_2} = \dot{V}_G(C_{O_2}(I) - C_{O_2}(E)) \tag{7}$$

where $\dot{M}O_2$ is the O_2 consumption rate (mg O_2 min^{-1}); $\dot{V}_G$ is the volumetric ventilation rate (mL water min^{-1}); $C_{O_2}(I)$ is the O_2 concentration in inspired water (mg O_2 mL^{-1} water); and $C_{O_2}(E)$ is the O_2 concentration in expired water (mg O_2 mL^{-1} water).

Because these oxygen consumption rates are calculated from oxygen concentrations immediately adjacent to the mouth and gills, they may underestimate total respiration because cutaneous gas exchange can represent an important proportion of total oxygen uptake, even for scaled fishes.

Percentage utilization (%U) of oxygen taken up at the gills can be calculated from the same data. Either oxygen tensions or concentrations can be used in this measure of the gills' oxygen extraction efficiency:

$$\begin{aligned}\%U &= (P_{O_2}(I) - P_{O_2}(E))/P_{O_2}(I) \times 100 \\ &= (C_{O_2}(I) - C_{O_2}(E))/C_{O_2}(I) \times 100\end{aligned} \tag{8}$$

where $P_{O_2}(I)$ is the O_2 tension of the inspired water (mmHg) and $P_{O_2}(E)$ is the O_2 tension of the expired water (mmHg).

The energetic cost of gill ventilation has been determined by comparison of oxygen consumption rates at velocities below and above the transition from active ventilation to passive ram ventilation on sharksuckers, which are similar to remoras, attached to the inside of a tunnel respirometer by their dorsal cephalic suction disks. Glossary

Afferent Activity conducted toward the brain, normally sensory. Incoming, e.g., in the case of nucleus A projecting to nucleus B, the neurons in nucleus B would receive an afferent input from nucleus A.

Brainstem A variably defined term that includes the brain regions where most cranial nerves have their origin and/or termination, i.e., the hindbrain and midbrain. Alternatively, the base of the brain extending forward from the spinal cord and including the medulla oblongata and midbrain.

Caudal Toward the tail.

Cell body The major part of a neuron including the nucleus but excluding processes such as axons.

Chemoreceptors Type of cell that is specialized to detect chemical stimuli and convert them into signals within the nervous system.

Cranial nerves Nerves leaving the brain.

Discharge activity Measured electrical activity in nerve fibers.

Efferent Outgoing, e.g., in the case of nucleus A projecting to nucleus B, the axons that arise from neuron cell bodies in nucleus A would be efferent projections of that nucleus. Note that the adjectives efferent and afferent can apply to the same set of axons; the terms are used in reference to the nucleus from which they arise vs. the nucleus to which they project, respectively.

Electromyogram (emg) Measured electrical activity generated during muscle contractions.

Entrain To cause rhythmically active systems to assume an imposed rhythm.

Episodic breathing Bouts of active gill ventilation separated by periods of cessation of ventilation, characteristic of inactive fish in well-oxygenated water.

Mechanoreceptors Sense organs that respond to movement or change in position.

Medulla oblongata Hindmost portion of the brainstem that contains the vagal motor and sensory areas, the respiratory rhythm generator, and cardiovascular control center.

Motor Causing muscles to contract.

Motor nuclei Groups of motor neurons supplying efferent axons to specific motor nerves that innervate particular muscles.

Nucleus of the solitary tract The part of the brain that is a relay center for afferent information providing reflex control of the respiratory and cardiovascular systems.

Phasically active Activity that varies continuously, often in phase with rhythmically active systems such as respiration.

Ram ventilation Ventilation of the gills by swimming forward with the mouth open while suspending activity in the respiratory muscles.

Rostral Toward the head.

Sensory Responding to or relaying information from stimulated sense organs.

Sensory projections Afferent nerves relaying information to specific parts of the brain.

Tonically active Unvaryingly active over long periods.

Transected Cut through or divided, usually referring to surgical intervention.

Introduction

Water contains less oxygen per unit volume than air but is considerably more dense and viscous. Consequently, compared with air breathers, fish have to work harder to move water to obtain the same amount of oxygen and they normally exhibit continuous rhythmical breathing movements. However, the work done to move water is mitigated by using a unidirectional flow to ventilate their gills: in at the mouth and out over the gills (**see also Gas Exchange**: Respiration: An Introduction). This means that the kinetic energy imparted to the water by the respiratory muscles is maintained in one direction, unlike the tidal ventilation of a lung when the direction has to be reversed.

To ensure this rhythmic, unidirectional water flow, gill ventilation requires a complex and coordinated interaction of two muscle pumps: the buccal pump in all fishes and the opercular pump in bony fishes (teleosts) or the analogous septal pump in cartilaginous fishes (elasmobranchs). The synchronized activity of these pumps needs to be controlled and coordinated by the brain. This article is about how the brain generates and coordinates the rhythmic activity of the muscles involved with these pumps.

The muscles used for gill ventilation are inserted around the jaws, the opercular flaps in bony fishes (teleosts) and pharyngeal skeleton supporting the branchial (gill) arches. They are innervated by a dorsal group of cranial nerves exiting from the brainstem. This series of nerves contains sensory fibers and in most cases visceral motor components. The arrangement of these nerves in the dogfish, *Scyliorhinus canicula*, an elasmobranch, is schematized in **Figure 1**.

There are four cranial nerves innervating muscles involved in normal gill ventilation. The Vth cranial nerve, the trigeminal, provides the major innervation to the mouth region of all vertebrates, including the maxillary branch to the upper jaw and mandibular branch to the lower jaw, responsible for motor control of the jaw-closing muscles. The VIIth cranial nerve, the facial, provides the hyomandibular branch to the branchial muscles in the hyoid arch that, in teleosts, includes the opercular muscles; in elasmobranchs, the facial nerve innervates the spiracle, an inhalant opening in front of the gill slits. Together, the IXth cranial nerve, the glossopharyngeal, and the Xth cranial nerve, the vagus, are called the branchial nerves. They innervate respiratory muscles within

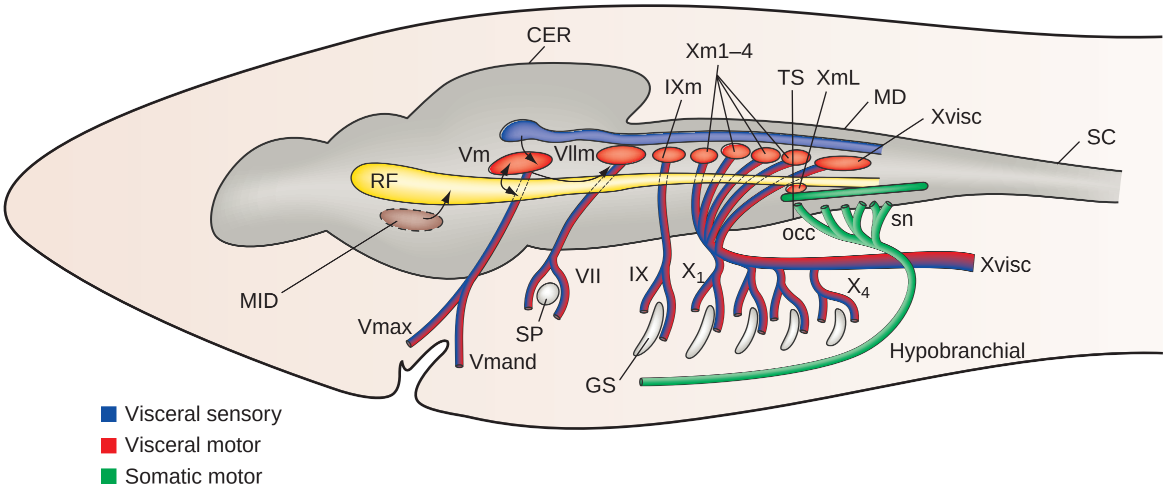

Figure 1 Schematic diagram of the left side of a dogfish to show details of the cranial nerves innervating the respiratory system, together with the location of their motor and some of their sensory nuclei in the brainstem. The nerves and nuclei are color coded and are listed from the most rostral to the more caudal: Red are motor nuclei: Vm, trigeminal nucleus supplying Vmand, mandibular branch of Vth cranial nerve; Vmax, maxillary branch of V; VIIm, facial nucleus supplying VII facial nerve; IXm, glossopharyngeal nucleus supplying IX; Xm1-4, vagal motor nuclei supplying branches of X1-4; Xvisc is the visceral vagus. Blue are sensory nuclei supplying V, VII, XI, and X. Yellow is the reticular formation (RF). Brown represents midbrain nuclei (MID) including the tegmentum. Green is occipital (occ) and anterior spinal (sn) nerves supplying the hypobranchial nerve. TS marks the line indicating the TS shown in **Figure 2**. Arrows indicate possible interactions; details are given in the text. CER, cerebellum; GS, gill slit; MO, medulla oblongata; SC, spinal cord; SP, spiracle.

the gill arches that are important in maintaining the integrity of the gill arches and the curtain of gill lamellae. They also innervate mechanoreceptors and chemoreceptors on the gills that are important in ventilatory control. All of these nerves have their efferent cell bodies and afferent sensory projections located dorso-medially in the brainstem (**Figures 1–3**).

The Central Respiratory Rhythm Generator

The respiratory rhythm driving ventilation is generated in the central nervous system (CNS). It is a feed-forward command signal related to the goal of providing adequate oxygen to fuel the animal's rate of aerobic metabolism (**see also Gas Exchange**: Respiration: An Introduction). Generation of a respiratory rhythm has a lineage as ancient as the evolution of multicellular animals. Evidence suggests that the central nervous mechanisms generating the respiratory rhythm are highly conserved from fish to mammals. Furthermore, the location of the respiratory rhythm generator (RRG) in all vertebrates is concentrated in the brainstem, and specifically the medulla oblongata. If the brainstem is transected to isolate the medulla oblongata, rhythmic ventilatory movements continue in fish and these can resemble the patterns in intact animals, suggesting that the RRG is contained solely in the medulla.

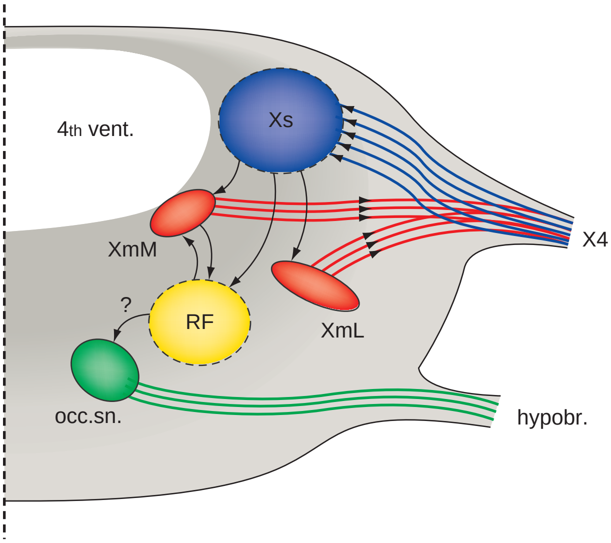

Figure 2 Schematic diagram of TS through brainstem of dogfish at point labeled on **Figure 1** to show spatial and possible functional relationships between nuclei supplying respiratory nerves. Color code and labels as in **Figure 1**. Additional labels: 4th vent. 4th ventricle; XmL, lateral vagal preganglionic neurons; XmM, preganglonic neurons in the dorsal vagal motor nucleus; Xs, dorsal sensory nucleus of vagus; X4, 4th branchial branch of vagus. Arrows indicate possible functional connections; details are given in text.

However, despite years of detailed investigation, the nature of respiratory rhythm generation in all vertebrates, including mammals, remains in dispute regarding the two mechanistic models: pacemaker neurons showing spontaneous rhythmic oscillations or neural networks relying on synaptic interactions. These two mechanisms have been separated functionally by bathing preparations in chloride-free saline. This blocks the synaptic inhibition, intrinsic to neural networks, but is without effect on the spontaneous activity generated by pacemaker neurons.

Various techniques have localized and characterized the RRG in fish. Although each technique has certain limitations, some common features have emerged. Local destruction of neurons in the hindbrain of the tench, *Tinca tinca*, and recordings of respiration-related electrical discharge activity from neural cells in the brainstem of several fishes suggest that an extended, diffusely organized neuronal network within the medulla generates the respiratory rhythm. Recordings of electrical activity in this region and injection of a marking substance to precisely locate where the electrode was recording from, identified a longitudinal strip of neurons with spontaneous, respiration-related bursting activity. These neurons extend dorsolaterally throughout the whole medulla and comprise elements of the Vth, VIIth, IXth, and Xth motor nuclei that drive the respiratory muscles, together with the descending trigeminal nucleus and the diffuse reticular formation (RF). All the motor nuclei are interconnected, and each receives an afferent projection from the descending trigeminal nucleus and has efferent and afferent projections to and from the RF (**Figure 1**). Finally, areas in the midbrain, such as the tegmentum, have efferent and afferent connections with the RF (**Figure 1**). The respiratory rhythm apparently originates in a diffuse respiratory pattern generator in the RF. This remains functional under anesthesia, providing circumstantial evidence that it can work independently of external inputs from the periphery or elsewhere in the CNS, although maintenance of a respiratory rhythm in intact animals generally relies on an element of respiratory drive from peripheral chemoreceptors. There is some evidence that the size of the population of respiratory neurons varies with conditions so that more cells may be active during periods of respiratory distress, such as in hypoxia.

These studies also revealed differences among fishes. Neural tracers injected into branches of the cranial nerves innervating respiratory muscles are transported into the brainstem and accumulate in the cell bodies of neurons providing axons to the injected nerve (**Figures 3(a)–3(c)**). In the brainstem of the dogfish, such studies show that the neurons providing axons to the respiratory branches of each of the cranial nerves have motor nuclei distributed in a sequential series (**Figure 1**). In contrast, in pacu, *Piaractus mesopotamicus*, a teleost, the Vth nerve is located in a separate, more rostral position, while the cell bodies of the cranial nerves V, VII, IX, and X have an

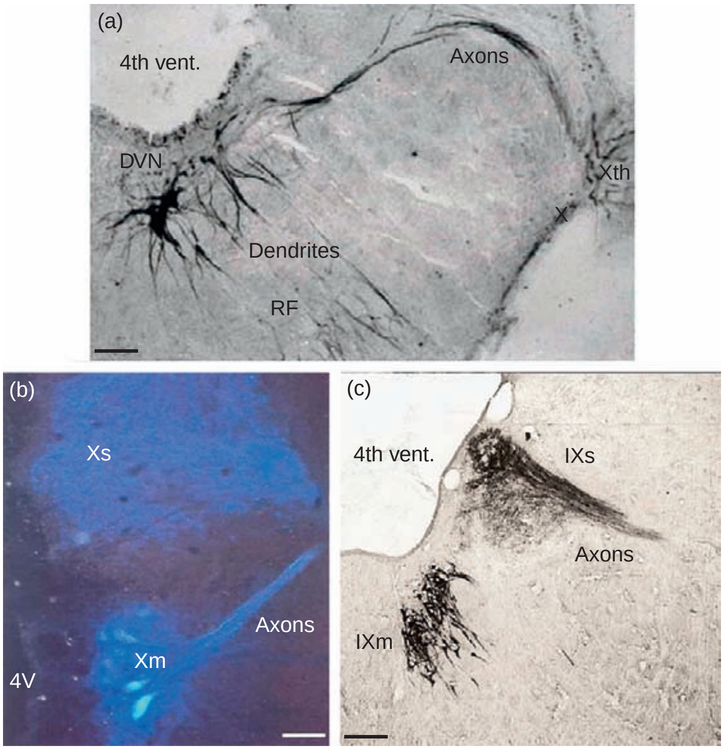

Figure 3 (a) TS of dogfish brainstem 3 mm rostral of obex following injection of cobalt chloride into the right vagus nerve. The darkly stained structures close to the 4th ventricle (4th vent.) are neurons with their cell bodies in the dorsal vagal motor nucleus (DVN), having axons that project out to the X cranial nerve (Xth) and dendrites that project ventrolaterally into an area occupied by the reticular formation (RF). (b) TS of sculpin brainstem to show motoneurons (Xm) in the dorsal vagal motor nucleus close to the 4th ventricle (4V) with axons projecting to the vagus nerve and the projection of the vagus nerve into the diffuse dorsal sensory area (Xs) revealed by injection of the fluorescent neural tracer Fast Blue into a vagal ganglion. (c) TS of dogfish brainstem 4 mm rostral of obex following injection of horse radish peroxidase into the right glossopharyngeal nerve. The darkly stained structures located ventrally, close to the 4th ventricle (4th vent.) are motor neurons (IXm) having dendrites that project ventro-laterally into an area occupied by the reticular formation. The more diffuse area located dorsally is the dorsal sensory area (IXs) with axons projecting to the IXth cranial nerve. Scale bars are 50 μm for (a) and (b) and 25 μm for (c).

overlapping distribution in the caudal brainstem. Simultaneous recordings of neuronal activity from the medulla oblongata and an electromyogram (emg) from the respiratory muscles of carp showed that adjacent neurons have firing patterns related to different muscle sets, suggesting lack of a strict spatial topography. In contrast, recordings of efferent activity from the central cut ends of the nerves innervating the respiratory muscles of the dogfish and the pacu revealed that the Vth cranial nerve fires in advance of the VIIth, IXth, and Xth cranial nerves, with some evidence of sequential firing of this latter series in the dogfish and ray (**Figure 4**). The resultant coordinated contractions of the appropriate respiratory muscles may relate to their original segmental arrangement before the evolution of the brain, head, and jaws with their cranial musculature, each with its separate neural oscillator, an arrangement that is seen during development and apparently retained in the hindbrain of the dogfish in the sequential topographical arrangement of the motor nuclei, including the subdivisions of the vagal motonucleus (**Figure 1**). Based on developmental studies of the role of neural crest cells, a separate origin for the jaws as feeding structures, independent of the visceral arches, has been suggested and this view is supported by a study of marker genes. A possible evolutionary antecedent of the jaws may be the velum of filter-feeding protochordates that provides the major water flow in larval cyclostomes.

Our partial knowledge of the nature and topography of the RRG in fish has been traced back, in evolutionary terms, as far as the jawless cyclostomes. The lamprey, *Petromyzon* sp., has a larval form, the ammocete, which may in its ontogeny recapitulate vertebrate phylogeny because it has a muscular velum that pumps water and uses the pharyngeal clefts to filter-feed. The feeding current flowing unidirectionally through the clefts is generated in part by their ciliated epithelia but there are also muscular pumps associated with the velum and anterior branchial pouches that act against the elastic recoil of the branchial basket. The jawless adult has an oral sucker with which it attaches to fish, such as the salmon. Consequently, its mouth is closed off and it breathes via seven pairs of branchial pouches that are ventilated bidirectionally (i.e., it is a tidal breather). Ventilation is again

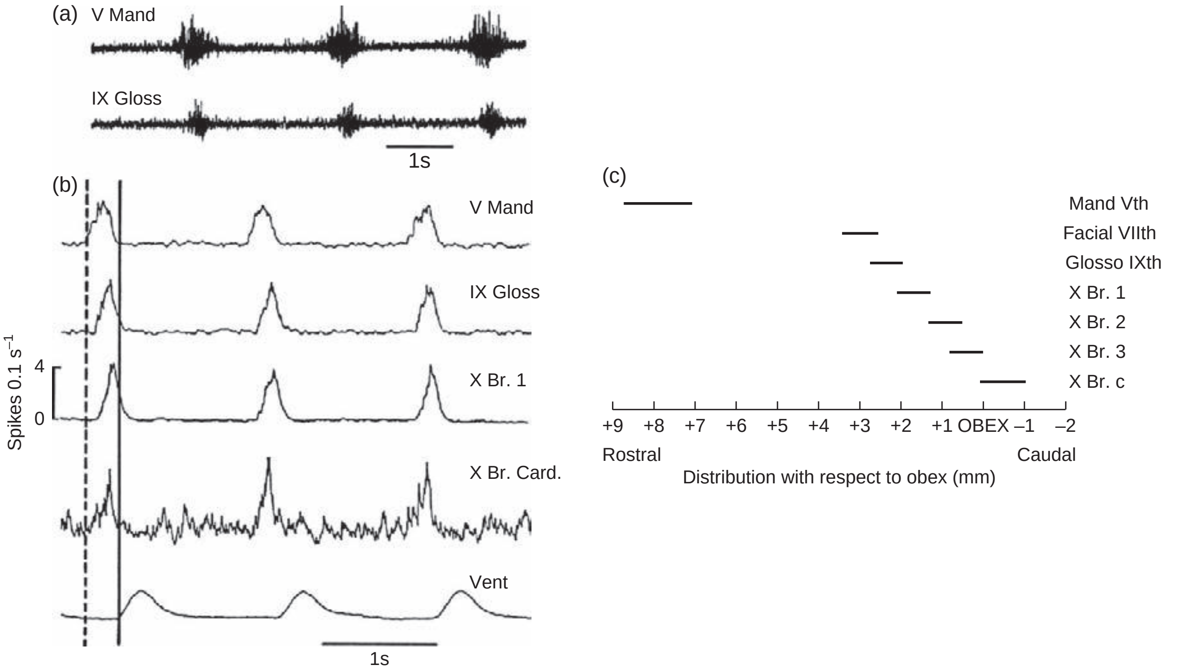

Figure 4 Spontaneous activity in cranial nerves supplying respiratory muscles and the heart in a decerebrate dogfish plus the rostro-caudal distribution of motor nuclei supplying these nerves. (a) Spontaneous bursts of activity recorded simultaneously from the Vth and IXth nerves. (b) Integrated activity recorded from the Vth, IXth, and branches of the Xth supplying a gill slit (X Br 1) and the heart (X Br card), plus movements of a gill septum (Vent). C, rostro-caudal distribution of motor neurons supplying respiratory branches of the Vth, VII, IX, and X plus the cardiac branch of X (XBr.c).

by contraction of the muscles around the branchial basket forcing water out through the pouches, with elastic recoil drawing water back into the pouches. Generation of its respiratory rhythm has provided a model for what may be the ancestral form of the vertebrate RRG.

Spontaneous bursts of respiration-related activity have been recorded from the isolated brainstem of the lamprey. As in teleost and elasmobranch fishes, periodic bursts of activity recorded from motor nuclei supplying the Vth cranial nerve, located in the rostral half of the medulla, precede those recorded from respiratory motor nuclei in the caudal half of the medulla, innervating the VIIth, IXth, and Xth cranial nerves. A brain–gill–velum preparation of the ammocete larva showed that velar pumping was driven by an RRG in the trigeminal region with descending pathways driving the branchial motoneurons; this hierarchy is retained in the adult even though the trigeminal motoneurons are no longer active as the velum ceases to act as a pump. Activity continues in the trigeminal nucleus when it is isolated from the rest of the brain, suggesting that rhythm generation involves neurons located within this region. Recent evidence suggests that rhythm generation in these rostral neurons fits a group pacemaker model as their activity continues in an isolated brainstem, bathed with chloride-free saline. Electrical stimulation of this area excites the other respiratory motoneurons directly and could entrain the respiratory rhythm. These observations suggest that the motor pattern for respiration is at least partly generated and coordinated in the rostral half of the medulla in the lamprey, possibly in the trigeminal nucleus, and is transmitted to respiratory motoneurons through descending pathways. However, the caudal region of the brainstem, including the motor nuclei of VII, IX, and X, is capable of generating rhythmic activity following transection at the level of the Vth nucleus, suggesting a separate rhythm generator possibly responsible for strong contraction of the muscles of the gill pouches or coughs used to clear the branchial basket of obstruction. Midline transaction of the rostral medulla disrupts the normal respiratory rhythm while leaving the coughs unaffected (**Figure 5**). Although the true nature of the RRG remains unresolved, the mechanisms uncovered in the cyclostomes seem to be somewhat similar to those retained in jawed fishes, implying that they utilize a mechanism that may be an ancestral link back to velar ventilation of a feeding apparatus.

Influences from the Midbrain

Although the RRG clearly resides in the medulla oblongata, several investigators have reported modulation of the respiratory rhythm following lesions or stimulation of the midbrain. Therefore, areas outside of the medulla can influence the respiratory rhythm. Two groups of neurons

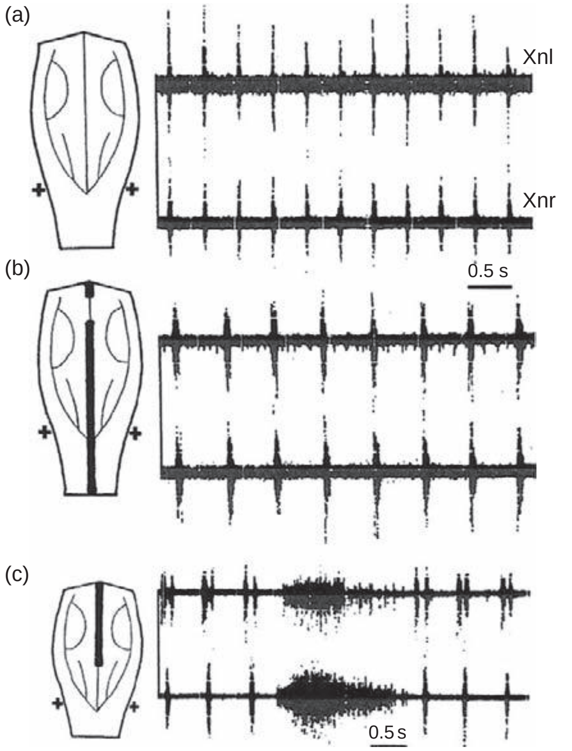

Figure 5 Effects of brain lesions on coordination of respiratory bursts in the isolated brainstem of the lamprey. (a) Synchronized respiratory bursts in left and right vagal roots prior to midline section. (b) Synchronization unaffected by sectioning of all but 0.3 mm of rostral midline. (C) Loss of synchronization after section of the rostral midline with the caudal intact. The cough is still concurrent on both sides. Redrawn from figures 7A, 7B, and 8 in Rovainen CM (1985) Respiratory bursts at the midline of the rostral medulla of the lamprey. *Journal of Comparative Physiology A* 157: 303–309.

that influence respiration have been described in the carp. Neural tracing has revealed type A neurons that have direct connections with the RF. When these neurons are electrically stimulated at frequencies close to the intrinsic respiratory rhythm, the generator is entrained to the imposed rhythm. However, these neurons are not directly involved in sustaining the normal rhythmic ventilation pattern. Activity in these neurons also anticipates the onset of a bout of ventilation during intermittent breathing (see below). A second group, called 'type B neurons', directly influences motor output to the respiratory muscles. Electrical stimulation of these neurons elicits activity in the respiratory muscles and they may act to adjust the balance of activity between the different cranial muscles during gill ventilation. Neural tracing revealed two routes from type B neurons to respiratory motor centers, a direct route and an indirect route via the RF. Electrical stimulation revealed that the either route could induce a rapid twitch response in the respiratory muscles, while the indirect route also has a long latency response that is likely to be integrative. These relationships are summarized in **Figure 6**.

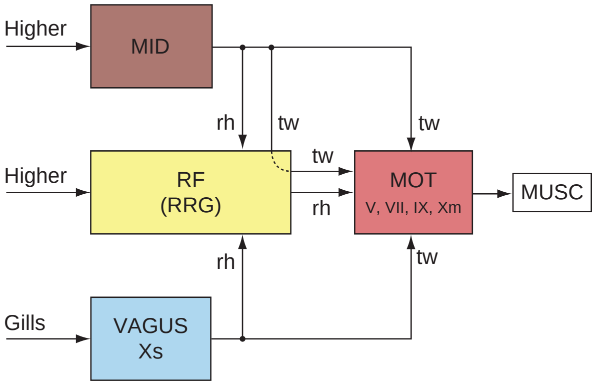

Figure 6 Possible connections in the brainstem controlling respiratory activity in fish. Relationships are described in the text. Color coding and interconnections correspond to **Figures 1** and **2**. Redrawn from figure 1.5 (1) in Ballantijn CM (1987) Evolution of central nervous control of ventilation in vertebrates. In: Taylor EW (ed.) *Neurobiology of the Cardiorespiratory System*, pp 3–27. Manchester: Manchester University Press.

Mechanoreceptors

The respiratory muscles in fish contain length and tension receptors, in common with other vertebrate muscles, and the gill arches bear a number of mechanoreceptors with various functional characteristics. By recording activity in nerves supplying the gill arches, slow-adapting position receptors on the gill arches and phasic movement receptors on the gill filaments and rakers have been described in the carp. These may function to protect the gill sieve from clogging or damaging material as strong mechanical stimulation of the gill arches is known to elicit forced expulsion of water and suspended material from the mouth in the so-called cough reflex. These mechanoreceptors should reinforce the respiratory rhythm because they will be stimulated by normal ventilatory movements of the gill arches and filaments. Indeed, when gill arches of a lightly anesthetized fish were artificially moved, the respiratory rhythm was regularly reset by the imposed movements in a manner related to the phase of the respiratory cycle at which the movement was imposed, with 1:1 entrainment achieved when the imposed rhythm was close to the natural rhythm. Thus, phasic mechanoreceptor activity likely serves to stabilize the generation of the respiratory rhythm, preventing the central generating circuits from being disrupted by other inputs.

Central stimulation (toward the brain) of nerves innervating respiratory muscles in the carp with short trains of electrical stimuli also entrained the respiratory rhythm to the imposed stimuli (**Figure 7**). Central stimulation of

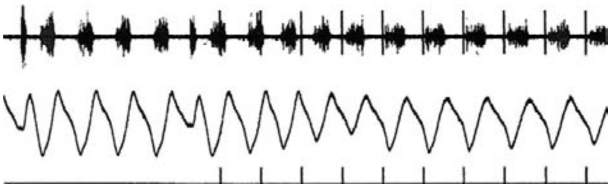

Figure 7 Recruitment of respiratory rhythm by central electrical stimulation of the vagus in the carp. Traces are in descending order: EMG of levator hyomandibulae (identified for the dogfish in **Figure 10**); ventilatory movement of an opercular bone (opening upwards); stimulus marker. Stimuli given at 900 ms led to 1:1 entrainment after the 5th stimulus. Redrawn from figure 7B in De Graaf PJF and Roberts BL (1991) Effects of sensory input on the breathing rhythm of the carp. *Journal of Experimental Biology* 155: 77–91.

branchial branches of the vagus in the dogfish with bursts of electrical pulses entrained the efferent activity in neighboring branchial and cardiac branches. In addition to stimulating ventilatory activity, increased rates of water flow can also inhibit active ventilation. In fast-swimming fishes, such as tuna and some sharks, stimulation of branchial mechanoreceptors by elevated rates of water flow may trigger cessation of active ventilatory movements during ram ventilation, when the mouth is held open to allow a continuous stream of water to ventilate the gills and powered by the locomotory rather than the branchial muscles. This confers the dual advantages of leaving the effort of ventilation to the powerful locomotory muscles and reducing drag.

The branchial branches of the IXth and Xth cranial nerves innervate a range of tonically and phasically active mechanoreceptors as well as chemoreceptors on the gill arches of fish and project directly to a dorsal sensory nucleus lying above the equivalent motor nuclei in the medulla (see **Figures 1**, **2**, and **3**(**b**) and **3**(**c**)). The sensory area, in turn, projects centrally to the respiratory motor nuclei (**Figure 2**). However, sensory fibers from branchial receptors may terminate in different locations within the brainstem and consequently have different affects on integration. Some vagal afferent fibers seem to project to vagal motoneurons innervating branchial muscles by short loops, either directly or via the RF and may be involved in the reflex contraction of adductor muscles on the gill filaments in response to mechanical stimulation of the gill filaments or gill rakers (see **Figure 2**). Stronger stimulation may induce the coughing reflex with simultaneous contraction of respiratory pump muscles that receive inputs from the RF.

Vagal afferent fibers also connect with the trigeminal complex that receives inputs from proprioceptors in the respiratory pump muscles innervated by the trigeminal Vth cranial nerve. As proprioceptive reflexes are involved in entrainment and stabilization of the respiratory rhythm, their inputs must be connected fairly directly with the rhythm-generating neurons. Some recent work indicates that chemoreceptor stimulation, relayed via the vagus, only affects ventilation when the midbrain is intact, implying that the dorsal sensory areas project to the midbrain that then influences the RRG. However, microinjection of glutamic acid into identified areas of the vagal sensory projection in sculpin, identified by injection of a fluorescent tracer (see **Figure 3**(**b**)), elicited specific, highly localized responses, including changes in ventilation frequency and amplitude (**Figure 8**). Glutamate has been identified as the neurotransmitter for afferents into the nucleus tractus solitarius (NTS) in mammals.

Episodic Breathing

Inactive fish often interrupt their normal regular rhythm of gill ventilation in normoxic or hyperoxic waters and

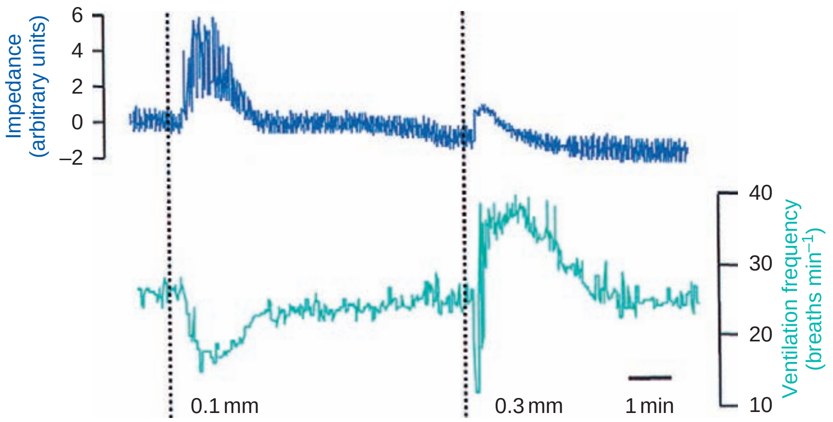

Figure 8 Microinjection of glutamate into the brainstem of the sculpin at two depths 0.2 mm apart, on a single trajectory, elicits very different respiratory responses. Impedence is a measure of ventilatory movements. Redrawn from figure 6 in Sundin L, Turesson J, and Taylor EW (2003) Evidence for glutamatergic mechanisms in the vagal sensory pathway initiating cardiorespiratory reflexes in the shorthorn sculpin *Myoxocephalus scorpius*. *Journal of Experimental Biology* 206: 867–876.

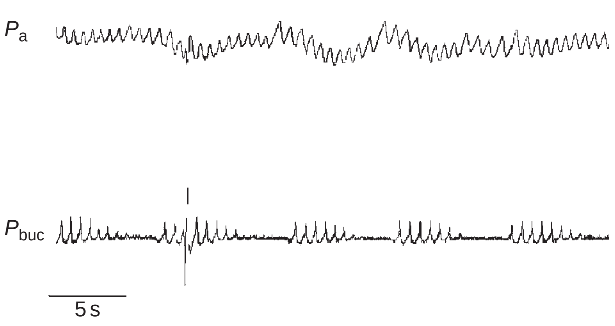

Figure 9 Episodic breathing pattern in undisturbed, normoxic pacu. Heart rate rises during each bout of gill ventilation. Previously unpublished data from C. Leite. P_a, arterial blood pressure; P_{buc}, pressure in the buccal cavity.

exhibit episodic (or intermittent) breathing patterns (see **Figure 9**). As muscles work optimally during bouts of moderate activity, compared to continuous low levels of activity, this may save energy.

Type-A neurons located in the midbrain of carp appear to play a key role in the control of episodic breathing. They typically fire just before the onset of a breathing bout during intermittent ventilation. In addition, during a ventilatory pause, stimulation of this area of the midbrain brings forward the onset of the next breathing bout. However, something other than the absence of activity in these neurons seems to be involved in the cessation of episodes of breathing. This is likely to be the stimulation of an internal receptor by the rise in blood-oxygen level above a threshold for cessation of breathing; however, this remains to be established. Central electrical stimulation of the vagus nerve also initiates ventilation in carp breathing intermittently, which is likely to be a response to stimulation of fibers innervating gill chemoreceptors.

Recruitment of Feeding Muscles

During routine aquatic ventilation in fish, expansion of the oro-branchial cavity relies largely on elastic recoil in the muscles and branchial skeleton (i.e., on the tendency of the branchial skeleton to resume its former shape following its distortion by contraction of the respiratory muscles), particularly in cartilaginous fish such as sharks and in the cyclostomes. However, during the vigorous, forced ventilation following exercise or deep hypoxia, both elasmobranch and teleost fishes recruit additional muscles into the respiratory cycle. These are normally used for active expansion of the oro-branchial cavity to ingest food but can also enhance inspiration of water into the buccal cavity during the mouth-opening phase. These muscles form a complex ventral sheet, inserted between the pectoral girdle, the lower jaw, and the ventral processes of the hyoid and branchial skeleton (**Figure 10**). They are innervated by the hypobranchial nerve, which contains elements of the occipital nerves and the anterior spinal nerves (**Figures 1** and **2**). The hypobranchial nerve in fish is the morphological equivalent of the hypoglossal nerve, which innervates the muscles of the tongue in

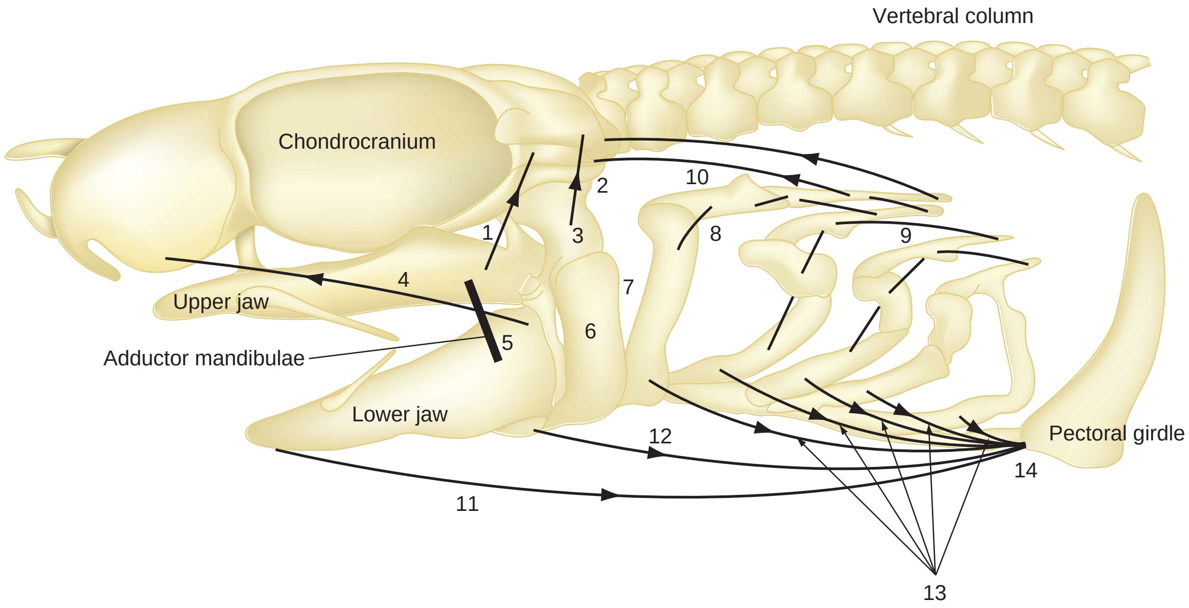

Figure 10 Diagrammatic illustration of the dogfish cartilaginous skull and branchial skeleton to show the insertion of muscles. Respiratory muscles (1–9), are inserted around the jaws and gill arches and are innervated by cranial nerves V, VII, IX, and X. The adductor mandibulae is the main jaw closing muscle. Feeding muscles (11–14) are inserted onto the pectoral girdle and innervated by the hypobranchial nerve complex (occipitals and anterior spinals) They are used to actively expand the branchial basket during forced ventilation.

reptiles, birds, and mammals. These tongue muscles are used for suckling by infant mammals, an activity likely to require its own central oscillator.

Intravenous injection of noradrenaline, which simulates the response of fish to deep hypoxia or intense disturbance, caused a previously silent hypobranchial nerve to fire respiration-related activity. The mechanisms involved in recruitment of hypobranchial motoneurons into the respiratory rhythm have not been studied but the motoneurons supplying the occipital nerves have an overlapping distribution with vagal motoneurons supplying respiratory muscles and with the caudal extension of the RF (see **Figures 1–2**). In the dogfish and ray, rhythmic opening and closing of the mouth occur during ingestion of food, implying the central generation of a feeding rhythm. The respiratory and feeding rhythms in fish are thought to be generated by separate groups of interneurons. It is now well established that in mammals the masticatory and suckling rhythms are generated in the hindbrain, in the RF. The pre-Bötzinger nucleus that forms part of the RF is now considered to be the primary site for respiratory rhythmogenesis in neonatal mammals. As was detailed above, it is the RF that is thought to contain the RRG in fish, indicating the early evolution of a functional role in the generation of rhythmical contractions for this discrete area in the brainstem. Its subsequent retention in the tetrapods was associated with some adaptive changes in its role, possibly associated with the evolution of lung breathing and the need to control contractions of thoracic as well as cranial muscles.

Air-Breathing Fishes

Air-breathing fishes have evolved a variety of air-breathing organs (ABOs) for obtaining oxygen from above the water surface but retain gills, ventilated by cranial muscles, for the uptake of a variable proportion of their oxygen requirements, dependent on species and conditions, and for excretion of most of their carbon dioxide (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction). Many facultative air breathers, such as the tarpon (*Megalops cyprinoides*), rely on gill ventilation and restrict blood flow to the ABO in normoxic water but increase rates of air breathing and perfusion of the ABO with hypoxic exposure and particularly during exercise. During these periods, opercular beating becomes imperceptible, indicating cessation of effective gill breathing or a switch to ram ventilation while swimming. Access to air reduces the lactic acid load during burst swimming and prolongs aerobic exercise in tarpon; however, they are able to repay an accumulated oxygen debt during recovery by increased rates of gill ventilation.

In all air-breathing fish, gulping of air at the water surface is achieved through the action of the same muscles as used for feeding or for forced ventilation in water-breathing fishes. These are elements of the jaw musculature, innervated by cranial nerve V, together with the hypobranchial musculature, innervated by occipital and anterior spinal nerves. They function together in a coordinated action either for feeding or for gulping air, actions that are independent of the visceral arches and may derive from their separate evolutionary origins as feeding muscles. In the primitive ray-finned (actinopterygian) fish, the bowfin (*Amia calva*), which utilizes a well-vascularized swimbladder as an ABO, there appear to be two types of air breath, one that involves exhalation followed by inhalation (designated type I air breaths) and one that simply involves inhalation (type II air breaths). Type I breaths are possibly respiratory in nature, whereas type II breaths have a buoyancy-regulating function. Spectral analysis indicates an inherent rhythmicity to type I (i.e., respiratory-related) air breathing, both in normoxia and hypoxia that may be driven by the changes in blood O_2 status during the interbreath interval, rather than by an RRG for air breathing. Control of the switch between ventilation of the gills and the ABO is likely to relate to stimulation of chemoreceptors by reduced oxygen levels at the gills or in the ABO (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes). However, the central sites responsible for control of air-breathing reflexes in fish are still unknown.

Reorganization of the CNS associated with the evolution of air breathing has been poorly studied in fish. Actinopterygian air-breathing fishes probably have an RRG for gill ventilation located in the RF of the hindbrain similar to that of water-breathing fish. In the bowfin, catecholamine infusion stimulates gill ventilation, apparently via a central mechanism, but has no effect on air breathing in normoxia or hypoxia, indicating that central sites controlling gill ventilation and air breathing are pharmacologically and possibly spatially different. However, the sequence of events associated with air breathing in the bowfin suggests that the action of air breathing would require little change in the pattern of neural control required for suction feeding and/or coughing, with the exception of control over opening of the glottis at the entrance to the ABO. Neural tracers revealed that the ABO in the bowfin is innervated by vagal motor neurons that may supply the glottis or smooth muscle in the walls of the ABO. An isolated brainstem preparation from the long-nosed gar, *Lepisosteus osseus*, showed two distinct motor patterns in fictive respiratory activity recorded from the root of the Vth cranial nerve, a high-frequency, low-amplitude pattern, associated with gill breathing and a low-frequency, high-amplitude pattern associated with ventilation of the lung during air breathing (**Figure 11**). This latter activity was associated with phasic activation of the Xth cranial nerve. The differing motor patterns and recruitment of vagal motoneurons suggest the presence of two separate oscillators.

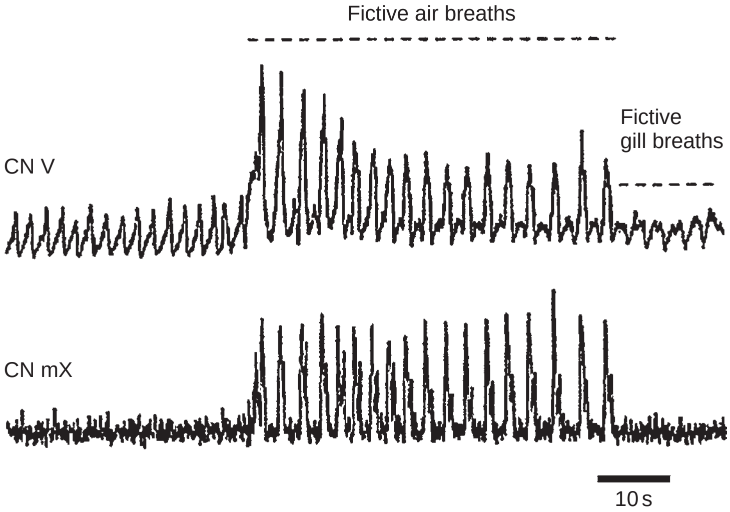

Figure 11 Integrated bursting activity recorded from the roots of the Vth cranial nerve (CNV) and a medial root of X (CNmX) of an isolated brainstem preparation of the gar *Lepisosteus osseus*. Fictive gill breathing is interrupted by a bout of fictive air breathing with stronger bursts in CNV and bursting activity in CNmX. From figure 2B in Kinkead R (2009) Phylogenetic trends in respiratory rhythmogenesis: Insights from ectothermic vertebrates. *Respiration Physiology and Neurobiology* 168: 39–48.

There may be separate origins for air-pumping mechanisms in actinopterygian fishes and the lobe-finned (sarcoptergian) lungfish together with their evolutionary cousins, the amphibians. However, both utilize the same sets of muscles to pump air into the lung, and consequently may possess the same central oscillators. African lungfish (*Protopterus aethiopicus*) may possess two separate central rhythm generators, one for gill ventilation and the other for air breathing. The sequence of airflow in the breathing cycles of lungfish and amphibians, such as bullfrogs, is essentially similar. In amphibians, there is evidence that evolution of air-breathing rhythms may have required a new motor pattern in the CNS rather than one evolved from progressive modification of the branchial rhythm generator. Episodic breathing rhythms were recorded from an isolated brainstem of a bullfrog, implying that they are generated centrally in the absence of patterned inflow from receptors. Microinjection of glutamate into rostral areas of the bullfrog-isolated brainstem in an area of the RF that corresponds to that identified as responsible for respiratory rhythmogenesis in fetal mammals, caused brief breathing episodes. It seems that the neural networks associated with respiratory rhythmogenesis have been well conserved during vertebrate evolution.

Summary

Respiratory rhythmogenesis resides in the brainstem of all vertebrates, including fish, and the isolated medulla oblongata can generate a respiratory rhythm. However, the site of the primary generator is poorly defined and its activity is modulated by centers in the midbrain and stabilized by peripheral inputs from mechanoreceptors on the gills. The respiratory rhythm in fish may become episodic or cease completely during ram ventilation. When oxygen demand is high, feeding muscles can be recruited into the respiratory cycle to provide active inspiration of water during the mouth-opening phase. Air-breathing fish utilize the same muscles to gulp air at the water surface. There is some evidence of separate RRGs for water and air breathing but their properties and locations are unclear

Glossary

Acidosis Decreased pH in water or blood.

Hypercapnia High levels of carbon dioxide in blood.

Hypercarbia High levels of carbon dioxide in water or air.

Hyperoxia High levels of oxygen in water or arterial blood.

Hyperventilation An increase in ventilation.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Normoxia Normal levels of oxygen in water or arterial blood.

Respiratory alkalosis An increase in pH in arterial blood due to excessive ventilation leading to excretion of carbon dioxide.

Ventilation stroke volume The volume of water pumped with each compression of the orobranchial cavity during breathing in fish.

Ventilation volume The total amount of water pumped over the gills in a period of time (usually 1 min); the product of the rate of breathing multiplied by the volume of water pumped with each breath.

Introduction

While there is no doubt that the primary drive to breathe in fish is the need to obtain sufficient oxygen to fuel metabolism, fish also need to excrete the CO_2 that is produced as a by-product of this metabolism in order to regulate pH levels within their tissues around an optimum for enzyme and protein function. These two needs (to obtain oxygen and to excrete CO_2) are tightly linked because CO_2 is produced indirectly in the process of using O_2 to produce adenosine triphosphate (ATP) (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange).

The exchange of these gases takes place primarily at the gills in most fish, as well as across the skin in some species, and through accessory air-breathing organs in others (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes). In general, to meet the metabolic demands of the tissues for O_2 uptake and CO_2 excretion, levels of internal (blood) and external (water) O_2 and CO_2 must be sensed so that appropriate ventilatory responses can be generated to match O_2 supply to tissue demand and to match CO_2 excretion to its rate of production.

Adjusting ventilation is one of the most important reflex responses maintaining relatively constant levels of CO_2/H^+ in the tissues. Because of differences in the solubility of oxygen and CO_2 in water (CO_2 is roughly 20 times more soluble), it takes much higher water flow rates over the gills to obtain O_2 from the water than to excrete an equivalent amount of CO_2 into the water. As a result, CO_2 excretion is easily achieved from the ventilation required to obtain oxygen. Regardless, fish respond to increased levels of environmental CO_2 (hypercarbia) and/or decreases in pH (acidosis) by increasing their gill ventilation. Similarly, increases in internal arterial CO_2 (hypercapnia) and decreases in pH associated with increased metabolism also stimulate gill ventilation. Clearly, fish have a ventilatory response to CO_2 and H^+, despite the ease of CO_2 removal across the gills. This response is the topic of this article.

Reflex Responses

Exposure to elevated levels of aquatic CO_2 (hypercarbia) typically elicits an immediate increase in ventilation volume through increases in the volume of water pumped with each breath (stroke volume) and/or breathing frequency. This hypercarbic response is additive with those induced by hypoxia (low oxygen) and hyperoxia (high oxygen). Consequently, exposure to a hypoxic, hypercarbic environment (usually these two occur together in nature) produces a greater response than exposure to either condition alone. This acute, or immediate, response can, in some species, be followed by secondary changes that slowly return ventilation to resting levels despite a sustained hypercarbic exposure.

The increase in the amount of aquatic CO_2 required to elicit a ventilatory response (the threshold level) varies greatly among species. Some species (eel, *Anguilla anguilla*), carp (*Cyprinus carpio*), and tambaqui (*Colossoma macropomum*), and traira (*Hoplias malabricus*)) require fairly high levels of CO_2 (>5% CO_2) before they respond, while others (zebrafish (*Danio rerio*), rainbow trout (*Oncorhynchus mykiss*)) are very sensitive, responding to very small changes in aquatic CO_2 (<1% CO_2). This finding may reflect species-specific tolerances to CO_2, with ventilatory responses to CO_2 only being elicited at environmentally relevant levels (**Figure 1**).

Similar responses occur in most air-breathing fish. In most species, gill ventilation increases in response to relatively low levels of hypercarbia (<3%) despite relatively stable levels of arterial P_{CO_2}. This is a reasonable response since the majority of CO_2 in air-breathing fishes is excreted via the gills rather than the air-breathing organ (ABO). Even so, in some air-breathing fish, further increases in aquatic CO_2 (>2–10%) inhibit gill breathing and stimulate air breathing, often, also with no accompanying changes in arterial P_{CO_2} (**Figure 2**). Just as in water-breathing fish, it appears that a water-sensing CO_2 receptor stimulates gill ventilation but its input is transformed centrally (in the brain) to excite air breathing and inhibit water breathing with increasing levels of stimulation. Just as with aquatic CO_2, some air-breathing fish show no response to increasing levels of CO_2 in inspired air, while others show an increase in ventilation of the air-breathing organ (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

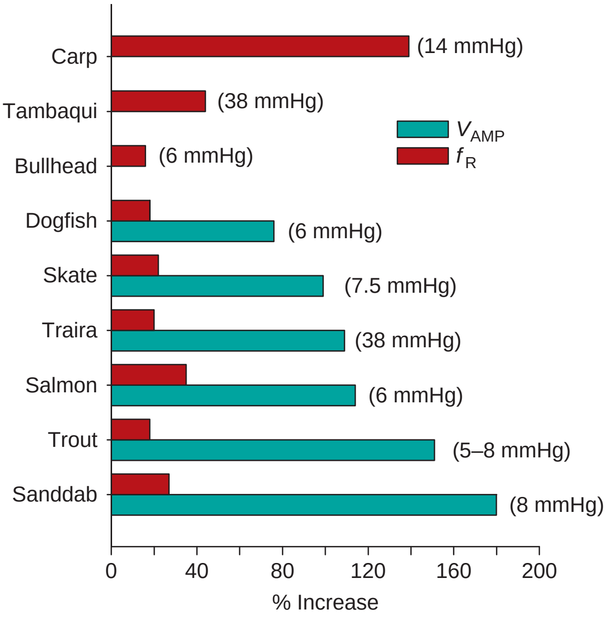

Figure 1 Increase in breathing frequency (f_R) and tidal volume (V_{AMP}) upon exposure to CO_2 (levels shown in brackets for each species). The threshold level of CO_2 required to produce a response, and the magnitude of the response varies between species as a function of factors such as CO_2 tolerance, gill surface area, body weight, activity levels, temperature, and chemosensitivity. The relative contribution of changes in f_R and V_{AMP} to the increase in total ventilation also varies between species. (Adapted from Gilmour KM (2001). The CO_2/pH ventilatory drive in fish. *Comparative Biochemistry and Physiology A*. 130: 219–240.

The hypercapnic ventilatory response in fish appears to be relatively weak when compared to the hypoxic ventilatory response (**see also Hypoxia**: Respiratory Responses to Hypoxia in Fishes). Thus, hyperoxia reduces ventilation despite the fact that it is accompanied by a rise in arterial CO_2 and a fall in pH. This finding suggests that O_2 delivery in fish is regulated at the expense of CO_2 excretion. This is also true in terrestrial vertebrates, where CO_2 is the primary drive to breathe (e.g., at altitude, mammals hyperventilate despite the production of a significant rise in pH (respiratory alkalosis) due to the heavy breathing). This suggests that while the primary drive to breathe varies between aquatic and terrestrial vertebrates under resting, normoxic conditions, under hypoxic conditions, terrestrial vertebrates behave more like fish because the need to match O_2 supply with O_2 demand predominates.

Location of CO_2 Chemoreceptors

Gill (Branchial) Chemoreceptors

The ventilatory response to CO_2/H^+ in fish arises primarily, if not exclusively, from receptors distributed throughout the gill arches innervated by the IX (glossopharyngeal) and X (vagus) cranial nerves. These chemoreceptors have been identified primarily on the basis of respiratory reflexes to CO_2/H^+ that are eliminated by sectioning the nerves to the gills or removing gills completely (**Figure 3**). However, while it is clear that there are receptors in the gill that monitor the CO_2 in the water, it is not entirely clear whether receptors exist in the gills that can respond specifically to changes in the CO_2 of arterial blood.

Indirect evidence suggests that there are such internal CO_2 receptors. Following exhaustive exercise in normoxic water, ventilation remains elevated although arterial P_{O_2} returns to normal. Arterial P_{CO_2}, however, also remains elevated and pH deceased. Reducing the post-exercise acidosis with carbonic anhydrase injections (an enzyme that enhances CO_2 excretion at the gills (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbonic Anhydrase in Gas Transport and Exchange)) reduces this hyperventilation. Furthermore, in rainbow trout, intra-arterial injections of CO_2/H^+ stimulate ventilation. These data argue strongly for the presence of

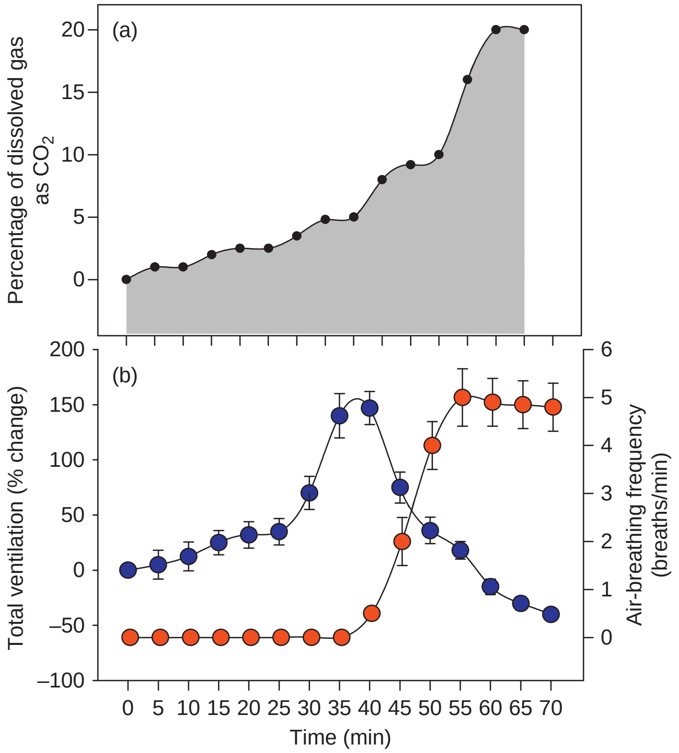

Figure 2 As aquatic levels of CO_2 rise (a), air-breathing fish (Jeju – *Hoplerythrinus unitaeniatus*) switch (b) from gill ventilation (blue symbols) to air breathing (red symbols). Adapted from Boijink C, de L , Florindo L-H, Leite CAC, Kalinin AL, Milsom, WK, and Rantin FT (2010) *Journal of Experimental Biology* 213: 2797–2807.

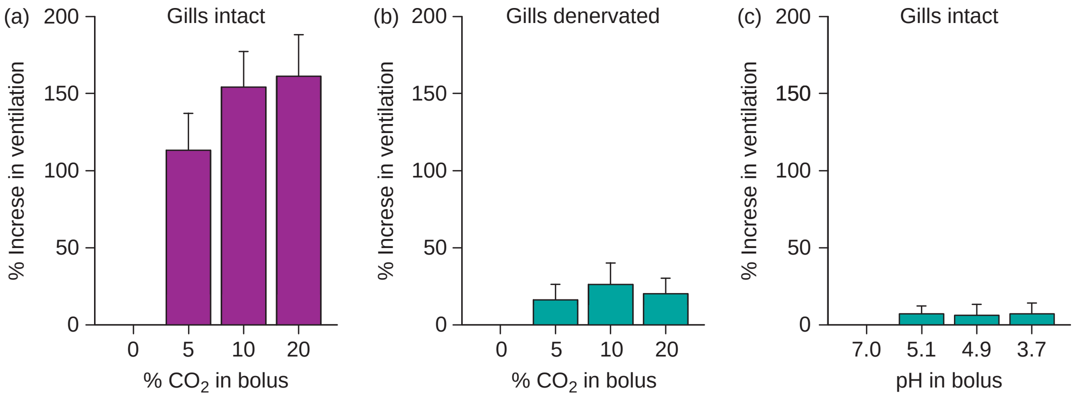

Figure 3 The effects of injecting water over the gills containing different levels of CO_2 (a) before and (b) after denervation of the gills as well as (c) water containing different levels of H^+ (i.e., at different pH) but constant levels of P_{CO_2} in the jeju. Note that the effects of increasing levels of CO_2 are eliminated by denervating the gills and that changing pH has no effect if the P_{CO_2} does not change. (Adapted from de Lima Boijink C, Florindo L-H, Leite CAC (2009) *Journal of Experimental Biology* 213: 2797–2807

internal receptors monitoring changes in the CO_2/H^+ levels in arterial blood. Other lines of evidence, however, suggest that there are no receptors monitoring such changes. In many studies, intra-arterial injections of CO_2/H^+ had no effect on ventilation (in spiny dogfish (*Squalus acanthias*), Atlantic salmon (*Salmo salar*), rainbow trout, tambaqui, and traira). Furthermore, injections of acetazolamide (a drug that blocks carbonic anhydrase) that lead to CO_2 retention and blood acidification also do not alter ventilation (**Figure 4**). This issue remains to be resolved.

Air-breathing fish (chondrosteans, holosteans, and teleosts, as well as the sarcopterygian lungfish) have not been well studied in this respect. Thus, there is no evidence to suggest where the receptors reside that produce responses to CO_2/H^+ in these fish. Based on the location of the receptors responsible for changes in gill ventilation in exclusively water-breathing fish, as well as the receptors sensing aquatic O_2 that stimulate both gill and lung ventilation in the African lungfish, *Protopterus* (peripheral O_2-sensitive chemoreceptors are also CO_2 sensitive in air-breathing vertebrates),

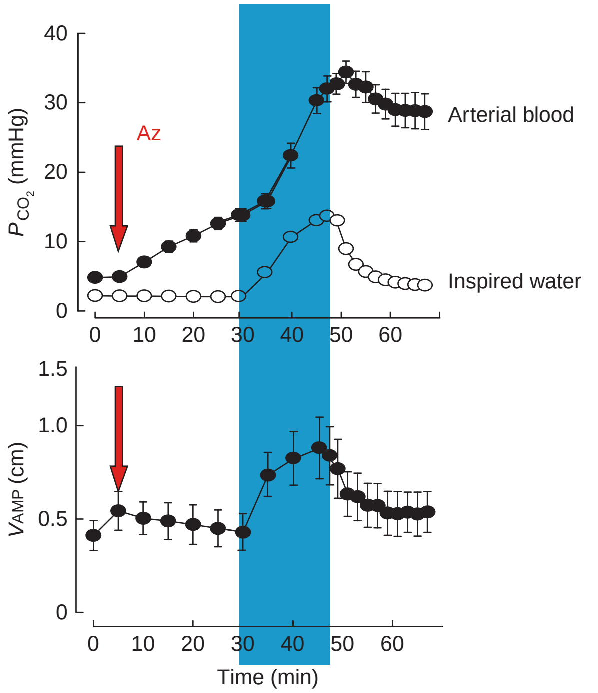

Figure 4 Increasing arterial PCO_2 using the drug azetazolamide (Az; which inhibits CO_2 excretion) has no effect on breathing (ventilatory amplitude, V_{AMP}) but elevating CO_2 tension in the water stimulates breathing. When the CO_2 in the water is returned to normal, breathing slows again despite the fact the arterial CO_2 levels remain elevated. This suggests that all responses are to changes in P_{CO_2} in the external water, not in the blood. (Adapted from Gilmour KM, Milsom WK, Rantin FT, Reid SG, and Perry SF (2005) Cardiorespiratory responses to hypercarbia in tambaqui *(Colossoma macropomum)*: Chemoreceptor orientation and specificity. *Journal of Experimental Biology* 208: 1095–1107.

they will likely be found on all gill arches, but may be more predominant on the first two arches (which have a reduced gas-exchange function in many air-breathing fish).

Extra-Branchial Receptors

There are some indications that extra-branchial CO_2/H^+ chemoreceptors may also exist. There are cases where the increase in ventilation stroke volume elicited by aquatic hypercarbia was not eliminated by branchial denervation and it has been suggested that the sites of the receptors giving rise to the residual response could be located elsewhere in the oro-buccal cavity, which has also been suggested for extra-branchial O_2 chemoreceptors.

Gustatory and Olfactory Receptors

Gustatory chemoreceptors are sensory cells of epithelial origin that are incorporated into taste buds in the oral cavity, palate, gill arches, skin, and barbels (**see also Smell, Taste, and Chemical Sensing**: Morphology of the Gustatory (Taste) System in Fishes). Their afferent sensory information is transmitted to the brain via cranial nerves VII, IX, and X. They respond to both CO_2 and H^+. Stimulation of them leads to a reduction (rather than an elevation) in ventilation amplitude and frequency. It has also been suggested that stimulation of CO_2-sensitive chemoreceptors in the olfactory epithelium inhibits breathing as it does in amphibians, reptiles, and mammals.

The only receptors that have been found to be sensitive to CO_2 in lungs and other air-breathing organs of air-breathing fish are pulmonary stretch receptors. Slowly adapting pulmonary stretch receptors in both the African (*Protopterus*) and South American (*Lepidosiren*) lungfish are inhibited by normal, physiological levels of CO_2, but those in the gar (*Lepisosteus osseus*) and the bowfin (*Amia calva*) are not. There is also evidence that olfactory/gustatory chemoreceptors sensitive to CO_2 in inspired air inhibit breathing.

Central Receptors

Experimental evidence supporting the existence of central (brain) CO_2/H^+ chemoreceptors in water-breathing fish is equivocal. While there is some evidence suggesting that such receptors exist, most studies have failed to find evidence for chemoreceptors that influence breathing within the brain. There is, however, stronger evidence for their existence in air-breathing fish (**Figure 5**). They have been shown, unequivocally, to be present in the Sarcopterygian lungfish, and there is strong evidence for their presence in gar and Siamese fighting fish (*Beta splendens*), but not *Amia* or Alaska blackfish (*Dallia pectoralis*).

To summarize, present data suggest that the ventilatory response to CO_2/H^+ primarily arises from receptors

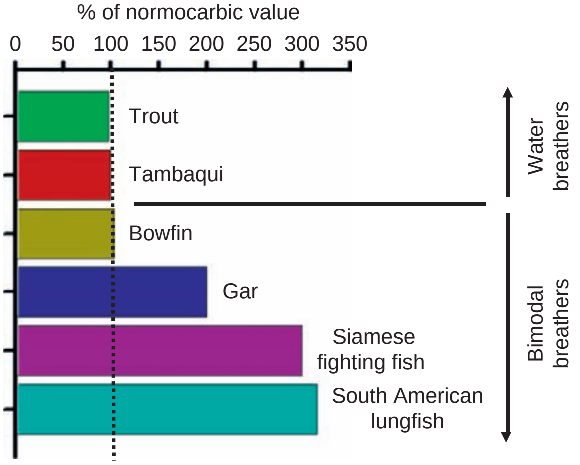

Figure 5 There are no effects of changes in the CO_2/pH of cerebro-spinal fluid on ventilation in water-breathing fish but there are significant increases in bimodal breathing fish (fish that breathe water and air) except for the bowfin (100% is the normal resting level of ventilation).

distributed throughout the gill arches sensitive to aquatic CO_2. Fish gill arches share a common embryological origin with the carotid and aortic arches of tetrapods, and the branchial distribution of water-sensing CO_2 chemoreceptors and water/blood-sensing O_2 chemoreceptors that modulate cardiorespiratory function in fish is phylogenetically consistent with the distribution of peripheral chemoreceptors that monitor only blood CO_2/pH and O_2 in tetrapods.

Stimulus Specificity

Aquatic hypercarbia is accompanied by alteration in water pH, and exposure to this water leads to changes in the P_{CO_2} (hypercapnia) and pH (acidosis) of arterial blood in the fish. Furthermore, these changes in arterial P_{CO_2}/pH induce a Root effect in hemoglobin in many fish, leading to reductions in arterial O_2 content (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). As a result, responses to aquatic CO_2 could be due to changes in any one, or combination of, water CO_2, water pH, arterial CO_2, arterial pH, or arterial O_2 content. It was once thought that a change in arterial O_2 content was the proximate stimulus driving ventilation under hypercarbic conditions, but it is now clear that CO_2/pH directly affects gill ventilation.

Fish respond rapidly when they encounter environmental hypercarbia or injections of CO_2 equilibrated water into the buccal cavity. They respond poorly to injections of water of different pH; environmental acidification has little effect on ventilation in the absence of changes in CO_2. This suggests that the receptors responding to external stimuli respond specifically to changes in CO_2 in the water (**Figure 3**).

To the extent that there is evidence for ventilatory responses arising from receptors responding to internal stimuli (i.e., stimuli in arterial blood), there is a better correlation between the changes in ventilation and changes in arterial pH rather than in arterial P_{CO_2}.

At present, it is thought that the chemosensory cells in the gills are neuroepithelial cells in the branchial epithelium. Certainly, there is strong evidence that neuroepithelial cells in zebrafish sense O_2 by means of a mechanism similar to that in mammalian O_2-chemoreceptors, relying on an O_2-sensitive background K^+ channel (**see also Control of Respiration**: Oxygen Sensing in Fish). The O_2-chemoreceptors of mammals and other tetrapods also exhibit sensitivity to CO_2, raising the possibility that the same situation holds true for fish-gill neuroepithelial cells. In support of this, recent studies have shown that some cultured branchial neuroepithelial cells from zebrafish contain carbonic anhydrase, an enzyme that plays a key role in mammalian CO_2 chemotransduction. Some of these branchial neuroepithelial cells depolarize under hypercapnic conditions. This process also appears to rely on a background K^+ channel, and roughly half of the cells also respond to changes in O_2. Interestingly, this implies that although these receptors may only respond to changes in aquatic CO_2 and not $[H^+]$, at the cellular level, they do this by responding to CO_2-induced changes in intracellular pH.

Glossary

Chemoreceptor A type of cell that is specialized to detect chemical stimuli and convert them into signals within the nervous system.

Depolarization The reduction in electrical potential difference (voltage) measured across a cell membrane. This means the inside of the cell becomes less negative with respect to the outside of the cell. Depolarization occurs during the upsweep of the action potential (opposite of repolarization).

Equilibrium potential The membrane potential (voltage) at which there is no net flow of current for a particular ion. This value can be calculated for any ion using the Nernst equation and is based on the intracellular and extracellular concentrations of that ion.

Ion channel A protein or a group of proteins that form water-filled pores which span the cell membrane. These pores, when open, allow a rapid but selective flow of ions through the cell membrane. Each channel type is specific for one inorganic ion (sodium, calcium, potassium, or chloride).

Neuroepithelial bodies (NEBs) Clusters of neuroepithelial cells that are found in the lung and airway epithelium in neonatal mammals. NEBs are O_2 sensitive.

Neuroepithelial cells (NECs) Within the context of this article, these are cells that exist within the epithelial layer of the gill and are capable of storing and releasing a chemical transmitter from the cytosol. Some authors also refer to these cells as neuroendocrine cells. NECs are the putative oxygen chemoreceptors in aquatic vertebrates.

Oxidative phosphorylation A process in the mitochondrion in which the synthesis of adenosine triphosphate (ATP) is driven by (1) the transfer of electrons along the electron-transfer chain to molecular O_2, and (2) coupling to an electrochemical H^+ gradient.

Partial pressure of O_2 (P_{O_2}) The atmospheric pressure exerted by O_2 alone proportional to the total concentration of this gas. It is typically measured in either mmHg (torr) or kPa.

Postsynaptic Denotes a cell that occurs after the synaptic cleft (an intercellular space) with respect to the flow of information in the nervous system.

Resting membrane potential The measured voltage difference across the plasma membrane for a cell that is not stimulated, but is at rest. The resting potential is based on the concentrations of all charged ions inside and outside of the cell, and also the resting permeability of the membrane.

Introduction

Oxygen is a major element of nearly all important biological macromolecules and played a critical role in the evolution of life on Earth. However, in its diatomic or molecular form, O_2, this gaseous molecule is capable of accepting electrons and participating in oxidation–reduction reactions necessary for the production of metabolic energy within cells. It is this metabolic dependence on O_2 for cellular energy production that defines aerobic organisms and is a characteristic of most eukaryotes.

Another important characteristic of eukaryotes is the presence of numerous mitochondria within the cytosol, for it is within this organelle that O_2 promotes energy production for the entire cell. Oxygen diffuses freely from the cell's cytosol, through both the outer and inner mitochondrial membranes, and finally into the matrix of the mitochondrion, where it acts as the final acceptor of electrons from the electron-transport chain.

The electron-transport chain is a set of proteins that pumps hydrogen ions (H^+) from the mitochondrial matrix to the intermembrane space, where it stores potential energy by establishing an electrochemical gradient of H^+ (i.e., a pH gradient) so that these ions flow passively back to the matrix. It is the energy of H^+ returning to the mitochondrial matrix that is harnessed by another protein complex, an adenosine triphosphate (ATP) synthase, which converts adenosine diphosphate (ADP) to ATP, the currency of cellular energy. This entire process is called oxidative phosphorylation. From the above description, it will be apparent to the reader that O_2 is required for this process. Without it, ATP production in the cell is compromised and this may have dire consequences for the life of the cell (**see also Hypoxia**: Anaerobic Metabolism In Fish and The Expanding Hypoxic Environment). Not surprisingly, the amount of O_2 reaching a cell must be maintained, or even defended, to ensure survival.

If we now advance this discussion to a multicellular organism, such as a vertebrate composed of tissues, organs, and a vascular system, delivery of O_2 to every cell is tightly regulated to avoid ischemic tissue damage and cell death caused by O_2 lack, or hypoxia. But how does a multicellular organism, such as a vertebrate, regulate sufficient uptake of O_2 (e.g., via respiration) to maintain an adequate supply to every cell? More specifically, how is low O_2 in the environment sensed so that this regulatory process can be initiated in the first place? These questions are addressed here.

Most of what is known about the cellular mechanisms of O_2 sensing has come from decades of research on respiratory chemoreceptors of mammals that are sensitive to changes in O_2. Chemoreceptors are cells that are specialized to respond to specific chemicals in their environment. For example, olfactory and lingual epithelia bear chemoreceptors that underlie the sense of smell and taste, respectively. Chemoreceptors are specialized in that they retain a gamut of protein complexes within the plasma membrane, and signaling proteins within the cytosol, that are devoted to detecting specific molecules or even ions. Naturally, chemoreceptors must have access to a sampling environment, and they must also have a means of communicating with other cells so that the chemical message can be relayed to appropriate regions of the central nervous system. Respiratory chemoreceptors that are sensitive to O_2, therefore, are cells that may detect changes in the partial pressure of O_2 (P_{O_2}) in the air, water, or blood, and initiate appropriate physiological changes.

In mammals, there are two important types of respiratory chemoreceptors that regulate changes in ventilation. Type I cells (or glomus cells) are chemoreceptors of the carotid body that sample the chemical content of the blood, such as the partial pressure of O_2 (P_{O_2}). The carotid body is a paired organ found at the bifurcation of the common carotid artery, where it divides into the internal and external carotids. It is the primary O_2-sensing organ in mammals and elicits hyperventilation in response to low arterial P_{O_2}. Neuroepithelial bodies (NEBs) of the airway and lung epithelium are clusters of chemoreceptive cells that also respond to hypoxia, but are believed to play a role in controlling respiration during the neonatal period. As is explained in the following sections, O_2 chemoreceptors of mammals have morphological and physiological properties similar to those of fish. In fact, one of these similar properties is their anatomical location. The site of the mammalian carotid body is derived from the same embryonic structure as the gills, where O_2 chemoreceptors are found in fish. For this reason, we may make some comparisons between O_2 chemoreceptors of mammals and fish to help understand how O_2 sensing might occur in the latter.

Reflex Responses to Hypoxia

In all vertebrates, including fish, a reduction of O_2 in the environment will produce a variety of reflex responses, including hyperventilation, a change in heart rate (in fish, hypoxia slows heart rate; **see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia), and changes in vascular resistance, in order to allow the animal to adapt to changing environmental conditions. These reflex responses, however, are not reviewed here (**see also Hypoxia**: Respiratory Responses to Hypoxia in Fishes). But it is important to note that studies characterizing the way in which fish respond to hypoxia were instrumental in determining that respiratory chemoreceptors were located within the gill region. However, it was not until extracellular electrical recordings were obtained from the nerves innervating the gills that the presence of gill O_2 chemoreceptors could be verified. When isolated gill arches were subjected to hypoxia, recordings from gill nerves displayed an electrical discharge consistent with hypoxic stimulation of gill chemoreceptors. These same studies also indicated that gill O_2 chemoreceptors may respond to hypoxia detected in the water (externally oriented chemoreceptors) as well as hypoxia detected in the arterial blood supply (internally oriented chemoreceptors).

Microscopic Observations of Gill O_2 Chemoreceptors

Since the early 1980s, studies using both light and electron microscopy have provided morphological evidence implicating a group of cells, called neuroepithelial cells (NECs), as the most suitable candidates for O_2 chemoreceptors in the fish gill. Today, there is physiological evidence to support this view (see following sections). Studies over the last three decades have shown that NECs are found in the gills of nearly every fish species examined, and their morphology is conserved across species.

Neuroepithelial cells of the gills are typically about 10 μm in diameter (depending on species) and are located primarily in the epithelium of the gill filaments. Specifically, NECs reside in a region where they are as close as possible to the constant flow of water over the gills during ventilation – an advantageous position for chemoreceptors to be located (see **Figure 1** for the general orientation of NECs (green) in the gill filaments and **see also Design and Physiology of Arteries and Veins**: Branchial Anatomy). Gill NECs generally do not form clusters but exist as solitary cells, unlike O_2 chemoreceptors of the mammalian carotid body or lung epithelium. **Figure 2** illustrates the general distribution of NECs (green) in the gill filaments of three teleost species.

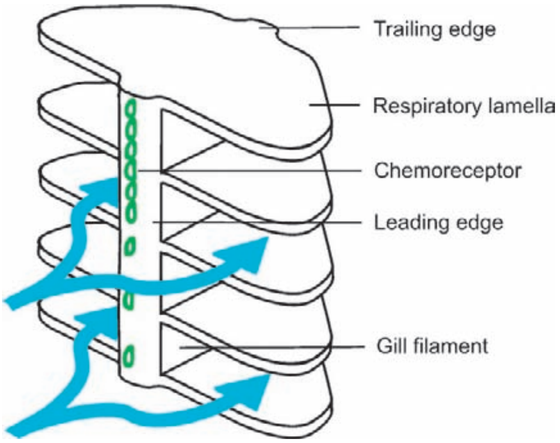

Figure 1 Schematic representation of a teleost gill filament. This illustration shows a region of gill filament that gives rise to several respiratory lamellae, where gas exchange occurs. The leading edge of the filament faces the flow of water (shown by blue arrows) over the gills during ventilation, while the trailing edge represents the filament tissue furthest away. Oxygen-sensitive chemoreceptors (i.e., neuroepithelial cells (NECs), shown in green) reside within the epithelium of the gill filaments, where they may sense changes in oxygen from the water or arterial blood flow.

NECs have been shown, through immunohistochemical experiments, to retain a great number and variety of neuroactive chemicals. These include the neurotransmitter serotonin, enzymes that produce the neurotransmitters nitric oxide and catecholamines, as well as several neuropeptides. In addition, NECs have been shown to retain cytoplasmic synaptic vesicles, which store and release neurotransmitters following an appropriate signal. These morphological characteristics are consistent with the model that NECs are capable of storing and producing neuroactive chemicals within the gill and, potentially, releasing them during a bout of hypoxia. But in order for the release of a neurotransmitter from a chemoreceptor to have a physiological response at the systemic level, for example, hyperventilation or bradycardia, the chemoreceptor must be in a position to communicate with the peripheral nervous system. (**see also Integrated Control and Response of the Circulatory System**: Central Control of Cardiorespiratory Interactions in Fish).

Evidence from studies using electron and confocal microscopy indicate that gill NECs receive a rich supply of nervous innervation from the glossopharyngeal and vagus cranial nerves. These two nerves are collectively referred to as the gill or branchial nerves. The consensus appears to be that gill NECs receive a mixture of both sensory and motor innervation, the former being most important for transferring a chemical signal from the NECs (i.e., release of a neurotransmitter) to the nervous system. **Figure 3** illustrates the innervation of a gill NEC (green) by a bundle of nerve fibers (red). The bundle of fibers is composed of neuronal axons, the cell bodies of which are likely located within the ganglia of the gill nerves.

The characteristics described above, retention of synaptic vesicles, storage of neurotransmitters, and sensory innervation, provide convincing evidence that gill NECs display all of the morphological requirements expected of O_2 chemoreceptors. Indeed, these characteristics have supported the notion that gill NECs are the phylogenetic precursors of mammalian O_2 chemoreceptors.

Chemoreceptor Response to Hypoxia

Sensing of Hypoxia

Under normal, or normoxic, conditions there is an adequate supply of O_2 to all tissues and cells and respiratory chemoreceptors are relatively inactive. Thus, under these conditions, ventilatory and cardiac rates are at basal

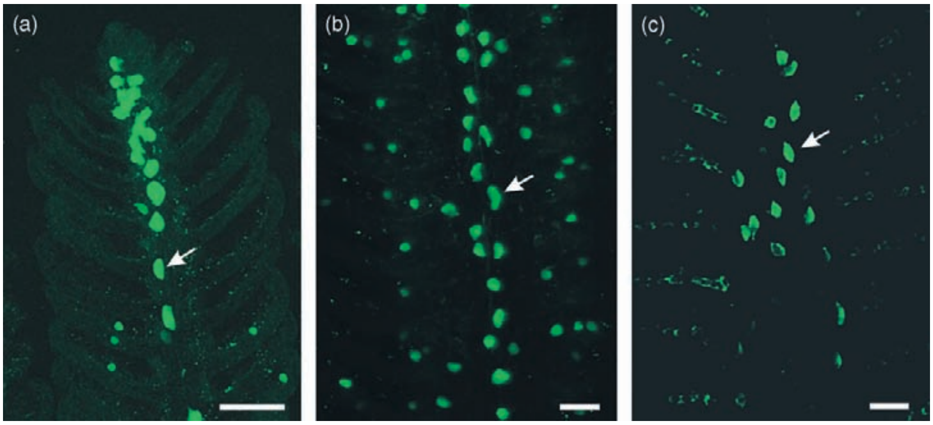

Figure 2 NECs are found in the gill filaments of most teleost fish. NECs (labeled in green and indicated with arrows) are usually solitary and are organized along the longitudinal axis of the filament. NECs are shown in zebrafish, *Danio rerio* (a), goldfish, *Carassius auratus* (b), and rainbow trout, *Oncorhynchus mykiss* (c). The orientation in all three panels corresponds to that of the schematic shown in **Figure 1**. Images are composites of several optical sections taken using a confocal microscope. NECs are colored green because they are labeled with antibodies that identify cells that contain the neurotransmitter, serotonin. Scale = 30 μm.

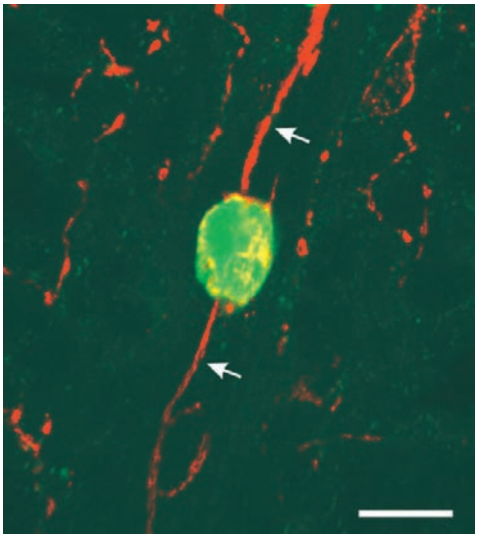

Figure 3 Neuroepithelial cells (NECs) are innervated. A single NEC of the zebrafish gill filament is shown (green) by labeling with serotonin antibodies. This cell receives innervation by nerve fibers (shown in red and indicated with arrows). Scale = 10 μm.

levels. However, once environmental (aquatic, in the case of fish) P_{O_2} begins to decrease, the reflex responses described in the preceding section will be initiated. But how is this drop in environmental P_{O_2} detected or sensed by respiratory chemoreceptors?

Since O_2 is a gas, it will flow down its concentration gradient, crossing epithelial barriers, cell membranes, and into the cytosol (**Figure 4**). For example, if we define water P_{O_2} as 140 mmHg (19 kPa), arterial P_{O_2} as 100 mmHg (13 kPa), tissue P_{O_2} as 60 mmHg (8 kPa), then normal intracellular P_{O_2} of a cell or chemoreceptor would be even less, perhaps 20–30 mmHg (3–4 kPa). It follows, then, that if water P_{O_2} decreases, intracellular P_{O_2} must also decrease. Once the decreased P_{O_2} reaches the cytosol of a chemoreceptor, it may be sensed by a molecule or mechanism that binds or associates with O_2.

In fish, the molecular O_2 sensor that mediates the cellular response to hypoxia is currently unknown. However, there is much evidence from studies on mammalian O_2 chemoreceptors that may provide clues as to the identity of the O_2 sensor in fish. Since it is apparent that respiratory chemoreceptors of mammals and fish appear to be related phylogenetically, we may make a legitimate comparison here. Generally, there are two different hypotheses that have emerged in the recent literature that may explain the location of the O_2 sensors in mammalian chemoreceptors. The sensor may be present in the plasma membrane, or elsewhere in the cytosol, such as the mitochondrion. It is not the author's intent to exhaustively describe here all of the previous or contemporary models for mammalian O_2 sensors, though the curious reader is encouraged to consult the 'Further reading' section at the end of the article for recent reviews. Only a few examples are mentioned here, instead. It should be pointed out here that it is generally accepted in most cases that hypoxia will lead to a decrease in membrane permeability to K^+ ions. However, this matter is discussed in the section entitled 'Transduction of the hypoxic stimulus'.

The membrane hypothesis of O_2 sensing proposes that the molecular O_2 sensor is confined to the plasma

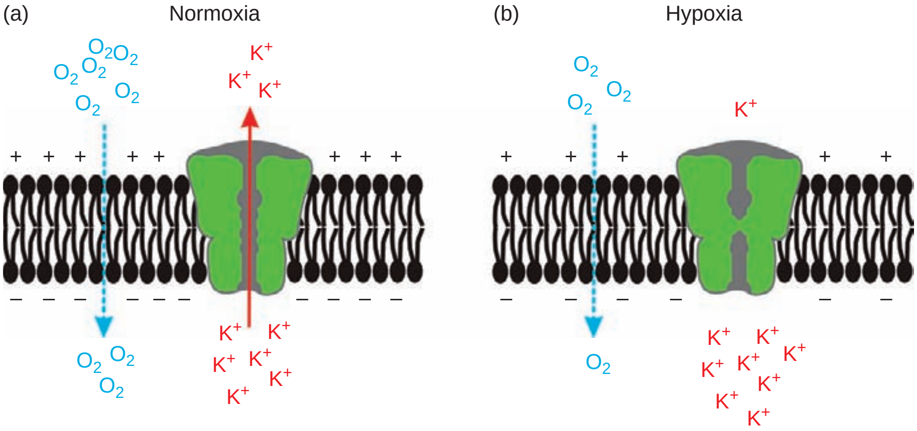

Figure 4 Schematic representation of the current working model of hypoxic chemotransduction in oxygen-sensitive NECs of the fish gill. The normal, or normoxic, condition is shown in (a), while the low oxygen, or hypoxic, condition is shown in (b). Gaseous O_2 diffuses freely across the phospholipid bilayer of the cell membrane (black) down its concentration gradient. Potassium ions (K^+) are transported out of the cell passively through selective ion channels, some of which are O_2 sensitive (green transmembrane structure), down their electrochemical gradient. In (a), O_2-sensitive K^+ ion channels are open, leading to a high membrane permeability of K^+ and a separation of charge across the cell membrane. In this case, the membrane is said to be polarized, such that the inside of the cell is relatively negative compared to the outside of the cell. In (b), a decrease in the partial pressure of O_2 is detected by an unidentified cytosolic O_2 sensor, and a closed conformation of the O_2-sensitive ion channel is favored. This closing of K^+ channels leads to a slight depolarization, as shown by the separation of fewer positive and negative charges across the cell membrane, and represents the conversion of a chemical to an electrical signal.

membrane. Evidence supporting this model was obtained from experiments using carotid body type I cells from rat. An enzyme, called hemoxygenase-2 (HO-2), was identified within the complex of a specific type of membrane-bound K^+ ion channel. In the presence of O_2, HO-2 produces the gas, carbon monoxide (CO), which in turn increases the activity of these ion channels and, consequently, the K^+ ion permeability of the membrane. A decrease in CO production by HO-2 during hypoxia, therefore, will decrease K^+ permeability. Thus, HO-2 is a candidate for an O_2 sensor in the cellular response to hypoxia because, depending on O_2 status, it can affect membrane permeability. The significance of the latter point will become clear as we proceed. This model, however, does not appear to be valid in mouse, suggesting that it may be species specific.

An alternative membrane model suggests that the sensing of hypoxia may occur via a membrane-bound nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and its production of hydrogen peroxide (H_2O_2). In neuroepithelial bodies (NEBs) of the rabbit lung, K^+ permeability is increased by H_2O_2 under conditions of normoxia. But during hypoxia, a decrease in O_2 substrate will lead to decreased K^+ permeability because of decreased H_2O_2 production.

By contrast, there is much evidence to indicate that O_2 sensing is tied to metabolic energy production in the mitochondrion, perhaps at the site of a cytochrome oxidase in the electron-transport chain. There are two models that explain how a decrease in oxidative phosphorylation during hypoxia may be coupled to plasma membrane K^+ permeability in carotid body type I cells. The first proposes that since ATP increases the activity of a specific type of K^+ channel, a decrease in intracellular ATP concentration during hypoxia (because of reduced ATP production by oxidative phosphorylation) would lead to a decrease in membrane K^+ permeability. The second model proposes that a similar drop in ATP production during hypoxia would lead to an increase in the cytosolic AMP/ATP ratio. Increased AMP/ATP would then induce activation of AMP-activated protein kinase and inhibition of O_2-sensitive K^+ channels by phosphorylation. Therefore, these two models predict that the O_2 sensor is associated with energy production in the cell.

As stated already, the literature on cellular mechanisms of O_2 sensing is dominated by experiments on mammalian O_2 chemoreceptors. Recent studies, however, have proposed that hydrogen sulfide (H_2S) may act as a sensor or transducer of intracellular P_{O_2} and mediate responses to hypoxia in vertebrates, including fish. In this model, constitutive levels of intracellular H_2S are balanced by its production and its oxidation by available O_2. The model proposes that during hypoxia, decreased O_2 leads to reduced oxidation of H_2S and its subsequent accumulation in the cell. Although application of exogenous H_2S mimicked hypoxia and led to depolarization in gill NECs, thus indicating a change in membrane permeability, its effects on K^+ channels, or association with a mechanism of transduction, are not yet clear in chemoreceptors.

To summarize, in these models of O_2 sensing in respiratory chemoreceptors, a common theme is that a change in concentration of an environmental chemical (i.e., O_2) is sensed or received by a molecular O_2 sensor that is either confined to the membrane or found within the cytosol. In fact, there is little agreement as to whether a single O_2 sensor is common to respiratory chemoreceptors in all vertebrates, including fish. From the brief description of potential O_2 sensors provided above, the reader may appreciate that this is a highly controversial issue within the field. Indeed, there does not appear to be a universal O_2 sensor – one that is found in respiratory chemoreceptors of all animals. But the very interesting chemosome hypothesis, proposed recently by Prabhakar, states that involvement of not one but multiple O_2 sensors in the cellular response to hypoxia may be advantageous and allow for responses across a broad range of P_{O_2} levels. What happens next, that is, how the low O_2 signal is converted, or transduced, into a form that can be used by the cell, is the subject of the following section.

Transduction of the Hypoxic Stimulus

Having already alluded in the previous section to the fact that the sensing of intracellular hypoxia predominantly results in a decrease in K^+ ion permeability across the cell membrane, we now further discuss this concept with the effects of hypoxia upon membrane-bound ion channels and how these begin a process of chemotransduction that results in a physiological chemoreceptor response.

Excitable cells, such as neurons and chemoreceptors, retain a complement of ion channels within their membrane that each has specific molecular, biophysical, and pharmacological properties. Moreover, each type of membrane ion channel plays a specific physiological role in the cell. For example, the opening of Na^+ channels permits the large influx of positively charged Na^+ ions into the cell and this characterizes an action potential; activation of Ca^{2+} channels allows entry of Ca^{2+} into the cytosol to stimulate neurosecretion; and K^+ channels contribute significantly to setting the resting membrane potential and excitability of the cell, in part, because of the membrane's high permeability to K^+ ions. The latter point is important to the present discussion because it is the membrane's permeability to K^+ ions that is modified during hypoxia.

Very broadly, one can differentiate between K^+ ion channels that are gated (i.e., opened and closed) by changes in voltage across the cell membrane, and those that are not. Voltage-gated K^+ channels serve many important roles in cells, including repolarization following an action potential. But K^+ channels that are not gated by voltage change, the so-called 'leak' or 'background' K^+ channels, are not affected by voltage change, and it is this type of K^+ channel that is particularly important in generation of the resting membrane potential. Importantly, when a cell, such as a chemoreceptor, is at rest, background K^+ channels are open and allow for the continuous efflux (from inside to outside) of K^+ ions (**Figure 4**(**a**)). K^+ ions will tend to move out of the cell under normal physiological conditions because this is the direction of electrochemical flow, as dictated by the distribution of K^+ ions across the cell membrane. This electrochemical directionality is established by the pumping of K^+ ions into the cell via ATP-consuming transporters, which create a gradient. Therefore, because K^+ channels permit an efflux of positively charged K^+ ions, and because of the maintained distribution of K^+ ions across the membrane (i.e., a very negative equilibrium potential for K^+), there will be a separation of electrical charge across the membrane. The end result is that the inside of the cell is more negative relative to the outside of the cell, and the measured difference in voltage across the membrane is called the resting membrane potential. While resting potentials vary considerably from cell to cell, a value of −70 mV (millivolts) is typical. Generation of the resting membrane potential is far more complex than what is described here, and is actually determined by the permeabilities of several additional ions. The reader is, therefore, referred to other sources, such as those cited in the 'Further reading' section.

Given the importance of K^+ channels in influencing membrane potential, it is not surprising that throughout the course of evolution cellular chemoreceptors have acquired mechanisms by which to modify this potential, depending on O_2 status. In the previous section, it was indicated that after hypoxia is sensed by a membrane-bound or cytosolic O_2 sensor, there is a decrease in K^+ permeability of the membrane. Specifically, hypoxia inhibits K^+ channels so that there is a reduced efflux of K^+ ions (**Figure 4**(**b**)). In keeping with the diversity of hypotheses of how O_2 is sensed by the chemoreceptor cell, there are many types of K^+ channels that are targets of modification during hypoxia, such as those that are gated by voltage or even Ca^{2+} ions. There are even channels that are selective for other ions, such as Ca^{2+}, that display O_2 sensitivity. Perhaps the most interesting, however, is that of the background K^+ channel, as discussed earlier, because it is open at resting membrane potentials, rather than like voltage-gated K^+ channels that must first be activated by voltage change before hypoxia may affect its activity. In addition, background K^+ channels that are responsive to hypoxia have been found in type I cells of the mammalian carotid body and NECs of the fish gill, suggesting that this mechanism of chemotransduction may be highly conserved in vertebrates.

Figure 4 illustrates how background K^+ channels from fish or mammalian O_2 chemoreceptors behave during hypoxic stimulation. After a reduction in P_{O_2} is sensed, closure of K^+ channels reduces the membrane permeability to K^+, thereby inducing a relative depolarization of the membrane, or a reduction in the membrane potential. It is this membrane depolarization that characterizes the transduction of the hypoxic stimulus – the conversion of a chemical event to an electrical one. Studies of fish and mammalian chemoreceptors have shown that the electrical response of chemoreceptors exposed to hypoxia is indicative of reduced electrical current carried by K^+ ions through background K^+ channels. **Figure 5** shows an idealized recording using a technique, called whole-cell electrophysiological recording, in which the flow of electrical current that is carried across the cell membrane by ions can be recorded while the experimenter controls the membrane voltage. In this example, a NEC from the fish gill is subjected to a continuous change in membrane voltage from −100 mV to +50 mV (x-axis) while

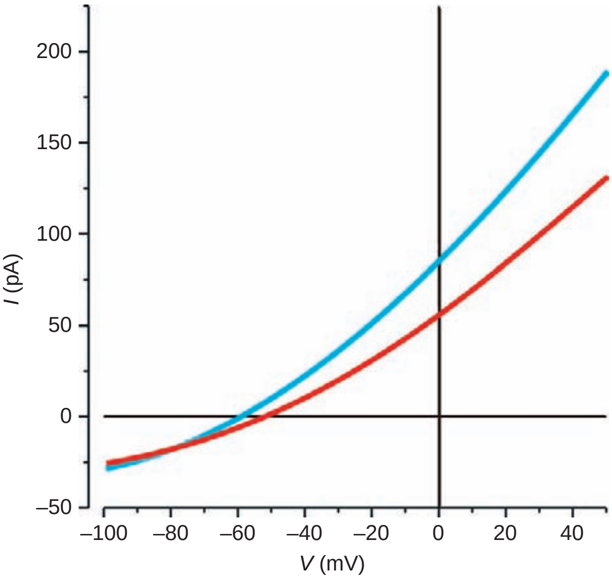

Figure 5 A simplified electrical recording of a neuroepithelial cell (NEC) responding to hypoxia. This illustration is based on actual electrophysiological recordings and demonstrates the current voltage (I–V) relationship observed in these cells. As the experimenter changes the voltage (i.e., membrane potential) across the cell membrane from −100 mV to +50 mV, an increased force pushes more K^+ out of the cell. In a normal, or normoxic, cell this may be recorded as a change in current from about −25 pA to 200 pA (blue line). If the cell is subjected to a lowered partial pressure of O_2, such as in hypoxia, the I–V relationship changes such that less K^+ flows out of the cell because more O_2-sensitive K^+ channels are closed. Compare this with the structural changes illustrated in **Figure 4**.

recording the evoked change in current (*y*-axis). Under control, or normoxic, conditions (blue line) this voltage change elicits a range of current from –25 pA (picoamperes) to about +200 pA. This is known as the current–voltage (*I*–*V*) relationship and reflects the electrical properties of the cell. By convention, in this example, a negative current value indicates an inward flow of current carried predominantly by K^+ ions, while a positive value indicates an outward current. After the cell is exposed to a reduction in P_{O_2} (red line) of the medium surrounding the cell (achieved by displacing O_2 with N_2 gas), there is an obvious decrease in outward current that can be observed at voltages ranging from –40 mV to +50 mV, indicating that the flow of K^+ ions through the membrane was reduced because of inhibition of background K^+ channels.

If we now combine our discussion of O_2 sensors with that of chemotransduction by K^+ channels in the plasma membrane, there is evidence from studies of mammalian type I cells in favor of a link between a metabolic O_2 sensor and inhibition of background K^+ channels during hypoxia. As the activity of background K^+ channels in these cells is regulated by the concentration of ATP and phosphorylation by adenosine monophosphate (AMP)-activated protein kinase, both mitochondrial models of O_2 sensing discussed earlier are plausible. Since the biophysical characteristics of the background K^+ channels found in gill NECs described so far are consistent with those of type I cells, it is reasonable to propose that O_2 sensing and chemotransduction in the fish gill occur in the same way as in the mammalian carotid body.

As a final step in the response of the O_2 chemoreceptor to hypoxia, the cell must now communicate this information to the nervous system to initiate adaptive physiological responses at the systemic level, such as hyperventilation and changes in heart rate that were described in a previous section. For this to occur, the hypoxic signal (which, at this point, exists as an electrical depolarization) must be converted back to a chemical form. In the carotid body, type I cells express plasma membrane Ca^{2+} channels that are voltage sensitive and activated by hypoxia-induced membrane depolarization. Activation of these channels causes a sudden rise in the intracellular concentration of Ca^{2+} ions and this leads to the release of neurotransmitters, stored in cytoplasmic synaptic vesicles, to the extracellular environment (i.e., synaptic cleft) where they can bind to specific receptors on postsynaptic sensory neurons. This is the accepted model for how type I cells detect, transduce, and relay the hypoxic signal to the nervous system. In NECs of the fish gill, Ca^{2+} channels have not yet been studied and so the problem of Ca^{2+}-dependent secretion of neurotransmitter following hypoxic depolarization cannot be addressed for the moment. However, it is plausible that NECs adhere to this conventional model since they do retain the neurotransmitter serotonin and synaptic vesicles (see previous section).

Neurochemistry

Despite the plethora of neurotransmitters and neuropeptides that have been localized to gill NECs across a variety of fish species, there is, unfortunately, very little direct evidence in support of neurochemical transmission between NECs and sensory nerve fibers in the fish gill during hypoxia. It is, therefore, difficult to predict what events occur after NECs are depolarized by hypoxic stimulation and what chemical signals are received by sensory nerves. At the ultrastructural level, hypoxia has been shown to induce degranulation of cytoplasmic vesicles, indicative of neurotransmitter release into the synaptic cleft. Though gill NECs in nearly all fish species are rich in serotonin, the questions of whether serotonin is being released, and if it represents the primary excitatory neurotransmitter that underlies communication from NECs to postsynaptic nerves during hypoxic stimulation, remain unresolved. In addition, no receptors have been identified on postsynaptic nerve terminals that may allow for binding of neurochemicals released from NECs.

If we look again to mammalian mechanisms of O_2 sensing, a variety of neurochemicals play excitatory, inhibitory, and modulatory roles. In the carotid body, acetylcholine, ATP, and dopamine appear to be important neurotransmitters, among others, and their respective receptors have been identified within the carotid body; while in lung NEBs serotonin is more important. In experiments in fish, where isolated perfused gill arch preparations were exposed to exogenous neurotransmitters to stimulate sensory pathways in the gill, acetylcholine had stronger stimulatory effects than serotonin. So, it would seem that a neurochemical explanation of hypoxic signaling in the gill is not straightforward, and may have characteristics similar to both carotid body and lung NEB O_2 sensing. To expand this idea, it may be found that the gill may utilize a variety of excitatory, inhibitory, and modulatory neurochemicals to produce the hypoxic response.

Conclusions

NECs of the gills in fish fulfil all of the requirements to be considered as O_2 chemoreceptors. They respond, physiologically, to hypoxia in the form of K^+ ion channel inhibition, which causes a decrease in permeability to K^+ ions, and membrane depolarization; they retain cytosolic secretory vesicles that store serotonin, among other neurochemicals; and they receive nervous innervation, thus providing a putative sensory pathway for transmission of a signal to the central nervous system. Despite what has been characterized so far, relatively little is known of O_2 sensing by NECs when one considers the wealth of information on mammalian O_2 chemoreceptors. For example, while a transduction mechanism has been identified in the cell membrane in fish, candidates for a molecular O_2 sensor in NECs have not been proposed. Furthermore, the chemical details of how neurotransmission between NECs and sensory nerve cells might occur during hypoxia have not been described. The disparity between the present understanding of O_2 sensing in fish and in mammals has been driven by the significance of the latter in biomedical research. However, as presented in this article, at the cellular level O_2 sensing in fish appears to closely resemble that of mammals, suggesting that the use of fish in this field may be of some benefit to biomedical research. For example, studying the model organism, the zebrafish (*Danio rerio*), may allow researchers access to developmental and genetic tools to uncover the fine details of O_2 sensing at the cellular and molecular level. Fish, like other vertebrates, have acquired elegant strategies for adapting to changing environmental conditions, such as hypoxia, throughout the course of evolution. At the very least, a clear understanding of how O_2 sensing in fish occurs will help explain how all aspects of O_2 sensing may have evolved.

Anion exchanger The major membrane protein of most erythrocytes. With its help, the half-time of chloride and bicarbonate equilibration between erythrocytes and plasma is decreased from a couple of hours to seconds in fish; the protein's transport function enables rapid buffering of acid loads by hemoglobin.

Beta-adrenergically stimulated sodium/proton exchange This ion-transport pathway is unique for teleost erythrocytes and plays a role in controlling red cell pH.

Heme oxygenase An enzyme with high erythrocytic activity, which plays a role in hemoglobin breakdown with carbon monoxide as one end product.

Organic phosphate metabolism Fish erythrocytes produce energy, mainly aerobically.

Oxygen-dependent ion transport Many ion transporters of the erythrocytic membrane respond to changes in ambient oxygen level. Often, it appears that it is not molecular oxygen as such, but reactive oxygen species which cause the apparent oxygen sensitivity.

Volume regulation After osmotic swelling, erythrocytes lose water mainly via osmotic coupling to net potassium, chloride, and taurine efflux, and after osmotic shrinking gain water via sodium and chloride influx.

Introduction

The major function of erythrocytes is to transport oxygen from the respiratory epithelium to the sites of consumption (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange). Most of the oxygen transported is carried bound to hemoglobin, the major erythrocytic protein at 10–20 mM concentration (concentration given as monomeric globin; 2.5–5 mM tetramers). A hemoglobin concentration of 20 mM is close to the solubility limit of the protein. This hemoglobin level increases the maximal amount of oxygen carried in blood close to 30-fold as compared to a situation in which oxygen would only be carried dissolved.

Aspects of the red cell function that affect hemoglobin function (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin) are particularly important from the respiratory point of view. The major physiological regulators of hemoglobin-oxygen affinity are pH, erythrocyte volume, and organic phosphate concentration. The first two are influenced by ion transport, and the last by energy metabolism.

Hemoglobin also acts as a major buffer in the body. The buffering requires that extracellular acids have access to hemoglobin. This becomes possible when bicarbonate movements are facilitated by the function of the anion exchanger.

In addition to hemoglobin function, erythrocytes play a role in the regulation of capillary function, also important for oxygen transport and thereby the respiratory function of erythrocytes.

The signaling molecules involved both in the regulation of membrane transport and in the regulation of capillary function in fish are poorly known. Gaseous signaling molecules that are known include molecular oxygen, reactive oxygen species (ROS), nitric oxide (NO), carbon monoxide (CO), and hydrogen sulfide (H_2S). The potential for erythrocytes to be involved in gaseous signaling is apparent, because their iron stores, which can participate in the free-radical metabolism (Fenton reactions), are very high and because hemoglobin breakdown has heme oxidase enzyme, with CO as one end product, as one component. The transport of nitrite and nitrate into the erythrocytes, and reactions of these nitrogenous compounds (interconversion, and conversion to NO), including the formation of nitrosohemoglobin, are involved in the regulation of capillary diameter and thereby tissue oxygenation. Notably, the amount of oxygen available to erythrocyte constituents is high. Even when all the other cells of the body are suffering from the lack of oxygen, there is enough oxygen in the erythrocytes (bound to hemoglobin) for their metabolism.

This article reviews respiratory aspects of erythrocyte function focusing on: (1) membrane transport and its regulation, because red cell pH and volume are major effectors of hemoglobin function; (2) metabolic pathways, which are involved in the control of erythrocyte organic phosphate level; and (3) the possible role of erythrocytes in the regulation of vascular tone.

Membrane Transport, Erythrocyte pH, and Volume

The scheme of the control of intracellular pH of fish erythrocytes is shown in **Figure 1**, and that of red cell volume regulation in **Figure 2**. Both are mainly influenced by ion transport across the erythrocyte membrane. Also, the ability of erythrocytes to buffer extracellular acid loads depends on rapid bicarbonate transport across the membrane facilitated by anion exchanger. Cyclostomes, that is, hagfish and lampreys, are devoid of rapid anion transport across the erythrocytic membrane. The anion exchange via the Band 3 protein of elasmobranch and teleost erythrocytes shortens the half-time for bicarbonate equilibration across the cell membrane from 1–2 h to seconds (the exact time depends on temperature). The anion exchange plays an important role in carbon dioxide transport (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion; **Figure 3**) and affects chloride and bicarbonate distribution between blood plasma and the erythrocyte. Both of these functions are important in controlling erythrocytic pH. In addition, the anion exchange is the major pathway for membrane transport of sulfate and phosphate.

The sodium/proton exchanger extrudes protons from the red blood cell and can increase intracellular pH. It is present in all fish erythrocytes except those of hagfish. Depending on the species, it can be activated by extracellular acidification, osmotic disturbances, and adrenergic stimulation, and its activity is increased by a decrease in oxygen tension. The major signal for activation in lampreys appears to be acidification, as for most sodium/proton exchangers of other cell types. The presence of adrenergically stimulated sodium/proton exchanger is unique for teleost erythrocytes, in some of which adrenergic stimulation is the major activatory signal for sodium/proton exchange, although in some teleost species the exchanger appears to be mainly involved in volume regulation after osmotic disturbances. Elasmobranch erythrocytes, the hemoglobins of which have much higher buffering capacity at the physiological pH range than teleost hemoglobins, do not have adrenerically stimulated sodium/proton exchange.

Teleost fish erythrocytes possess beta(3)-type adrenergic receptors, which appear to be coupled to sodium/proton exchange. The sodium/proton exhanger of teleost erythrocytes harbors a cAMP-responsive cytoplasmic site. The adrenergic sodium/proton exchange is able to displace protons from electrochemical equilibrium even in the presence of robust anion exchange, because the exchanger will continue to carry out a net extrusion of protons as long as the activity of the exchanger remains higher than the rate of uncatalyzed extracellular dehydration of carbonic acid to carbon dioxide and water. The changes in extracellular pH are observed both *in vitro* and *in vivo* if catecholamine levels are elevated. As an example, immediately after a fish is rendered hypoxic, its plasma pH increases as a result of hyperventilation. Thereafter, a marked extracellular acidification ensues (within tens of seconds), which reflects the stimulation of the sodium/

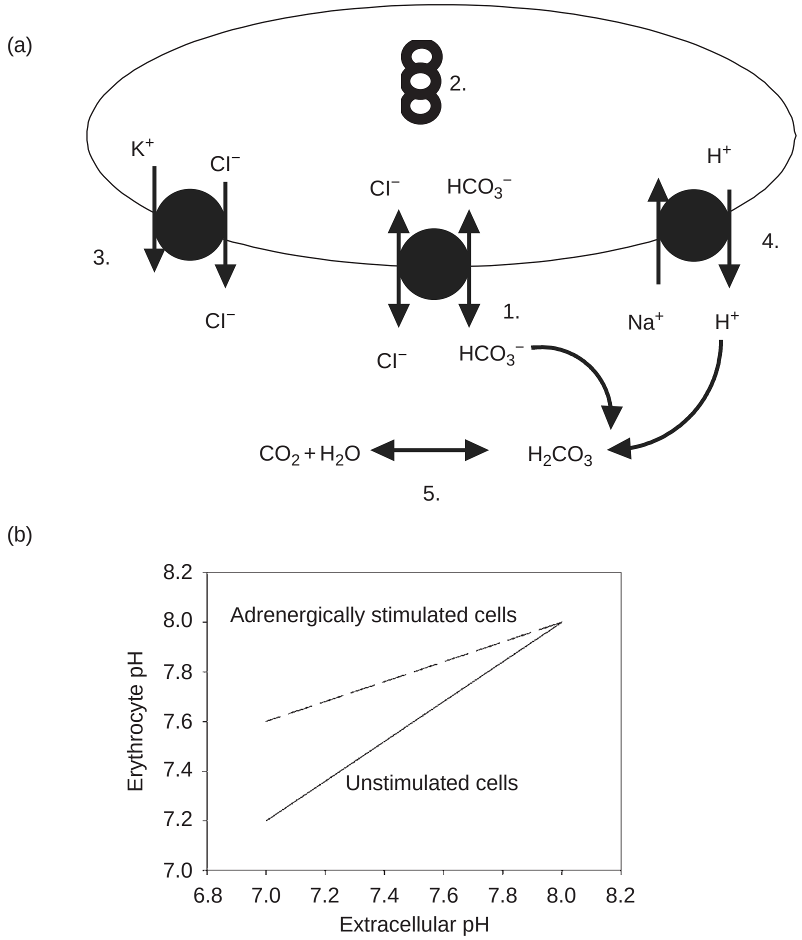

Figure 1 Control of erythrocytic pH in fish. (a) At rest, protons are passively distributed across the erythrocyte membrane as a result of rapid bicarbonate transport across the membrane (1). The intracellular compartment is more acid than the extracellular one. The intracellular pH in teleost erythrocytes is typically 7.3–7.4 at a resting extracellular pH of 7.8. When the extracellular compartment is acidified, the pH of the intracellular compartment decreases less than that of the extracellular one, because the negative charge of intracellular impermeable molecules decreases with decreasing pH. Thus, the bicarbonate ratio (inside/outside) increases, and the difference between extracellular and intracellular pH decreases. The decrease of the difference in pH depends on the properties of intracellular impermeable molecules (2). Typical values for the slope of pH (intracellular) vs. pH (extracellular) are 0.7–0.9. In the intracellular compartment, the hydration reactions of carbon dioxide and the dehydration reactions of carbonic acid (bicarbonate and protons) are catalyzed by carbonic anhydrase, increasing the reaction rates 50 000–100 000 times, compared with the extracellular compartment where the hydration/dehydration reactions proceed at the uncatalyzed rate (with a halftime up to several minutes at physiological conditions for fish). At high oxygen tensions the potassium chloride co-transport (3) is activated, and both potassium and chloride ions leave the cell because of the prevailing potassium gradient (*c*. 100 mM in the erythrocytes and 2–3 mM in blood plasma). The excreted chloride ions re-enter the cell via the anion exchanger in exchange for bicarbonate. Because bicarbonate (=base equivalent) leaves the cell, it is acidified. When teleost erythrocytes are adrenergically stimulated (see **Figure 4**), or respond to an osmotic disturbance, the sodium/proton exchange (4) is activated. Because of the prevailing sodium gradient (*c*. 140 mM in the extracellular compartment, and 30-40 mM within the erythrocytes), the transporter will carry out a net proton extrusion. The net proton extrusion occurs as long as the rate of proton extrusion is greater than the rate of extracellular dehydration of carbonic acid (5). Thereafter, proton extrusion proceeds at the same rate as bicarbonate influx, and no further pH changes occur. (b) The relationship between erythrocyte and plasma pH in unstimulated (solid line) and adrenergically stimulated (dashed line) erythrocytes.

proton exchange by catecholamines and the release of H^+ from the red blood cells. Afterwards the extracellular pH tends to increase. Since the rate of extracellular uncatalyzed dehydration of carbonic acid is important in affecting adrenergic pH changes, an addition of extracellular carbonic anhydrase will make the observed changes in the pH gradient across the erythrocytic membrane smaller or abolish them altogether without reducing the effects of adrenergic stimulation on cell volume.

The sequence of events occurring in adrenergically stimulated teleost erythrocytes is shown in **Figure 4**. Two properties of the adrenergically stimulated sodium/proton exchange make proton extrusion and increased intraerythrocytic pH particularly suited for

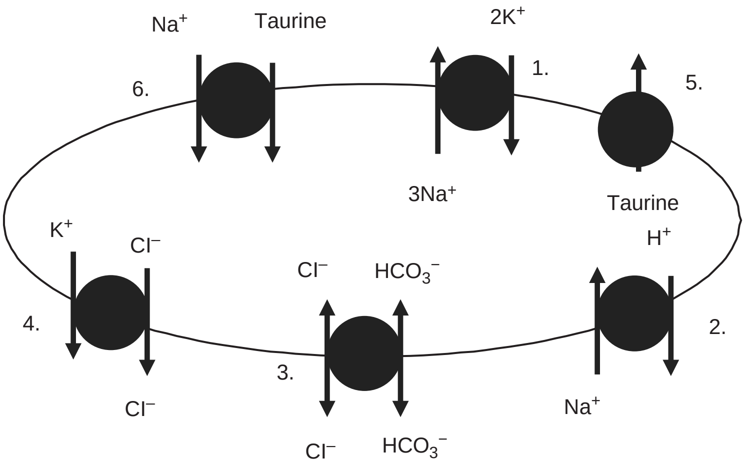

Figure 2 The mechanisms of volume regulation in erythrocytes. At rest, the red cell volume is maintained constant. Usually, the proportion of water is between 65% and 70%. The steady-state volume is maintained by the following mechanism: intracellular, impermeable (negative) polyions, mainly organic phosphates and hemoglobin, and their counterions generate an osmotic pressure difference across the membrane. Unopposed, this would lead to continuous inward water flux, until the cell would burst. However, the cell membrane is made functionally impermeable to one of the positive ions, sodium, as a result of the sodium pump (1) function. The pump extrudes the ions at the same rate as they enter the cells (1). When the environment becomes hyperosmotic and the erythrocyte shrinks, the sodium/proton exchange is activated (2), sodium enters the cell, and osmotically obliged water follows. The sodium/proton exchange is coupled to the chloride/bicarbonate exchange (3). Bicarbonate leaves the cell and chloride enters, drawing osmotically obliged water. The sodium and chloride, and consecutive water, movements into the cell restore the cell volume. If the environment becomes hypertonic, and the erythrocyte swells, the original volume is restored by the activation of potassium chloride co-transport (4) or taurine efflux (5), followed by osmotically obliged water. Very high (several tens of mM) taurine levels within the erythrocytes are reached, as the sodium-dependent taurine transporter (6) is active in the cells.

the regulation of hemoglobin-oxygen affinity during acute stress. First, the activity of the exchanger increases with decreasing oxygen tension. Second, the activity of the exchanger increases with decreasing pH. The adrenergically activated sodium/proton exchange is usually associated with very small buffering capacity of hemoglobin. Consequently, for a given proton extrusion activity, the changes in erythrocytic pH are much smaller in elasmobranch, which lack this mechanism and have large buffering capacity of hemoglobin, than in teleost fish.

Another much-studied transport pathway of teleost erythrocytes is potassium chloride co-transporter. The transport pathway has been studied mainly because of its putative role in cellular volume regulation, although its activity will also influence erythrocyte pH. The activity of the exchanger increases with increasing oxygen tension. Also, the sodium potassium chloride co-transport pathway is apparently oxygen sensitive. Transport via this pathway decreases with increasing oxygen tension. From the very fragmentary data available, it appears that the pathway is not present in all teleosts.

While the original suggestion about the oxygen sensitivity of ion transport in erythrocytes, that is, that binding of oxygen to hemoglobin influences ion transport either directly or indirectly, may hold for mammalian erythrocytes, it appears that the apparent oxygen sensitivity of ion transport in fish erythrocytes is caused by ROS, especially hydroxyl radicals. Erythrocytes are suitable for the regulation of ion transporter activity by hydroxyl radicals, because they contain large iron stores, and ions of iron are involved in Fenton reaction generating hydroxyl radicals. Generally, the hydroxyl radical level increases with increasing oxygen tension. Hydroxyl radicals inhibit the adrenergic sodium/proton exchanger and activate the potassium/chloride transporter.

Of the three cation transport pathways potentially affecting red cell pH and volume, and thereby the oxygen affinity of erythrocytic hemoglobin, only the sodium/proton exchange activity has unequivocally been shown to be important in environmental regulation of blood oxygen transport. The increased hemoglobin-oxygen affinity, largely as a result of adrenergically increased intraerythrocytic pH (increased erythrocyte volume may play a smaller role), is important in exercise, hypoxia, and other forms of stress where catecholamine levels are elevated. Depending on the species, the observed *in vivo* effects may be caused either by noradrenaline or by adrenaline. Because the effects are rapid and dependent on both oxygen tension and erythrocytic pH, which can vary in different parts of circulation, a possibility remains that the response is of different magnitude in different parts of circulation during circulatory timescale. However, the possibility of rapid pH changes, occurring in erythrocytes after adrenergic stimulation and interacting with different oxygen tensions, has been little studied because of technical difficulties.

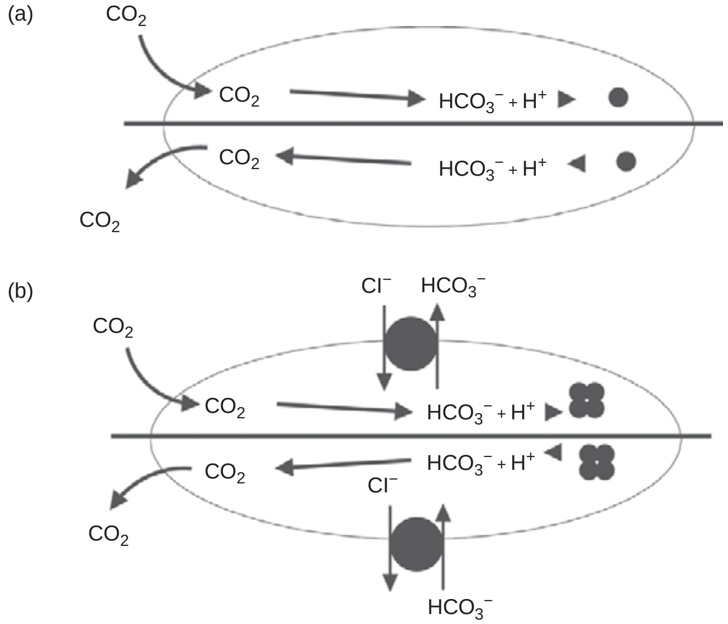

Figure 3 Schematic representations of carbon dioxide transport and excretion in fish. (a) Cyclostomes. In tissues carbon dioxide is formed, and diffuses down its concentration gradient to erythrocytes, where it is hydrated in carbonic anhydrase-catalyzed reaction to bicarbonate ions and protons. The protons are taken up by hemoglobin upon deoxygenation. The effectiveness of proton uptake is increased by increasing Haldane effect, and the amount of bicarbonate ions in solution increases by increasing in pH. In gills the sequence of events is reversed. Protons are given up from hemoglobin upon oxygenation; bicarbonate and protons are dehydrated to form carbon dioxide in a reaction catalyzed by carbonic anhydrase. The carbon dioxide formed diffuses down its concentration gradient out of erythrocytes and the animal. (b) Elasmobranch and teleost fish. The carbon dioxide formed in tissues diffuses to erythrocytes, where it is hydrated in carbonic anhydrase-catalyzed reaction to bicarbonate and protons. Bicarbonate ions leave the cell via the anion exchanger, and protons are taken up by hemoglobin upon deoxygenation. In gills, the sequence of events is reversed.

An increase in potassium chloride co-transport will decrease erythrocytic pH and erythrocytic volume. It has been suggested that such a decrease would facilitate oxygen release in hyperoxic conditions by reducing hemoglobin-oxygen affinity.

Control of Erythrocytic NTP Concentration

Organic phosphates affect hemoglobin-oxygen affinity by direct binding of the phosphate to hemoglobin, and indirectly by affecting intraerythrocytic pH (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin and Evolution of the Bohr Effect). An increase in erythrocytic organic phosphate concentration decreases and a decrease increases intracellular pH because organic phosphates are impermeable anions, which decrease bicarbonate (the major intracellular buffer) level at equilibrium. In fish, the major organic phosphates are the nucleoside triphosphates (NTPs): adenosine triphosphate (ATP) and guanosine triphosphate (GTP). ATP is the major end product of energy production. The potential pathways of the formation and breakdown of ATP and GTP are shown in **Figure 5**.

Because fish erythrocytes are nucleated and contain mitochondria, their energy metabolism is mainly aerobic respiration. The oxygen consumption of rainbow trout erythrocytes is approximately 150 μmol L^{-1} cells per hour. The oxygen consumption of white blood cells is about 20 times higher than that of erythrocytes whereby they make up approximately half of whole blood oxygen consumption.

The energy metabolism of fish erythrocytes can be supported by glucose, lactate/pyruvate, and amino acids, notably glutamate. It appears that at rest glucose may be the major metabolic substrate with the contribution of other substrates increasing with physical exercise. Virtually, all teleost erythrocytic membranes lack a glucose transporter, but monocarboxylate transporters (transporting, e.g., lactate and pyruvate) and various amino acid transporters are present.

Since the net negative charge of the impermeable breakdown products of NTPs is similar to that of the parent compounds, organic phosphates only increase intracellular pH if their total concentration in erythrocytes decreases as a result of the environmental challenge. Whereas the ATP level of erythrocytes is relatively stable and generally high (several millimolar), the GTP concentration varies from nearly undetectable to values markedly exceeding ATP concentration. However, although the regulation of hemoglobin-oxygen affinity by ATP (NTPs), and the

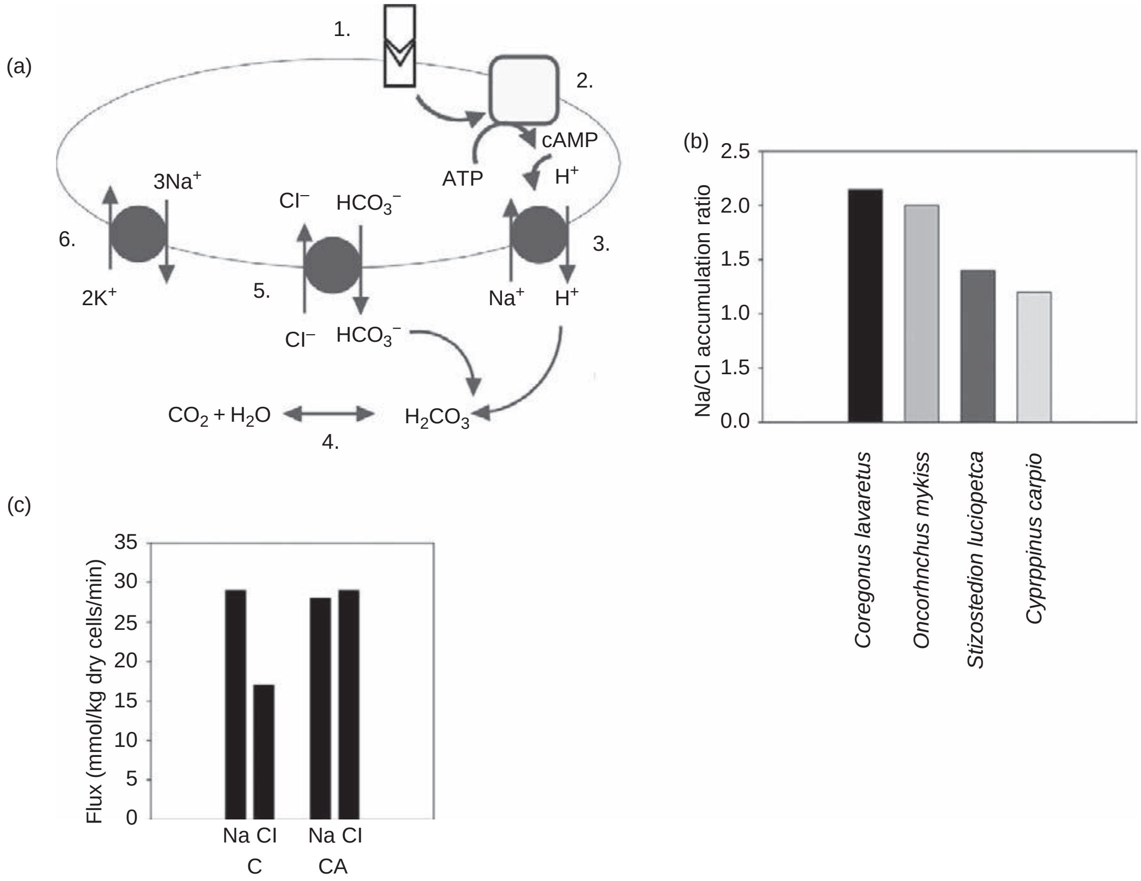

Figure 4 The mechanism of erythrocytic adrenergic response. (a) Beta-adrenergic compounds bind to the beta(3)-type receptors (1). This activates adenylate cyclase and cAMP is formed (2) activating the sodium/proton exchange (3). The increase of intraerythrocytic pH depends on the activity of the sodium/proton exchanger and on the buffering capacity of hemoglobin. The larger the exchanger activity and the smaller the buffering capacity, the larger the pH change. The intracellular pH changes occur as long as the rate of proton extrusion is greater than the rate of uncatalyzed dehydration of carbonic acid to carbon dioxide (4). The cell volume continues to increase with the coupling of proton and bicarbonate extrusion (5). The increased sodium influx causes increased sodium pump activity (6), and the ATP level tends to decrease. (b) The sodium/chloride accumulation ratio in some fish species after maximal adrenergic stimulation (time 30 min, 10 μM adrenaline, pH 7.1). The greater the ratio, the greater will be the adrenergic activity of the sodium/proton exchanger and the increase in erythrocyte pH. (c) The adrenergic net proton extrusion of rainbow trout erythrocytes (as given by the difference in sodium and chloride fluxes in the first 2 min of stimulation with 10 μM isoproterenol; (c) the net proton extrusion is inhibited by adding extracellular carbonic anhydrase (3 g l^{-1}; specific activity of the enzyme 2500 Wilbur-Anderson units/mg; CA), as a result of increased bicarbonate efflux (indicated here as increased chloride influx).

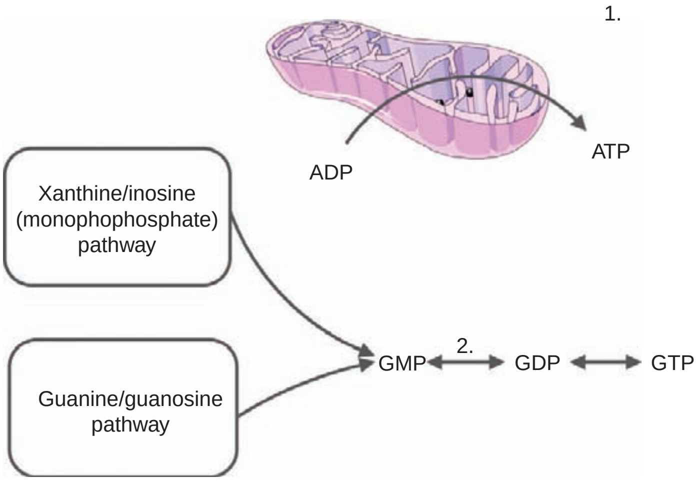
acclimation of oxygen transport in hypoxia were described in early 1970s for fish, the mechanisms by which ATP and GTP concentrations are regulated remain unclear. The suggestion that the ATP level would be adjusted as a result of direct oxygen-dependent changes in oxidative phosphorylation does not fit the profiles of oxygen dependence of ATP levels and oxidative phosphorylation. The activities of the enzymes in the catabolic or anabolic pathways of guanosine phosphates, possibly controlling GTP levels, are generally not known for fish. The rate-limiting step of GTP production may be at the level of guanosine monophosphate and its conversion to diphosphate by guanosine monophosphate kinase. The fragmentary information available suggests that the activity ratio of guanosine monophosphate kinase/adenosine monophosphate kinase is much higher in species (e.g., eel) with high GTP concentration than in those (e.g., hagfish, dogfish) with low GTP level. However, even if this is the case, the regulation of the GTP production/breakdown is unknown. What are the factors affecting anabolic/catabolic enzyme activities? Is transcriptional regulation of enzyme production involved?

Role of Erythrocytes in Regulating Capillary Function

Red cell function may also influence oxygen transport to tissues by affecting blood flow through capillaries (**see also Design and Physiology of Arteries and**



1.
ADP
ATP
Xanthine/inosine (monophophosphate) pathway
Guanine/guanosine pathway
GMP
2.
GDP
GTP

Figure 5 Schematic representation of the possible pathways of GTP and ATP metabolism. The ATP produced is mainly produced as an end product of aerobic metabolism from ADP in mitochondria (1). The GTP level may be regulated by guanosine monophosphate kinase activity (2).

Veins: Physiology of Resistance Vessels). Erythrocytes may, in this case, act as oxygen sensors. The regulation of capillary diameter may involve ATP release from the erythrocytes, which is oxygen dependent at least in mammals, nitric oxide signaling, and/or their interactions. ATP release from fish erythrocytes has been observed, but hitherto the effect of oxygen on the release has not been demonstrated.

It is generally accepted that NO plays a primary role in the regulation of capillary function. The NO-dependent regulation of capillary function may involve hemoglobin. Hemoglobin reacts with NO to form nitrosohemoglobin, which can be converted back to nitric oxide and hemoglobin, especially in hypoxic conditions, and the liberated NO can affect capillary endothelium. While most of the data available concern human erythrocytes, NO metabolism in fish erythrocytes has also been investigated. Notably, the cysteine residue cys93 of the beta-chain of hemoglobin is the site where primary nitrosohemoglobin formation occurs. Thus, fish hemoglobins with serine substituted for cysteine will not have this primary place for NO regulation.

That oxygen-dependent and NO-dependent phenomena interact has been shown in several cell types, including mammalian erythrocytes. However, the possible interactions between NO and oxygen have not been explored in detail in fish. For example, oxygen-dependent ion transport has usually been studied in conditions that virtually preclude NO production. Thus, the possibility remains that the apparently oxygen-sensitive ion transport of fish erythrocytes plays a role in the regulation of capillary function. Recently, it has also become apparent that H_2S is an important regulator of blood vessel function. At present, the importance of erythrocytes in affecting capillary H_2S concentration is not known, although it is clear that hemoglobin reacts with sulfide and that species differ markedly, both in the conversion of sulfide to the end products and in sulfide tolerance.

Glossary

Adenosine triphosphate (ATP) An almost universal carrier of chemical bond potential energy; fish use ATP made from catabolism of foodstuff or body reserve molecules to fuel energy-dependent processes.

Allosteric regulation A regulatory molecule affects the binding of a primary molecule via binding to a different place in the protein from that of the binding site of the primary molecule.

Bohr effect Effect of the proton concentration (pH) on the oxygen affinity of hemoglobin.

Guanosine triphosphate (GTP) The major erythrocytic organic phosphate of some fish. Usually its influence on hemoglobin-oxygen affinity is greater than that of ATP.

Haldane effect Proton binding to hemoglobin (as a function of oxygenation).

Heterotropic interaction Binding of a molecule affects the binding of molecules of different type.

Hill plot A logarithmic transformation of the oxygen equilibrium curve. From Hill plot chain-to-chain interaction, the oxygen affinity of the T-state and the oxygen affinity of the R-state can be seen.

Homotropic interaction Binding of a molecule affects the binding of consecutive molecules of the same kind.

Methemoglobin Oxidized hemoglobin which is unable to bind oxygen and in which heme iron is in ferric state.

Nucleoside triphosphates (NTPs) Many measurements of erythrocyte organic phosphates, originally thought to measure ATP, actually measure all NTPs.

Oxygen equilibrium curve It gives hemoglobin oxygen saturation as a function of oxygen tension.

Root effect A property of fish hemoglobin in which protons decrease the maximal oxygen saturation of hemoglobin. For practical purposes it is defined as a reduction of oxygen saturation at atmospheric oxygen tension.

R-state hemoglobin Relaxed (oxy) hemoglobin, at high oxygen tensions hemoglobin assumes relaxed state which has higher oxygen affinity than T-state hemoglobin.

T-state hemoglobin Tense (deoxy) hemoglobin, the form is the more stable hemoglobin form in the absence of oxygen (e.g., organic phosphates bind preferentially to T-state hemoglobin).

Hemoglobin Structure

The hemoglobin of most fishes is a tetrameric molecule with a molecular weight of 60 000–70 000 Da. It consists of four globin chains, two α- and β-chains. The globin chains have 140–160 amino acids and their molecular weights are between 15 000 and 17 000 Da. Every globin chain can bind one oxygen molecule. Thus, altogether four oxygen molecules can be bound, meaning that blood with fully oxygen-saturated hemoglobin contains 10–20 mM oxygen molecules, depending on the precise hemoglobin concentration of blood (**see also Blood**: Cellular Composition of the Blood).

Every globin chain contains eight helical portions (denoted A–H), which are folded on each other to form a globular tertiary structure. The folds may be either abrupt or more gradual. The α-like chain appears to be the more ancestral globin chain type. The ancestral vertebrates, hagfishes and lampreys, still have only one type of hemoglobin chain (although several different structures may be present). In these cyclostomes, hemoglobin can be either monomeric or aggregate to di- or tetramers. Notably, the single hemoglobin chain of cyclostomes is markedly different from both α- and β-chains of other vertebrates. In addition to α- and β-chains of adult hemoglobins, all vertebrates appear to have embryonic/larval (and mammals also fetal) globin chains. In teleost fish, the embryonic/larval ξ-globin chains seem to be produced in primitive erythrocytes and the adult-type globin chains in definitive erythrocytes. Tetrameric hemoglobins can be considered to be formed of two $\alpha\beta$ dimers (designated as $\alpha_1\beta_1$ and $\alpha_2\beta_2$) with rigid contacts between the chains, whereas the other existing contacts between chains ($\alpha_1\beta_2$ and $\alpha_2\beta_1$) are more flexible.

The globin chain with its 140–160 amino acids serves to make the binding of oxygen to heme iron reversible. Heme is situated in a hydrophobic pocket which is formed in the crevice lined by E, F, and G helical portions of the molecule. In all globins studied, the oxygen-binding heme group is covalently bound to a histidine residue in the F-helix (F8). Also, a phenylalanine at the interface of C and D helices (Phe CD1) is present in all studied globins. The phenylalanine is situated at the entrance of heme pocket, and makes an important contribution to its hydrophobic nature. In almost every vertebrate hemoglobin, the interaction of oxygen and heme iron is regulated also by a histidine residue in the E-helix (E7). A notable exception is hagfish, which has glutamine in this position. A change of only one or a few amino acids in the globin chains is required to change the three-dimensional structure of the hydrophobic heme pocket so that the access of oxygen to heme iron is affected, whereby the oxygen-binding properties of hemoglobin will be changed.

A major feature of teleost fish hemoglobins is their multiplicity. In some species, more than 10 hemoglobin components can be separated electrophoretically. The electrophoretically different hemoglobins may have different functional properties, as exemplified by the eel and rainbow trout. The cathodically migrating hemoglobins are characterized by a reverse Bohr effect (at pH range 7–8 in the absence of organic phosphate binding), whereas the anodic hemoglobins have a marked Bohr effect.

Another important feature of teleost fish hemoglobins is that they have very few titratable histidines in the globin chains (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect). Whereas teleost fish have four to five histidines per globin chain, the other vertebrates including elasmobranch fish typically have double this amount (e.g., the dogfish *Squalus* has nine in the α-chain and 10 in the β-chain). Thus, whereas most tetrameric hemoglobins have more than 35 histidine residues, teleost hemoglobins usually have less than 25. In addition to teleost fish, lampreys similarly have very few histidine residues in the single globin chain (e.g., the major hemoglobin component of *Petromyzon marinus* has only two, those in the heme pocket). The small number of titratable histidines is associated with a large dependence of intraerythrocytic pH on oxygen tension (large Haldane effect). With a decrease of oxygen tension from atmospheric (i.e., 150–160 torr) to zero pressure, the intraerythrocytic pH may increase by more than 0.3 units.

Fish hemoglobins characteristically have serine substituted for cysteine in the position 93 (F9) of the β-globin chain. This substitution was originally thought to be an important reason for the Root effect (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect), but now the cysteine residue is considered to be the primary site of nitrosohemoglobin formation. Fish hemoglobins also have the end-terminal amino acid of the α-chain acetylated. Because this prevents direct carbon dioxide binding to the residue, carbamino formation in fish hemoglobins is markedly reduced (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion).

Binding of Oxygen by Hemoglobin

The oxygen binding by hemoglobin is normally described using the oxygen equilibrium curve (OEC, or oxygen dissociation curve; **Figure 1**). In the curve, the relationship is shown between the percentage (or fractional) saturation of hemoglobin with oxygen (*y*-axis) and the (blood) oxygen tension (*x*-axis). Often, the Hill plot (**Figure 2**) is used to describe the oxygen binding by hemoglobin. The Hill plot is a logarithmic transformation of the oxygen equilibrium curve. The oxygen equilibrium of hemoglobin can be described using the empirical equation:

$$S/(1-S) = K_A P^n_{O2}$$

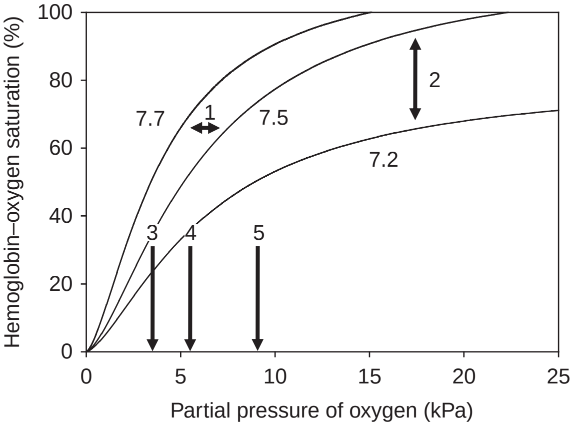

Figure 1 Oxygen equilibrium curve (OEC, or oxygen dissociation curve, ODC). The *y*-axis gives the oxygen saturation of hemoglobin (either in % or as fractional saturation) and *x*-axis the partial pressure of oxygen. Three hypothetical oxygen equilibrium curves (at pH 7.7, 7.5, and 7.2) are drawn. Arrow 1 indicates Bohr effect, i.e., a pH-induced decrease of hemoglobin–oxygen affinity without a decrease in maximal oxygen saturation. Arrow 2 indicates Root effect, i.e., a pH-induced decrease in the apparent maximal oxygen saturation of hemoglobin. Arrows 3, 4, and 5 indicate P_{50} values for the three oxygen equilibrium curves. P_{50} value is the partial pressure of oxygen at which hemoglobin is 50% saturated, and is commonly used to describe the oxygen affinity of hemoglobin.

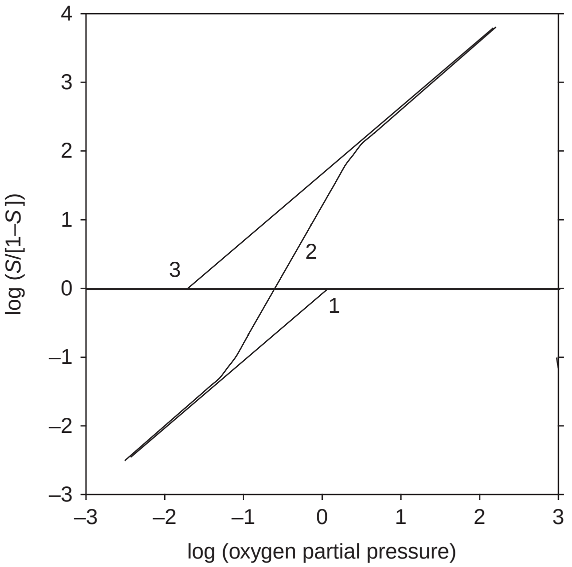

Figure 2 Hill plot. A logarithmic transformation of the oxygen equilibrium curve. The lower portion of the plot, which has a slope of 1, shows oxygen binding to the T-state hemoglobin. The numerical value of this, P_{50} value for T-state hemoglobin, is obtained by extending the plot to 50% oxygen saturation of hemoglobin (log(*S*/[1 − *S*]) = 0, where *S* is fractional oxygen saturation (1). The slope of the middle part of the plot gives the *n* (=Hill constant) (2), which indicates the cooperativity of oxygen binding (i.e., interaction between globin chains). The upper part of the plot has a slope of one, and shows the oxygen binding to the R-state hemoglobin, the numerical value of which can be obtained by extending the plot to 50 % oxygen saturation (3).

where S is the fractional oxygen saturation of hemoglobin, K_A the association constant for the overall hemoglobin-oxygen reaction, P_{O_2} the blood (solution) oxygen tension, and n the Hill coefficient. The Hill coefficient numerically represents the extent of the sigmoidal nature of the oxygen equilibrium curve, with higher n values reflecting more sigmoid oxygen equilibrium curves. The sigmoidicity of OEC indicates interaction between oxygen binding sites, for example, binding of oxygen to one site increases the likelihood of oxygen binding to the following site(s). The Hill coefficient gives an indication of the number of interacting oxygen binding sites (individual hemoglobin chains). The oxygen affinity of hemoglobin is often described using the P_{50} value instead of the whole OEC (P_{50} refers to oxygen partial pressure at which hemoglobin is 50% oxygen saturated). This value gives the oxygen tension at which hemoglobin is 50% saturated with oxygen. The two values, P_{50} and n, give a reasonable description of the oxygen-binding behavior of hemoglobin.

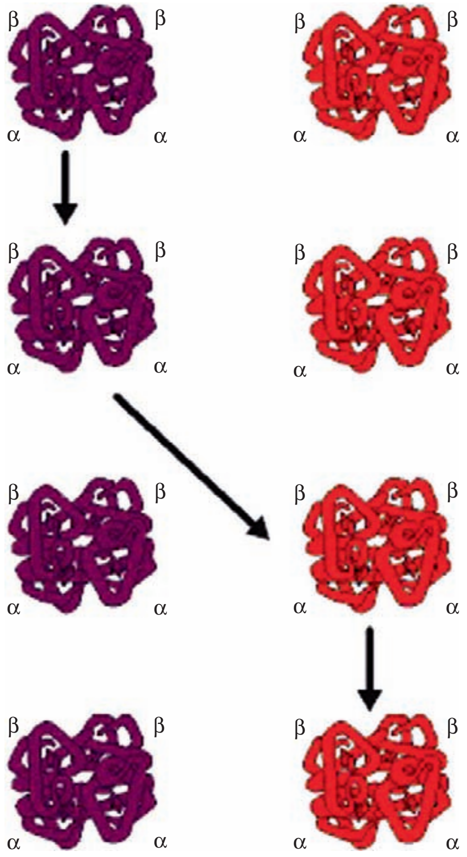

Figure 3 A schematic representation of T- and R-state hemoglobins. In the absence of oxygen, the probability of hemoglobin being in T-state (molecules on the left) is at least 10^6 times greater than that of the R-state (molecules on the right). Binding of organic phosphates (ATP and GTP; binding to a crevice between β-chains of T-state) and protons stabilizes the T-state as the bonds keeping the molecule in T-state are strengthened. Binding of oxygen first to hemes of α-globin chains increases the probability of occurrence of R-state hemoglobin. When an adequate amount of oxygen has bound (often after binding of two molecules of oxygen), the probability of the occurrence of the R-state becomes greater than that of the T-state. Arrows indicate the probable conformational changes of hemoglobin molecule upon oxygenation.

As a simplification, hemoglobin can exist in two conformations: tense (T-) or deoxy state and relaxed (R-) or oxy state (**Figure 3**). In actual fact, many intermediate conformations occur, that is, the T-form and R-form assume different conformations depending on the amount of bound oxygen. In simple terms, binding of oxygen by hemoglobin can be described in the following manner. When no oxygen is bound, virtually all hemoglobin molecules are in T-state, which has low oxygen affinity. In the Hill plot, this is seen as the lower asymptote of the plot. The oxygen affinity (P_{50} value) of T-state hemoglobin is obtained by extending the asymptote to the 0-value of $\log[S/(1-S)]$. Initially, oxygen seems to bind solely to α-chains, which have significant oxygen affinity also in the T-state hemoglobin. Binding of oxygen (to T-state) hemoglobin causes strain on the molecule, which is relieved when the molecule is converted from T-state to R-state. In most cases, this occurs when two molecules of oxygen have been bound to hemoglobin (i.e., α-chains have bound oxygen). In the Hill plot this is seen as a marked increase in the slope of the line describing the oxygen binding. At this time (10–90% oxygen saturation), the slope of Hill plot gives the n value, which indicates the number of interacting chains. Most often, n_{50} (i.e., Hill coefficient at 50% oxygen saturation of hemoglobin) is given as a measure of chain-to-chain interactions. At high oxygen saturations, any further oxygen-binding takes place to the R-state molecule. As a result, there is no interaction between globin chains (i.e., binding of oxygen to one site does not affect the structure of any other chains so that binding of oxygen to them would be affected), whereby the slope of Hill plot is one. The oxygen affinity (P_{50} value) of R-state hemoglobin is again obtained by extending the asymptote to the 0-value of $\log[S/(1-S)]$.

Factors Affecting the Oxygen-Binding Properties of Hemoglobin

The effect of oxygen on the binding of consecutive oxygen molecules is an example of homotropic interactions, where a molecule affects the binding of consecutive molecules of the same type. Although homotropic interactions are important in influencing the oxygen-binding properties of hemoglobin, physiological regulation of hemoglobin function relies mainly on heterotropic interactions, where different molecules affect the oxygen binding behavior. A prime example of heterotropic interactions is the binding of organic phosphates to a site which is different from the oxygen-binding site. The binding of organic phosphates to their binding site tends to affect the structure of the oxygen-binding site so that the accessibility of oxygen to and from the site (and thereby oxygen-binding properties) is affected. This constitutes an example of allosteric effect. Because hemoglobin assumes two major conformations which have different oxygen affinities, the effect of different factors on oxygen binding behavior can be reduced to the factors affecting the probability of the occurrence of the different conformations.

Proton Effects

The three-dimensional structure of hemoglobin is generated and maintained mainly by salt bridges, hydrogen bonds, and van der Vaals bonds. Protons affect all of these bonds, thus being major effectors of the three-dimensional structure of hemoglobin molecule. The structural effects of protons stabilize the T- (deoxy) state of hemoglobin. Thus, at physiological pH values a decrease in pH shifts the OEC to the right, that is, decreases hemoglobin-oxygen affinity (increases P_{50} value; **Figure 1**). This is called the (alkaline) Bohr effect. The effect was originally observed more than 100 years ago as the effect of carbon dioxide on hemoglobin-oxygen affinity and thus actually predates the formulation of pH concept. The Bohr effect is described in detail elsewhere (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect), so only the basic principles are given here. The magnitude of the Bohr effect is usually given by the Bohr constant ($\text{BC} = \Delta\log P_{50}/\Delta\text{pH}$), which varies greatly from positive values in the absence of organic phosphates in the cathodically migrating eel and trout hemoglobins to negative values exceeding −1, using P_{50} values in torr (=mmHg). In general, the Bohr effects of teleost fish and lamprey hemoglobins are large and those of elasmobranchs and hagfish small. Whereas in tetrameric teleost fish hemoglobins the Bohr effect must be due to proton binding to specific residues, and consecutive effects on oxygenation; in lampreys, it is due to oxygenation-linked aggregation of hemoglobin chains. There appears to be a negative correlation between the number of histidine residues and Bohr effect: the Bohr effect is large if the number of histidine residues per globin chain is small. The strength of the Bohr effect can also be given as the number of protons taken up upon deoxygenation. This is usually called the Haldane effect, and is an example of linked functions (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange). Whereas human and many mammalian hemoglobins take up maximally two protons per molecule, teleost fish hemoglobins maximally take up four. While most of the residues involved in generating the Bohr effect in fish still remain unknown, the role played by the C-terminal histidine residue of the β-chain is clear. In the cathodic hemoglobins of eel and rainbow trout, which are essentially devoid of Bohr effect, this residue is replaced by phenylalanine. In Bohr-effect hemoglobins, the hemoglobin can be fully saturated with oxygen at atmospheric oxygen tension. The Hill coefficient is, furthermore, pH insensitive.

In addition to the Bohr effect, a pronounced effect of protons in fish hemoglobins is the Root effect (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems and Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). In Root effect hemoglobins (**Figure 1**), full oxygen saturation is not reached, and the Hill-coefficient value decreases with decreasing pH, ultimately to values below 1. The simplest explanation for this is that binding of oxygen to the (α-chains of) T-state hemoglobin causes conformational changes to the molecule that prevent oxygen binding to the remaining β-chains. So far, the amino acid residues involved in the extreme stabilization of T-state in the Root effect hemoglobins have not been clarified, but the available information suggests that amino acids in the $\alpha_1\beta_2$-contact region may play a role.

Anion, Particularly Organic Phosphate Effects

Anions bind to the cavity between the β-chains of the T-state in tetrameric hemoglobins. Hagfish and lampreys are devoid of anion effects, because their hemoglobins do not form stable tetramers. The effectiveness of binding increases with the number of (hydrogen) bonds that the compound can form with the hemoglobin. The most important anions affecting hemoglobin function in fishes are the organic phosphates adenosine triphosphate (ATP) and guanosine triphosphate (GTP). In the hemoglobin of rainbow trout, the amino acid residues involved in organic phosphate binding have been clarified and involve the amino terminal glutamic acid, a lysine in the EF transition (EF6) and arginine in the H-helix (H21). Since GTP can form one hydrogen bond more than ATP, its influence on hemoglobin function is greater than that of ATP. In some fish hemoglobins, however, the effect of ATP is as great as that of GTP. While the structural basis of this is unknown, it is possible that the structure of the cavity between β-chains is affected.

The binding of organic phosphates stabilizes the T-state of hemoglobin. Thus, an increase in nucleoside triphosphate (NTP) concentration decreases the hemoglobin-oxygen affinity (**Figure 4**). In addition to affecting the hemoglobin-oxygen affinity, the binding of organic phosphates to hemoglobin increases *n* value.

Temperature Effects

Binding of oxygen to hemoglobin is exothermic. The apparent heat of oxygenation (ΔH_{app}) is given by the equation: $\Delta H_{\text{app}}=2.303R(\Delta \log P_{50}/\Delta[1/T])$. An increase in temperature will decrease hemoglobin-oxygen affinity of most hemoglobins. The apparent heat of oxygenation includes the actual heat of heme oxygenation and also the heat of solution of oxygen in water, the heats of conformational changes, and heats of ionization (proton and anion binding and release, including organic phosphate binding and release). This being the case, the apparent heats of oxygenation of pure hemoglobin solutions and hemoglobin in blood can be markedly different. In the latter, the large endothermic release of Bohr protons and of organic phosphates when oxygen is bound decreases the overall apparent heat of oxygenation. This indicates that there is a need to study both isolated hemoglobins and native red blood cells to gain a full understanding of how and why temperature affects the oxygen equilibria of hemoglobin.

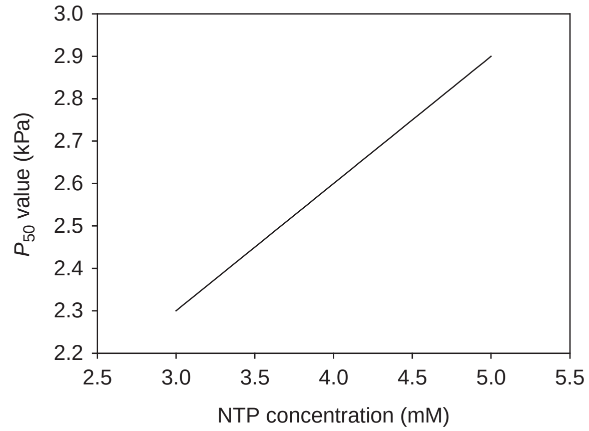

Figure 4 The relationship between hemoglobin-oxygen affinity (as given by the P_{50} value) and organic phosphate concentration in rainbow trout. Figure based on data from Soivio A, Nikinmaa M, and Westman K (1980). The blood oxygen binding properties of hypoxic *Salmo gairdneri*. *Journal of Comparative Physiology B* 136: 83–87.

The hemoglobin–oxygen affinity of some tunas and some sharks is either temperature insensitive, or their hemoglobin–oxygen affinity may even increase with increasing temperature. The fish with the overall lack of heat of oxygenation of hemoglobin or reversed temperature dependency of oxygenation are warm-bodied fishes. As a result of the nonexistent or even reversed temperature dependence of hemoglobin–oxygen affinity, these hemoglobins will not lose oxygen despite the marked temperature gradient (up to 20 °C from the peripheral tissues to the core). The hemoglobins of some tunas, the best-known warm-bodied fishes, have exothermic apparent heat of oxygenation when the first oxygen molecules are bound to hemoglobin, virtual lack of temperature dependence of oxygen binding at near 5% hemoglobin-oxygen saturation, and endothermic reaction when the last oxygen molecules bind. The endothermic reaction may be the result of pronounced endothermic proton release when the last oxygen molecules are bound to hemoglobin. In some species, marked reduction of temperature dependency of oxygen binding is achieved via organic phosphates: in the presence of ATP the oxygen affinity of hemoglobin is temperature insensitive or may even increase with increasing temperature. A physiological role of temperature-independent oxygen binding (or its reversed temperature dependency) for warm-bodied (heterothermic) fish is to minimize the loss of oxygen (from hemoglobin) during temperature increase (**see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks).

Hemoglobin Oxidation

The reversible binding of oxygen by hemoglobin requires that the heme iron is unstable in the ferric state. In free heme groups, iron is readily oxidized to ferric iron. In simplified terms, one can state that the major reason for embedding the heme in the protein moiety is to prevent irreversible oxidation. The less hydrophobic the heme environment is (i.e., the higher its oxygen affinity), the more likely the oxidation to ferric iron is. Of the specific amino acid residues the highly conserved histidine in the position E7 plays a major role in protecting the heme iron from oxidation.

The oxidation of heme iron results from an attack of nucleophiles. In undisturbed conditions the biologically most important nucleophiles are water and hydroxyl ions. Autoxidation occurs preferentially, if hemoglobin is in the deoxy-(T-)state. Because His(E7) both inhibits the access of water in the heme pocket and stabilizes heme–oxygen interaction after it has occurred, the major causes of hemoglobin oxidation are counteracted. The rate of hemoglobin autoxidation increases with increasing temperature, and probably with decreasing pH. Also, various chemicals such as nitrite cause hemoglobin oxidation. Notably, in contrast to autoxidation, nitrite-induced oxidation occurs more readily in oxy- than in deoxyhemoglobin.

The oxidized hemoglobin (called methemoglobin) has a three-dimensional structure that resembles the R-state more closely than the T-state. Similarly, partial oxidation shifts the equilibrium between T- and R-state of hemoglobin toward the R-state, whereby the oxygen affinity of the nonoxidized hemoglobin chains increases.

Glossary

Capacitance coefficient Formally defined as $\Delta C/\Delta P$, where C is concentration and P is the partial pressure of a gas. If the gas is present exclusively in physical solution, this is identical to the solubility of the gas.

Convection Bulk movement of a medium, e.g., gas, water, or blood.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

Introduction

A primary function of the blood in fish is to transport oxygen (O_2) from the gills to the metabolizing tissue where respiration takes place (**see also Tissue Respiration**: Cellular Respiration and Mitochondrial Respiration). The convective transport of O_2 by the blood is performed by the cardiovascular system, and the vast majority of O_2 is transported by hemoglobin through reversible binding to the iron moiety (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). The uptake of O_2 from the water across the gills and the delivery of O_2 from the systemic capillary to the mitochondria are driven by diffusion alone, and diffusion is solely governed by differences in the O_2 partial pressure (P_{O_2}) (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). Thus, at the gills, a high blood-O_2 affinity would maintain a high P_{O_2} gradient across the branchial epithelium and thereby facilitate loading. Conversely, a low blood-O_2 affinity would serve to elevate the P_{O_2} in the capillary and thereby increase O_2 delivery to the tissue (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange). Thus, the optimal blood-O_2 affinity reflects a compromise that simultaneously must meet the demands of O_2 loading at the gills and unloading at the tissues. A theoretical optimal blood-O_2 affinity is calculated by mathematical modeling of the gas-exchange system as described below. However, a serious caveat of this approach is the lack of complete data sets, and some of the input parameters for the models accordingly must be estimated based upon a number of assumptions.

The Blood-Oxygen Equilibrium Curve

Blood O_2 binding is usually described by the relationships between the blood P_{O_2} and O_2 concentration or hemoglobin-O_2 saturation (HbO_2 saturation), where the latter is expressed as percentage of the O_2-carrying capacity of the hemoglobin (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). A typical blood-O_2 equilibrium curve (OEC) is shown in **Figure 1**. As seen from this figure, there is a sigmoidal relationship between O_2 concentration and P_{O_2}, due to cooperativity in O_2 binding, and it is also apparent that the maximal change in O_2 concentration occurs slightly below the P_{O_2} that results in 50% saturation of the hemoglobin (P_{50}). The P_{50} of blood is often used to quantify blood-O_2 affinity. This P_{50} value is physiologically significant because a great deal of O_2 can be unloaded at the tissues with only a small change in P_{O_2} (steep part of the OEC). Therefore, fairly constant conditions for O_2 unloading are maintained. The sigmoidal shape of the OEC helps to increase the P_{O_2} gradient for both O_2 loading at the gills and O_2 unloading within the capillaries and represents a functionally important property of blood-O_2 binding.

It is well established that the O_2 affinity of a given species is determined by the intrinsic functional properties of the hemoglobin molecule as well as by the intra-erythrocytic concentrations of numerous effectors

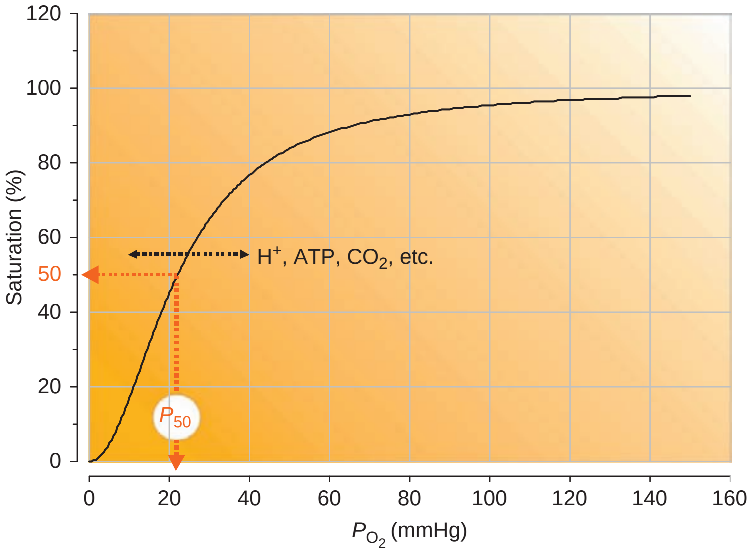

Figure 1 A typical sigmoidal O_2-equilibrium curve (OEC). The P_{50} is the partial pressure of O_2 at which hemoglobin is 50% saturated with O_2. The position (and thus P_{50}) of the O_2-equilibrium curve can be modified by variation in the intraerythrocytic concentration of certain effectors, such as H^+, CO_2, or ATP (or GTP), that bind to hemoglobin.

that modify the intrinsic properties by binding to hemoglobin. The most notable of these effectors are protons (H^+), CO_2 and, not the least, organics phosphates, which, in fish, are primarily adenosine triphosphate (ATP) and guanosine triphosphate (GTP). (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function). Both ATP and GTP reduce blood-O_2 affinity and provide a means for the fish to alter the blood-O_2 binding characteristics without having to express other hemoglobin molecules with different intrinsic binding properties. Many studies on a variety of fish species show that blood-O_2 affinity increases within hours after exposure to hypoxic conditions due to a reduction in red-blood-cell ATP and/or GTP levels. These reductions in organic phosphates facilitate O_2 uptake at the gills in response to a reduction in environmental O_2 levels.

The blood-O_2 affinity varies considerably among different fish species. As a general trend, fish inhabiting waters that are either chronically hypoxic, or where hypoxia occurs on a regular basis, tend to have higher blood-O_2 affinities than fishes inhabiting well-oxygenated environments. An increased blood-O_2 affinity in a hypoxic environment ensures high arterial-O_2 saturation and hence is expected to enhance systemic O_2 delivery.

Many studies have described the blood-O_2 affinity in fish, and there are numerous interpretations regarding how the specific O_2 affinity may represent an adaptation to various environments or behaviors. While most of these interpretations are intuitively appealing, it must be emphasized that they remain largely untested and hence not verified. As evident from the mathematical model presented below, the functional correlates of blood-O_2 affinity in a given species can only be evaluated if other physiological parameters, such as the diffusive capacities of the gills and the systemic circulation as well as cardiac output are included in the analysis. As a caveat, it should also be remembered that the blood-O_2 affinity may be correlated with physiological functions other than O_2 delivery *per se*. For example, in some endothermic fish, such as some sharks and tunas, temperature effects may interact to determine functional characteristics of blood-O_2 binding.

The Optimal Blood-Oxygen Binding Affinity

Because O_2 consumption of resting animals is likely to be independent of O_2 delivery, and hence P_{O_2} of the capillary blood, it is reasonable to argue that the exact position of the OEC, within a reasonable range of blood-O_2 affinities, has no influence on resting metabolism. However, when metabolism and the cellular need for O_2 increase, O_2 delivery becomes a limiting factor. Thus, it is not unreasonable to assume natural selection selected for an O_2 affinity that maximizes O_2 delivery during elevated metabolic rate and hence enables the maximal rate of O_2 consumption ($\dot{V}_{O_2max}$) possible. As outlined below, it is relatively straightforward to model $\dot{V}_{O_2max}$.

The O_2-transport cascade of fish can be described as a schematic of four steps, as illustrated in **Figure 2** (**see also Ventilation and Animal Respiration**: The Effect of Exercise on Respiration). As the first step,

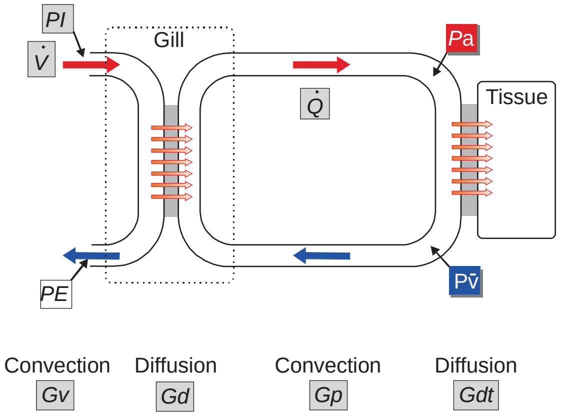

Figure 2 A schematic representation of the O_2-transport cascade from the surrounding water to the mitochondria where respiration takes place. Oxygen is transported in four steps, alternately by convection and diffusion, as indicated. Water is transported to the gill with a flow ($\dot{V}$) and a conductance, (*Gv*). Diffusion from water to blood is characterized by a diffusion conductance (*Gd*). The blood O_2 is transported with a blood flow ($\dot{Q}$) and a conductance (*Gp*), and finally diffusion from the blood to the tissue is characterized by a conductance (*Gdt*). Water enters the gills with an inspired partial pressure (*P*I) and leaves with an expired partial pressure (*P*E). In the model the arterial and mixed-venous partial pressures (*P*a and Pv, respectively) as well as PE are all dependent variables.

water is transported by convection across the gills (gill ventilation (Gv)), followed by diffusion across the gills to the blood (Gd) (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). Then, blood is convectively transported by the cardiovascular system to the peripheral circulation in the tissue (Gp), where the final diffusive step takes place as the O_2 reaches the mitochondria of the respiring cells (**see also Tissue Respiration**: Cellular Respiration and Mitochondrial Respiration).

A Quantitative Model of the Oxygen-Transport Cascade to Predict the Optimal Blood-Oxygen Affinity

To specifically evaluate the optimal blood-O_2 affinity (optimal P_{50}) to maximize $V_{O_2\text{max}}$ in fish, we constructed a simple mathematical model. This model incorporates a counter-current exchanger in the gills (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs), convective O_2 transport within the blood (**see also Ventilation and Animal Respiration**: The Effect of Exercise on Respiration) and diffusion from blood to tissue. We modeled how $V_{O_2\text{max}}$ is influenced by P_{50} and sigmoidicity of the OEC at several levels of inspired P_{O_2}. The equations used for the model are explained in the Appendix section, which also includes an overall description of the iterative procedure used to solve the various equations simultaneously. Input parameters consisted of data from rainbow trout (*Oncorhynchus mykiss*) – the only species of teleost studied in sufficient detail to provide the necessary physiological parameters. The specific parameters used in the model are listed in **Table 1**.

The results of the model are shown in **Figure 3**, where $V_{O_2\text{max}}$ is depicted as a function of P_{50} for various inspired P_{O_2} values in the two upper panels. The predictions during severe hypoxia (P_{O_2} of 10 and 20 mmHg) are expanded in the upper right-hand panel. The analysis clearly shows that $V_{O_2\text{max}}$ decreases with a reduction in inspired P_{O_2} as the level of hypoxia becomes more severe, which is consistent with *in vivo* observations. At all levels of inspired O_2, very high O_2 affinity (as indicated by a low P_{50}) causes $V_{O_2\text{max}}$ to decrease, while $V_{O_2\text{max}}$ only decreases a little as P_{50} increases above physiologically relevant values. As inspired O_2 levels are decreased, the maximal $V_{O_2\text{max}}$ occurs at lower P_{50} values showing that increased O_2 affinity does safeguard O_2 delivery, but there is still a wide plateau, where P_{50}

Table 1 Constants used in the calculations of the effect of P_{50} (P_{O_2} at which hemoglobin is 50% saturated) on maximal oxygen uptake in rainbow trout

Name	*Symbol*	*Unit*	*Value*
Hemoglobin concentration	C_{Hb}	mmol L^{-1}	1.0
Capacitance coefficient, water	βw_{O_2}	µmol L^{-1} $mmHg^{-1}$	2.24
Capacitance coefficient, blood	βb_{O_2}	µmol L^{-1} $mmHg^{-1}$	1.99
Diffusion conductance, gill	*Gd*	µmol min^{-1} kg^{-1} $mmHg^{-1}$	1.60
Diffusion conductance, tissue	*Gdt*	µmol min^{-1} kg^{-1} $mmHg^{-1}$	4.64
Cardiac output	$\dot{Q}$	mL min^{-1} kg^{-1}	53
Ventilation	$\dot{V}w$	mL min^{-1} kg^{-1}	1730

Cardiac output, ventilation, and hemoglobin concentration are from measurements on rainbow trout performing maximal exercise at 10 °C and the capacitance coefficients (solubilities), are literature values reported for 10 °C. The diffusion conductances, *Gd* and *Gdt,* given in the table are result of a preliminary test in which their values were adjusted so that the arterial and venous P_{O_2} values, coming out of the model using a P_{50} of 22 mmHg, corresponded roughly to the values measured on rainbow trout performing maximal exercise at 10 °C.

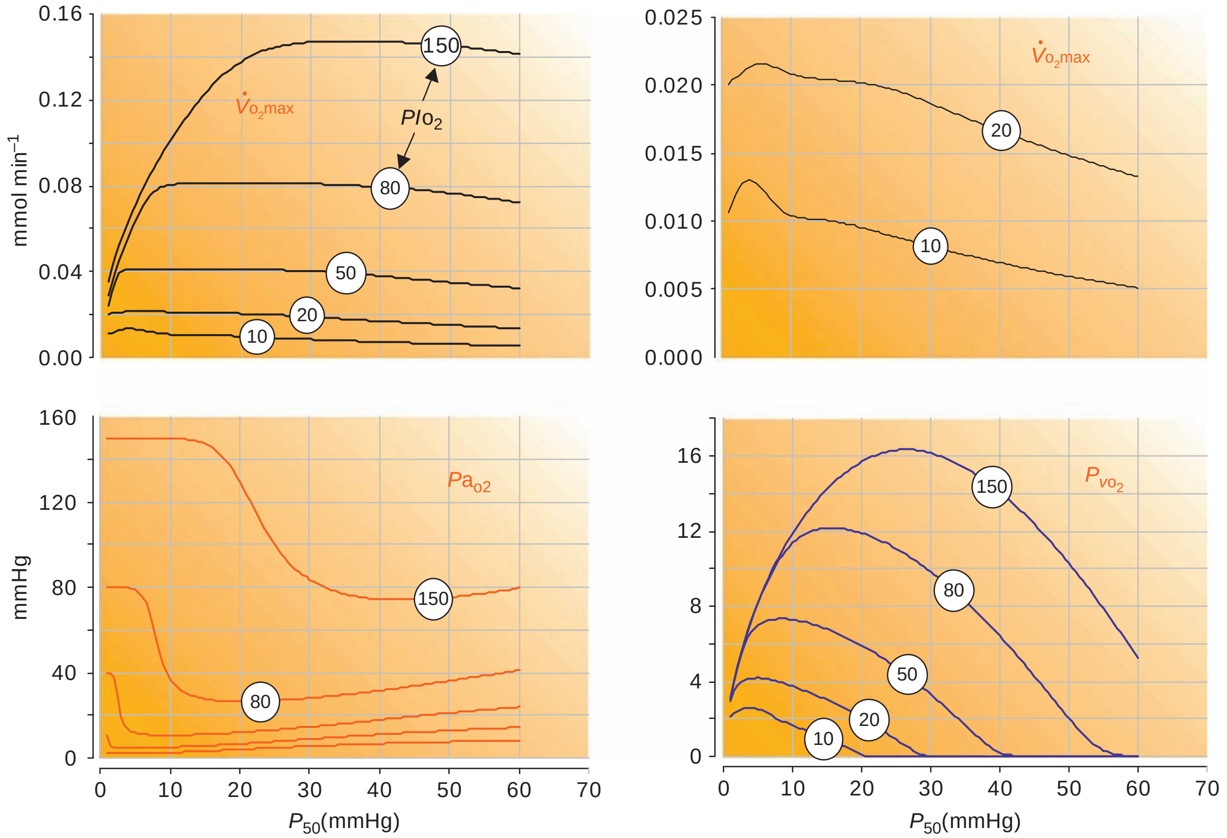

Figure 3 The effect of blood P_{50} (mmHg) on maximal O_2 consumption rate (V_{O_2max}), and resulting arterial and mixed-venous O_2 partial pressures (Pa_{O_2} and Pv_{O_2}) calculated using the model in the appendix. V_{O_2max}, Pa_{O_2} and Pv_{O_2} were calculated at a number of inspired O_2 partial pressures (PI_{O_2}), where the PI_{O_2} is indicated by numbers contained within small circles that refer to each entire respective curve.

has little effect on the predicted V_{O_2max}. The underlying mechanisms for the effects of P_{50} on V_{O_2max} can be understood, at least in part, from the calculated changes in arterial and venous P_{O_2} values shown in the two lower panels. As P_{50} increases, the P_{O_2} gradient over the gills is reduced and the blood does not reach full equilibrium with the water, which is evident from the fall in arterial P_{O_2} as P_{50} increases. This relationship reflects that low blood-O_2 affinity (high P_{50}) impairs O_2 loading at the gills, while the simultaneous reduction in venous P_{O_2} shows how unloading in the tissues benefits from the reduced blood-O_2 affinity. The low venous P_{O_2} values at the very high affinities (low P_{50}) are a consequence of the high affinity, so that venous O_2 concentration actually remains high (not shown in the figure).

It is important to realize that the arterial and venous O_2 levels (i.e., saturation, P_{O_2}, and concentration) are dependent variables of all the input parameters. Thus, the model ignores the normal physiological regulation of arterial blood gases, which, at first, may be regarded as a limitation of the model. However, we model only maximal O_2 uptake, and therefore there is no room for regulation of arterial blood gases – everything is at its maximum. Despite the great variability in the partial pressures of the arterial gases as P_{50} changes, there is remarkably little change in maximal O_2 uptake.

Conclusions

The overall conclusion of the model is that the optimal P_{50} decreases with inspired P_{O_2}. However, the optimum is very broad, and P_{50} only modestly influences the predicted V_{O_2max}. The model also shows that the relationship between P_{50} and V_{O_2max} is asymmetrical, such that V_{O_2max}, at most levels of inspired P_{O_2}, declines more at low, relative to high P_{50} values. Only in severe hypoxia ($P_{O_2} < 20$ mmHg; approximately the P_{50} of the blood used in these calculations) is there a pronounced effect on V_{O_2max} of increasing blood-Oxygen affinity (decreasing P_{50}).

Our analysis shows that a P_{50} below 25 mmHg reduces V_{O_2max} in normoxic water, but that an increased affinity does confer advantages in severe hypoxia. This pattern is consistent with the general finding that active fish with high $V_{O_2\mathrm{max}}$ tend to have lower blood-O_2 affinities than hypoxia-tolerant fish.

Appendix

The Equations Used to Predict the Optimal Blood-Oxygen Affinity

At the respiratory surface of the gill, the exchange of O_2 is described by two differential equations – one for water and one for blood:

$$\frac{\mathrm{d}Pw}{\mathrm{d}l} = \frac{Gd}{Gv}(Pw - Pb) \qquad (1a)$$

$$\frac{\mathrm{d}Pb}{\mathrm{d}l} = \frac{Gd}{Gp}(Pw - Pb) \qquad (1b)$$

Here, Pw and Pb are the P_{O_2} values in water and blood, respectively. l refers to the length coordinate along the exchange surface and Gd, Gp, and Gv are the diffusion, perfusion, and ventilation conductances, respectively. These equations are derived from mass balance and simply express that, at any point and on either side of the exchanger, the change in P_{O_2} along an infinitesimal length of surface is proportional to the amount of O_2 diffusing across the barrier (for a more detailed account of this and of the meaning of the different terms **see Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs)

The diffusion conductance is given by

$$Gd = \frac{KA}{t} \qquad (2)$$

Here K is Krogh's diffusion constant, A the area and t the thickness. In this model, we fix Gd at a constant and maximal value. The ventilation conductance is given by

$$Gv = \dot{V}w\beta w \qquad (3)$$

where $\dot{V}w$ is the ventilation volume and βw_{O_2} is the capacitance coefficient of O_2 in water (also called solubility). In the following calculations, we fix this at a constant and maximal value. The perfusion conductance is defined in a similar manner

$$Gp = \dot{Q}\beta b \qquad (4)$$

where $\dot{Q}$ is cardiac output and βb the O_2 capacitance coefficient of blood. Due to the inherently nonlinear nature of the O_2-equilibrium curve the latter is, however, not a constant but depends on the blood's P_{O_2}, Pb. Formally it is defined as the slope of the relation between concentration and partial pressure, that is,

$$\beta b = \frac{\mathrm{d}C_b}{\mathrm{d}P_b} \qquad (5)$$

The relation between hemoglobin-O_2 saturation and P_{O_2} is most conveniently described by the Hill equation, which gives a satisfactory description of the relationship with only two constants:

$$Sb = \frac{Pb^n}{P_{50}^n + Pb^n} \qquad (6)$$

Here, P_{50} is the blood P_{O_2} that results in 50% saturation of the hemoglobin and n (the so-called Hill coefficient) is a parameter describing the sigmoidicity of the curve. Taking the physically dissolved O_2 into account, the relation between concentration and partial pressure becomes

$$Cb = \beta b\, Pb + 4C_{Hb}\frac{Pb^n}{P_{50}^n + Pb^n} \qquad (7)$$

where C_{Hb} is hemoglobin concentration.

Gas exchange in the tissue is described by

$$\frac{\mathrm{d}P_b}{\mathrm{d}l} = \frac{Gdt}{Gp}(P_b - P_t) \qquad (8)$$

Here, Gdt is the blood to tissue diffusion conductance, which is determined mainly by the capillarity and Pt is tissue P_{O_2}. As we are only concerned about the maximal O_2 uptake we set Pt at 0.

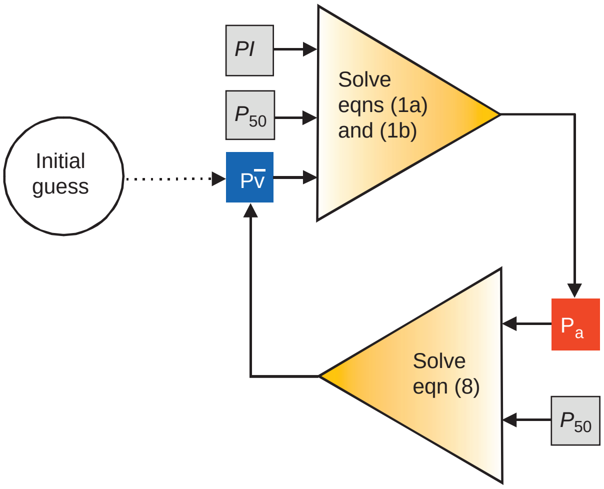

Figure 4 Diagrammatic illustration of the way the equations describing O_2 transport in the gill and in the tissue were simultaneously solved. For any given combination of the O_2 affinity (P_{O_2} that results in 50% saturation of the hemoglobin, P_{50}) and the inspired O_2 partial pressure (PI), an initial guess of the mixed-venous P_{O_2} was entered into the model and was used in the solution of the equations for gas exchange in the gill (eqns (Ia) and (Ib)). This resulted in an arterial O_2 partial pressure, Pa, (and an expired, PE, as well), which then was used in the solution of the equation for gas exchange in the tissue (eqn(8)). This resulted in a new mixed-venous P_{O_2}, which then could be used in the initiation of a new cycle, and so forth. This was repeated until Pa and Pv no longer changed.

How We Solved the Equations

Because we investigate how the O_2 affinity of the blood affects the maximal O_2 uptake, the input to the model is the P_{50} and the output is the O_2 uptake. In this situation, the arterial and venous P_{O_2} values as well as concentrations are all dependent variables that will automatically adjust to values dictated by the constraint that O_2 uptake over the gills must be matched exactly by the consumption in the tissues. In order to solve eqns (1a), 1(b), and (8) simultaneously, we adopted the iterative procedure outlined in **Figure 4** and applied the constants of **Table 1**.

Glossary

Acetazolamide A sulfonamide (2-acetylamino-1,3,4-thiadiazole-5-sulfonamide) that readily crosses cell membranes and inhibits carbonic anhydrase by binding to the zinc ion in the active site of the enzyme.

Acid–base balance The regulation of constant pH in the body fluid compartments by means of a suite of physiological responses for the excretion and/or accumulation of acid–base equivalents, and usually by adjusting P_{CO_2} and/or HCO_3^- levels.

Acid–base equivalents H^+ and HCO_3^- or substances that release or bind H^+ when dissolved in water.

Active site The portion of an enzyme that binds the substrate and catalyzes its reaction.

Benzolamide A sulfonamide (5-benzenesulfonamido-1,3,4-thiadiazole-2-sulfonamide) that crosses cell membranes relatively slowly. It inhibits carbonic anhydrase by binding to the zinc ion in the active site of the enzyme.

Carbonic anhydrase (CA) A zinc metalloenzyme that reversibly catalyzes the reaction of CO_2 and H_2O to form H^+ and HCO_3^-.

Dehydration reaction The reaction of HCO_3^- and H^+ to form CO_2 and H_2O.

Electrometric ΔpH assay A technique used to assess CA activity in which changes in pH are measured following the addition of CO_2 to a buffer containing CA. The rate of change of pH in the presence of the CA represents the rate of the catalyzed reaction since one proton is produced for each molecule of CO_2 that is hydrated.

Hydration reaction The reaction of CO_2 and H_2O to form carbonic acid (H_2CO_3), which rapidly dissociates to H^+ and HCO_3^-.

Isoform Different forms of the same protein produced from related genes or arising from the same gene by alternative splicing.

Orthologs The homologous genes (i.e., sharing a common evolutionary ancestor) that are found in different species.

Pillar cell A spool-shaped cell found in the fish gill lamellae. It has a trunk-like body that separates the epithelial layers of the lamella and cytoplasmic flanges that spread out and attach to neighboring flanges so as to delimit the vascular space.

Transmembrane proteins Proteins that span the plasma membrane.

Introduction

Carbonic anhydrase (CA) is an enzyme that catalyzes the reversible reactions of carbon dioxide and water: $CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$. Because the dissociation of carbonic acid (H_2CO_3) to protons (H^+) and bicarbonate ions (HCO_3^-) is very rapid, the reactions are typically summarized as: $CO_2 + H_2O \leftrightarrow H^+ + HCO_3^-$. The hydration ($CO_2 + H_2O \rightarrow H^+ + HCO_3^-$) and dehydration ($H^+ + HCO_3^- \rightarrow CO_2 + H_2O$) reactions proceed at a moderate pace even in the absence of a catalyst, but can become limiting to rapid physiological processes. For example, as blood passes through the gills of fish, HCO_3^- ions are dehydrated to molecules of CO_2 that then diffuse across the gills into the ventilated water (**Figure 1**). The uncatalyzed conversion of HCO_3^- to CO_2 may require more than 1 min to approach completion, yet the blood remains in the gills for only 1–3 s. It is red blood cell (RBC) CA that enables effective CO_2 excretion, increasing the rate of CO_2 hydration/dehydration reactions up to 25 000-fold so as to allow conversions between HCO_3^- and CO_2 to reach near completion in milliseconds. The importance of RBC CA to CO_2 excretion is clearly illustrated by the decrease in CO_2 excretion and elevation of blood CO_2 tension that occurs when RBC CA is inhibited (**Figure 2**).

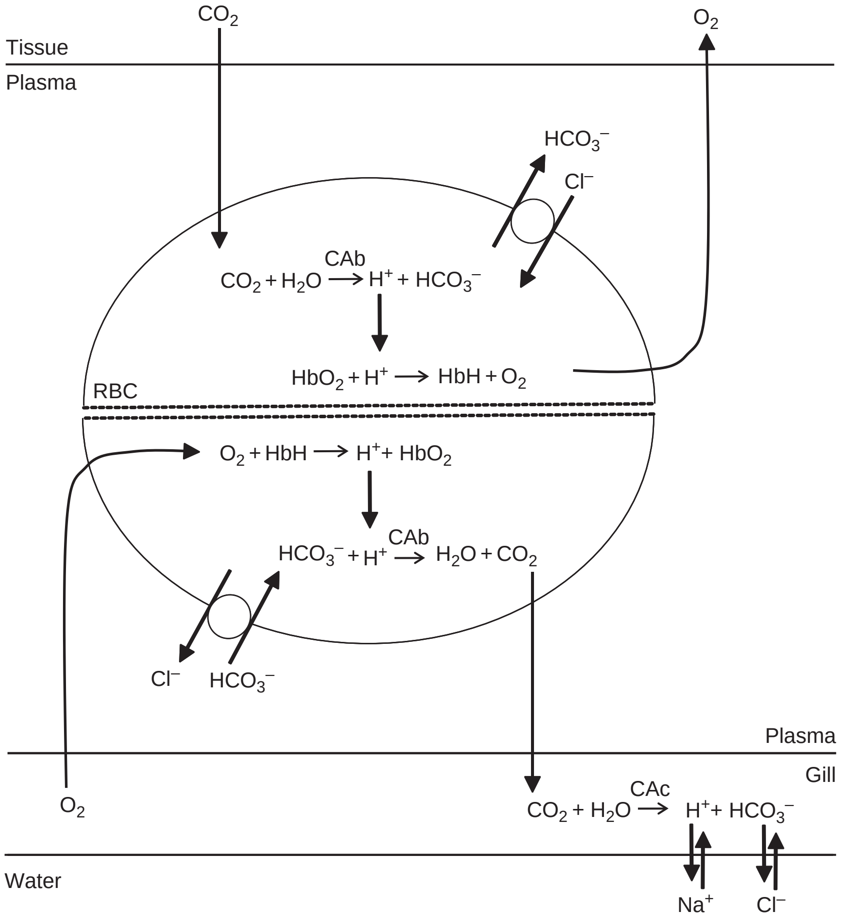

Figure 1 A schematic depicting the role of red blood cell (RBC) carbonic anhydrase (CAb) and gill epithelium cytosolic CA (CAc) in CO_2 excretion and acid–base balance, respectively, in a teleost fish. CO_2 diffuses from the tissues into the RBC where it is hydrated in the presence of CAb. Protons are buffered by hemoglobin (Hb) while HCO_3^- ions are removed to the cytoplasm by the anion exchanger band 3. These reactions are reversed at the gill. CO_2 that diffuses into the gill epithelium may be hydrated in the presence of CAc to provide H^+ and HCO_3^- used as counterions in, respectively, Na^+ and Cl^- uptake.

CA was, in fact, discovered (in 1932) in RBCs as a result of the realization that the uncatalyzed rate of HCO_3^- dehydration was too low to support CO_2 excretion during the time blood spent at the gas-exchange surface. Perhaps because it was first discovered in RBCs, or because RBCs provide a readily accessible and rich source of the enzyme, CA is often considered to be primarily involved in gas transfer, specifically CO_2 excretion (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion). The reality, however, is that CA plays a key role in a multitude of physiological processes ranging from calcification through metabolism and gas transfer to ionic regulation and acid–base balance. These varied roles reflect both the direct and indirect consequences of catalyzed CO_2 reactions: for example, enhanced rates of HCO_3^- supply for metabolism or acid–base equivalents for acid–base balance, as well as faster movement of CO_2 through fluid compartments and across membranes. The differing demands of the many roles played by CA have resulted in the existence of multiple CA isoforms that vary in molecular sequence, kinetic properties, tissue distribution, and subcellular localization. With few exceptions, these isoforms share in common a catalytic mechanism reflecting specific molecular structures.

Carbonic Anhydrase – The Enzyme

Three genetically unrelated families (α, β, and γ) of CA isoforms exist, but only the α-genes appear to be present in vertebrates. The α-CAs are monomeric metalloenzymes that employ a two-step, ping-pong catalytic mechanism centered around a zinc ion at the active site. Hydration is initiated when a zinc-bound hydroxide ion attacks the carbon atom of a CO_2 molecule held in a hydrophobic pocket adjacent to the active site. The product of this nucleophilic attack is a zinc-bound bicarbonate ion, which is then displaced by a water molecule:

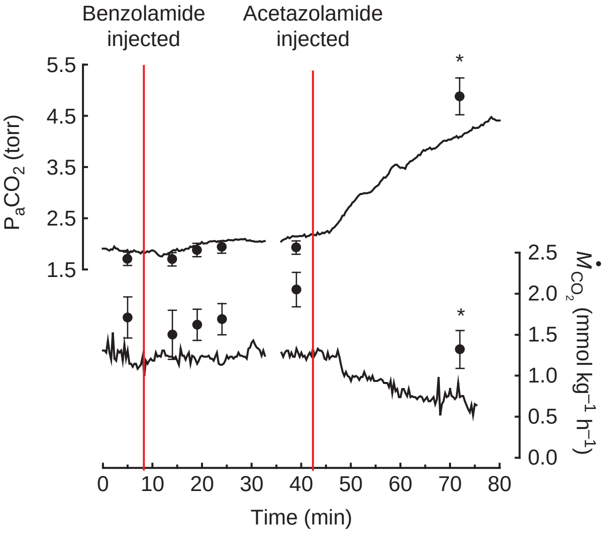

Figure 2 Injection of benzolamide into rainbow trout (*Oncorhynchus mykiss*) is without effect on CO_2 excretion ($\dot{M}$ CO_2) or the arterial partial pressure of CO_2 (P_aCO_2). Acetazolamide treatment, on the other hand, significantly reduces $\dot{M}$ CO_2 resulting in a substantial increase in P_aCO_2. The symbols represent mean data for five to six fish while the lines are representative recordings from a single fish. An asterisk indicates a significant difference from the value prior to CA inhibitor injection. Data are redrawn from Gilmour KM, Perry SF, Bernier NJ, Henry RP, and Wood CM (2001) Extracellular carbonic anhydrase in dogfish, *Squalus acanthias*: A role in CO_2 excretion. *Physiological and Biochemical Zoology* 74: 477–492

$$\mathrm{EZn\text{-}OH^- + CO_2 \leftrightarrow EZn\text{-}HCO_3^- + H_2O \leftrightarrow EZn\text{-}H_2O + HCO_3^-} \qquad (1)$$

The advantage of this pathway is its speed; the direct formation of HCO_3^- via this route is about five orders of magnitude faster than the uncatalyzed reaction involving the formation and subsequent dissociation of carbonic acid.

With water coordinated to the zinc ion, the enzyme is inactive. To regenerate the zinc-bound hydroxide ion for the next round of catalysis, a proton must be transferred from the zinc-bound water to the solution buffer (B):

$$\mathrm{EZn\text{-}H_2O \leftrightarrow EZn\text{-}OH^- + BH^+} \qquad (2)$$

This proton transfer appears to be the rate-limiting step in the catalytic mechanism; in some of the catalytically very active isoforms (e.g., mammalian CA II and CA IV; see below), the process is assisted by a proton shuttle, a histidine residue located at the entrance of the active site (His 64).

The molecular structures that support this catalytic activity are in general conserved across both isoforms and species (**Table 1**), suggesting that the catalytic mechanism described above, which was deduced largely from the study of a limited number of mammalian isoforms, applies broadly to all α-CAs. Where differences in these molecular structures do occur, they have in some cases been found to account for differences in catalytic activity among isoforms. The zinc ion is coordinated in the active site by three histidine residues (His 94, His 96, and His 119), each of which has an associated ligand (Gln 92, Asn 244, and Glu 117) that provides a stabilizing hydrogen bond. This motif is called the zinc-binding site and is conserved across the α-CA gene family except in the CA-related proteins (CA-RPs; see below), which lack catalytic activity. Adjacent to the zinc-binding site is a series of six nonpolar amino acids, the substrate-association pocket. The residues of this motif form a hydrophobic pocket responsible for isolating and guiding the substrate, CO_2, toward the zinc-bound hydroxide ion. Orientation of the zinc-bound hydroxide ion is supported by a third motif, the threonine-199 loop. Finally, the proton-shuttle residue (position 64) facilitates regeneration of the active form of the enzyme by accepting a proton from the zinc-bound water molecule and donating it to solution buffers. High-activity CA isoforms typically exhibit a histidine residue in this location substitution of which is associated with decreased catalytic activity.

CA Isoforms

Our knowledge of the α-CA gene family is most detailed for mammals, where 16 isoforms have been identified. For most of these isoforms, at least partial information on their kinetic properties, susceptibility to inhibitors, tissue distribution, and physiological function is available. Among the mammalian CA isoforms, three groups may be distinguished. The intracellular CAs include five cytosolic isoforms (I, II, III, VII, and XIII) as well as the two CA V homologs found in mitochondria. The extracellular CAs include five membrane-associated isoforms (IV, IX, XII, XIV, and XV) as well as the only isoform that is secreted, CA VI. The membrane-associated isoforms may be further subdivided into those anchored to the plasma membrane by a glycosylphosphatidylinositol (GPI) linkage (IV and XV), and those expressed as single-pass transmembrane proteins (IX, XII, and XIV). The final group includes three isoforms (VIII, X, and XI) that lack catalytic activity and are termed CA-RPs.

The mammalian CA complement provides a framework within which fish CA isoforms may be considered (**Figure 3**). Although fish orthologs of many of the mammalian CA isoforms have been discovered through homology-based cloning approaches and/or mining of genomic databases, our knowledge of many of these isoforms is limited to their molecular sequence. Much work remains to characterize the kinetic properties, inhibitor sensitivity, and tissue distribution of these isoforms, as well as to determine their physiological function(s). Moreover, research effort to date has focused on a handful of fish species yet fish as a group show tremendous diversity. Describing and understanding patterns of

CA sequences were individually aligned against human CA I (GenBank accession AAH27890) to identify the residues of the active site pocket; amino acid residues have been grouped according to molecular motif (see text). Within the zinc-binding site, residues marked Z are those that coordinate the zinc ion. Cytosolic CA isoforms are presented in the top group, with membrane-bound CA isoforms below. Among the cytosolic isoforms: CA II, CA III, and CA XIII represent consensus sequences among human, mouse, and rat sequences for these isoforms; human CA VII (AAL78167) was used; lamprey (*Petromyzon marinus*), dogfish (*Squalus acanthias*), and gar (*Lepisosteus osseus*) represent CA sequences cloned from lamprey (AAZ83742), dogfish or gar (AAM94169) blood; and two cytosolic isoforms, blood specific and general cytosolic, are presented for each of the teleost species, rainbow trout (*Oncorhynchus mykiss*, respectively AAP73748 and AAR99329) and zebrafish (*Danio rerio*, respectively NP_571185 and NP_954685). Among the membrane-bound isoforms: human CA IV (NM_000717), CA IX (NM_001216), CA XII (BC001012), and CA XIV (012113) and mouse CA VX (AF231113) are included as mammalian representatives; CA IV isoforms from dogfish (Df; AAZ03744), rainbow trout (AAR99330), and zebrafish (zfish; AAH78387) are included as fish representatives. The numbers present in the column head are residue numbers.

inter-specific diversity in CA isoforms as well as the properties and physiological functions of these isoforms represent an additional challenge.

As in mammals, fish CA isoforms belong to the α-CA gene family and fall into three distinct groups. CA-RPs have been identified that correspond to mammalian CA VIII and X (two forms) but not XI. Within the extracellular isoform grouping, fish orthologs corresponding to the secreted form, CA VI, and the transmembrane CAs IX, XII, and XIV have been identified. Among the GPI-linked membrane-associated isoforms, however, the picture that is emerging for fish is more complex than that

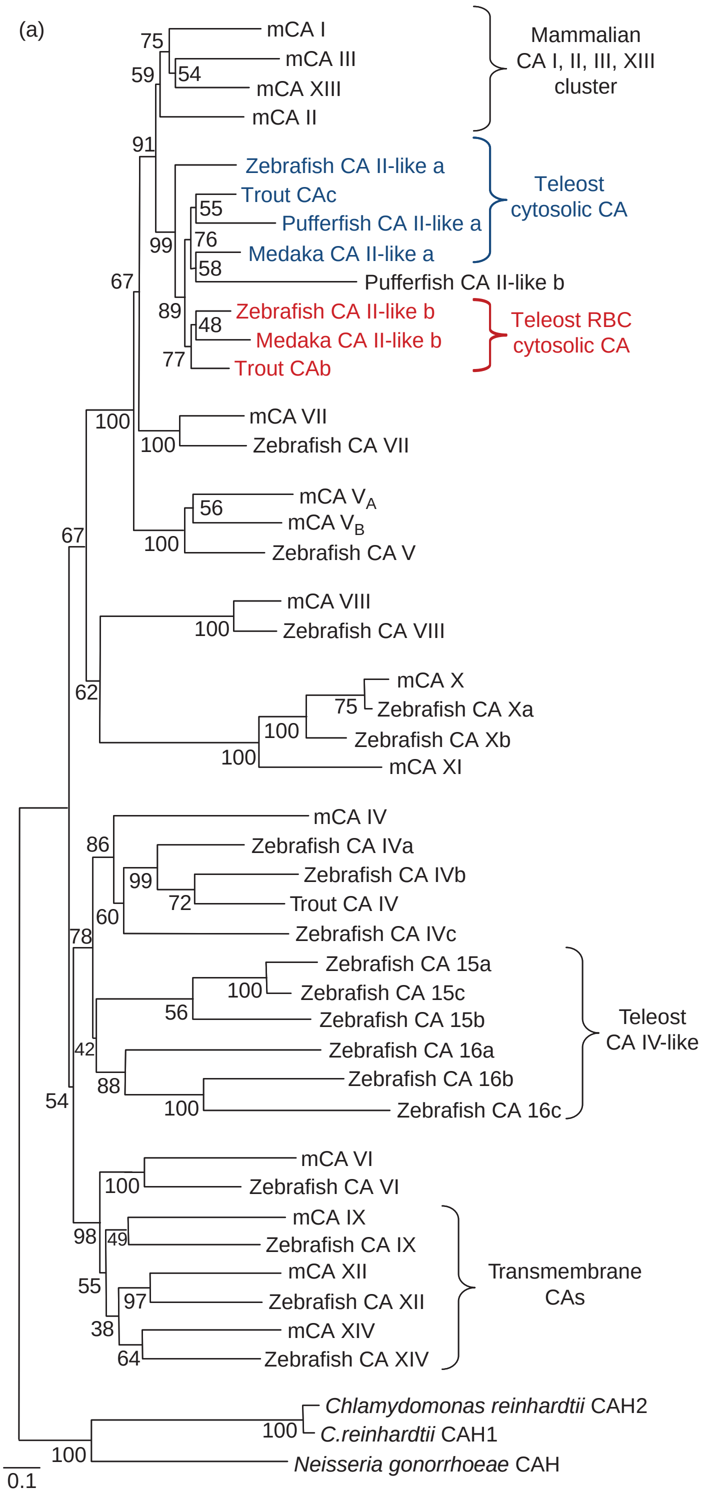

Figure 3 (*Continued*)

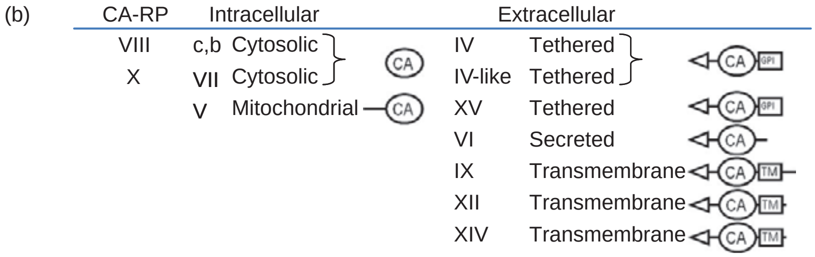

Figure 3 (a) A summary of the phylogenetic relationships among mammalian (mouse, m) and fish (medaka *Oryzia latipes*, pufferfish *Tetraodon nigroviridis*, rainbow trout *Oncorhynchus mykiss*, and zebrafish *Danio rerio*) CA isoforms. (b) A summary of the CA isoforms found in fish illustrating in addition the presumed domain structure of each isoform, where TM indicates transmembrane domain and GPI indicates a glycosylphosphatidylinostiol anchor. (a) Modified from consensus tree created by Lin T-Y, Liao B-K, Horng J-L, *et al*. (2008) Carbonic anhydrase 2-like a and 15a are involved in acid–base regulation and Na^+ uptake in zebrafish H^+-ATPase-rich cells. *American Journal of Physiology* 294: C1250–C1260.

in mammals. In addition to CA IV, at least some fish species possess two CA IV-like isoforms, with all of these isoforms showing three variants, for a total of nine CA IV-like isoforms. A CA XV-like isoform has been identified in another fish species. More information is needed to develop an understanding of the physiological significance of this CA IV diversity in fish.

The intracellular isoform grouping is also a point of significant divergence between fish and mammals. Like mammals, fish possess both the mitochondrial CA V (although possibly only one rather than the two forms found in mammals) and CA VII, the cytosolic CA that is thought to be basal to the remaining cytosolic isoforms. Whereas the CA I, II, III, and XIII gene cluster then arose in mammals, with CA II as the workhorse in both CO_2 excretion and acid–base regulation, fish appear to possess either one (e.g., lamprey, *Petromyzon marinus*) or two (e.g., teleost fish) cytosolic CAs. The emergence of two cytosolic CAs in teleost fish reflects a whole genome duplication of the teleost common ancestor that subsequently gave rise to two closely related cytosolic CA isoforms that appear, based on the limited data available, to differ in tissue distribution, kinetic properties, and physiological function. One isoform is expressed predominantly in RBCs and exhibits a higher catalytic efficiency than the second form, which is more widely distributed but shows little RBC expression. These differences suggest that the higher-activity RBC isoform has been tailored to favor CO_2 excretion while the slower isoform, which shows moderate to high expression in kidney and gill, respectively, contributes to acid–base and ionic regulation.

Methodological Approaches for Discerning CA Function

The existence of numerous CA isoforms and the (presumed) differences among these isoforms in kinetic properties, subcellular localization, and tissue distribution reflect the varied physiological functions of CA. Within fish, however, our knowledge of the distribution, kinetic properties, and physiological functions of specific CA isoforms is limited. With the availability of sequence information, it is possible to examine the tissue distribution of CA messenger ribonucleic acid (mRNA) expression, but the localization of CA protein is made challenging by the scarcity of fish CA isoform-specific antibodies. The kinetic properties of CA isoforms can be determined by assessing the dependence of CA activity on substrate concentration; a similar approach can be adopted to evaluate sensitivity to different CA inhibitors.

The most widely used technique for assaying CA activity is the electrometric ΔpH approach, which involves measuring changes in pH in response to the addition of CO_2 to a buffer containing the CA source of interest. The rate of change of pH in the presence of the CA source represents the rate of the catalyzed reaction because one proton is produced for each molecule of CO_2 that is hydrated. Isolation of subcellular fractions by differential centrifugation followed by assays of CA activity can yield information on what CA isoform(s) is present. For example, CA activity that persists when membrane fractions are isolated and washed (to remove any cytosolic CA that may have loosely associated with membranes during isolation) is likely due to a membrane-linked CA isoform. If the CA activity is resistant to denaturation by the detergent sodium dodecylsulfate (SDS), then this deduction is strengthened because membrane-associated CA isoforms typically are more stabilized by intramolecular disulfide linkages than are cytosolic CAs. Finally, phosphatidylinositol-specific phospholipase C (PI-PLC) can be used to cleave a GPI linkage, releasing GPI-linked CA from its membrane association and allowing GPI-linked membrane-associated CA to be distinguished from transmembrane isoforms.

These types of approaches have been used in combination with *in vivo* work or tissue preparations to elucidate the function of CA in different physiological systems.

A standard approach is to assess physiological function before and after selective inhibition of the CA isoform thought to be involved. The two main classes of CA inhibitors are metal-complexing anions and sulfonamides, both of which exert their effects by binding to the zinc ion of the enzyme, preventing it from playing its essential role in the catalytic mechanism. Consequently, developing CA inhibitors that are selective for a particular isoform has proved to be challenging. One successful approach has involved manipulating the size or charge of the inhibitor to limit its ability to cross plasma membranes, thereby conferring the ability to distinguish between intra- and extracellular isoforms. For example, whereas the sulfonamide inhibitor aminobenzolamide rapidly crosses membranes and therefore inhibits both intra- and extracellular CA isoforms, a polymerized form, polyoxyethylene-aminobenzolamide (F3500), is restricted to the extracellular environment by virtue of its large size (molecular weight ~3500 Da).

Physiological Functions of CA in Gas Transport and Exchange

Creative use of the tools described above – sequence information, localization of gene expression, protein or activity, assessment of kinetic properties and/or inhibitor sensitivities, and application of inhibitors *in vivo* or in reduced preparations – has enabled the role of CA isoforms to be identified for a variety of physiological processes. Particular effort has been focused on addressing the roles of CA isoforms in gas exchange, acid–base balance, and ion transport – physiological processes that are inextricably linked in fish.

CA plays an essential role in CO_2 excretion (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion and Red Blood Cell Function). In the RBC, cytosolic CA (the blood-specific isoform in teleost fish) catalyzes the hydration reaction to facilitate loading of CO_2 into the blood at the tissues. Effective removal of CO_2 from the blood during its brief residence in the gills is made possible by CA-catalyzed HCO_3^- dehydration to molecular CO_2 (**Figure 1**). Inhibition of RBC CA by acetazolamide impairs CO_2 excretion, raising blood CO_2 tension and causing a respiratory acidosis (**Figure 2**). In elasmobranch fish, a second CA isoform also contributes to CO_2 excretion. CA IV is anchored to the plasma membrane of gill pillar cells (**Figure 4**; **see also Design and Physiology of Arteries and Veins**: Branchial Anatomy) where it catalyzes the dehydration of HCO_3^- to molecular CO_2 within the plasma, thereby providing an alternative pathway to the RBC for HCO_3^- dehydration (**Figure 4**). By providing protons for plasma HCO_3^- dehydration, the relatively high plasma-buffering capacity of elasmobranch fish is important in allowing this pathway to contribute to CO_2 excretion. Evidence supporting this dual pathway for CO_2 excretion in elasmobranch fish comes from the selective inhibition of extracellular CA using F3500 or low concentrations of the slowly permeating sulfonamide benzolamide, which raises blood CO_2 tension and lowers pH in elasmobranch but not teleost fish (**Figures 2** and **4**); teleost fish lack branchial CA IV.

CA also contributes to acid–base balance and ion transport in fish. Active salt uptake at the gill in freshwater fish is necessary to offset salt loss by diffusion to the dilute external environment. Branchial cytosolic CA (the general cytosolic isoform in teleost fish) catalyzes the intracellular hydration of CO_2 to provide the H^+ and HCO_3^- used as counterions for the active uptake of, respectively, Na^+ and Cl^- ions (**Figures 1** and **4**; **see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes); Na^+ and Cl^- uptake are reduced when branchial cytosolic CA is inhibited using permeant sulfonamides such as acetazolamide. Compensation of acid–base disturbances is achieved through manipulation of these same exchanges. That is, H^+ and HCO_3^- effluxes (which are of course linked to Na^+ and Cl^- influxes, respectively) are differentially modified so as to adjust plasma HCO_3^- levels, thereby correcting pH. The role of CA in such acid–base compensation has been confirmed by demonstrations of reduced acid–base equivalent excretion following CA inhibition.

In freshwater fish the kidney contributes to both ionic and acid–base regulation by reabsorption of salt and HCO_3^-, respectively, from the filtrate (**see also Role of the Kidneys**: The Kidney). Again, CA is involved (**Figure 5**). Reabsorption of HCO_3^- from the filtrate relies on both membrane-associated and cytosolic CA isoforms. Filtered HCO_3^- ions are dehydrated to CO_2 in the presence of luminal membrane-associated CA; CA IV is present but other membrane-linked CA isoforms may also be involved. Molecular CO_2 diffuses into the cell where it is hydrated, a reaction catalyzed by cytosolic CA (the general cytosolic isoform in teleost fish), resulting in HCO_3^- that is exported across the basolateral membrane to the blood, and H^+ that is recycled across the apical membrane into the lumen to participate in HCO_3^- dehydration. This process results in the net translocation of HCO_3^- from lumen to blood, and is adjusted according to the requirements of the fish for acid–base regulation. Inhibition of either cytosolic CA (using acetazolamide) or luminal extracellular CA (using F3500) impairs HCO_3^- reabsorption.

Marine teleost fish actively excrete salt across the gill while drinking seawater to offset diffusional salt gain and osmotic water loss driven by their hyperosmotic environment (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction).

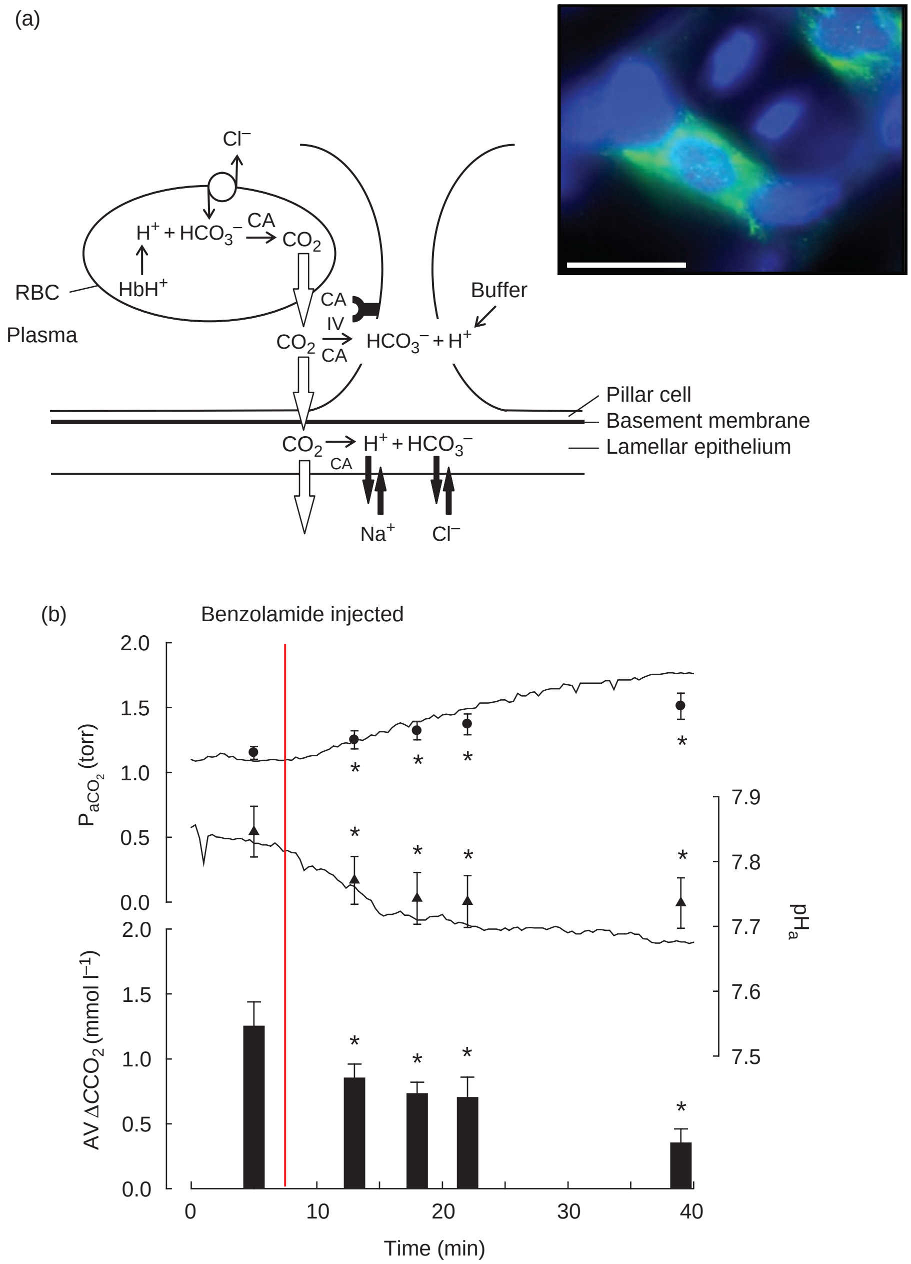

Figure 4 (a) A schematic depicting the roles of red blood cell (RBC) carbonic anhydrase (CA) and pillar cell CA IV in CO_2 excretion in an elasmobranch fish. The possible contribution of gill epithelium CA to acid–base balance is also illustrated. This model of CO_2 excretion in an elasmobranch fish differs from the teleost model in allowing for substantial HCO_3^- dehydration in the plasma catalyzed by pillar cell CA IV. The inset micrograph presents a representative light micrograph in which immunohistochemistry has been used to localize dogfish CA IV (green immunofluorescence); nuclei were visualized using 4′,6′-diamidino-2-phenylindole. Scale = 5 μm. (b) The contribution of extracellular CA to CO_2 excretion in dogfish (*Squalus acanthias*) is demonstrated by injecting benzolamide to selectively inhibit extracellular CA, which results in a significant impairment of HCO_3^- removal from the blood at the gills (ΔC_{CO_2}; calculated as arterial–venous differences in blood HCO_3^-) leading to a significant rise in the arterial partial pressure of CO_2 (P_{aCO_2}) and a concomitant fall in arterial pH (pH_a), unlike the situation for a teleost fish as depicted in **Figure 2**. The symbols represent mean data for five to seven fish while the lines are representative recordings from a single fish. An asterisk indicates a significant difference from the value prior to benzolamide injection. (a) Modified from Gilmour KM and Perry SF (2010) Gas transfer in dogfish: A unique model of CO_2 excretion. *Comparative Biochemistry and Physiology A* 155: 476–485. (b) Modified from Gilmour KM, Perry SF, Bernier NJ, Henry RP, and Wood CM (2001) Extracellular carbonic anhydrase in dogfish, *Squalus acanthias*: A role in CO_2 excretion. *Physiological and Biochemical Zoology* 74: 477–492.

Water absorption across the intestinal epithelium relies in part on base excretion into the intestinal lumen, a process that involves at least two CA isoforms (**Figure 6**). Cytosolic CA (the general cytosolic isoform) catalyzes the hydration of CO_2 to provide HCO_3^- ions that are exported across the apical membrane in exchange for Cl^-.

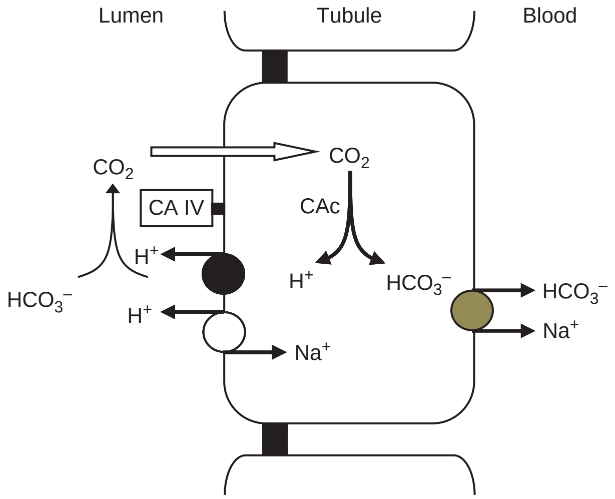

Figure 5 A schematic representation of the contribution of CA to HCO_3^- reabsorption by the teleost kidney proximal tubule. Luminal CA IV (and/or other membrane-bound isoforms) catalyzes the dehydration of filtered HCO_3^- by H^+ provided by Na^+/H^+ exchange and/or H^+-ATPase. The CO_2 so formed diffuses into the cytosol and is hydrated in the presence of cytoplasmic CAc, with HCO_3^- exiting basolaterally via a Na^+/HCO_3^- co-transporter and H^+ being recycled across the apical membrane. Modified from Gilmour KM and Perry SF (2009) Carbonic anhydrase and acid–base regulation in fish. *Journal of Experimental Biology* 212: 1647–1661.

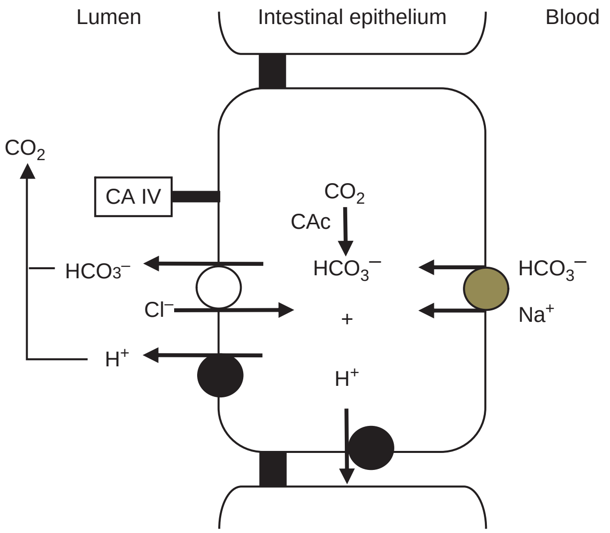

Figure 6 A schematic representation of the contribution of CA to HCO_3^- secretion by the marine teleost anterior intestine. Cytosolic CA (CAc) catalyzes the hydration of CO_2 to HCO_3^-, which fuels the apical anion exchanger driving HCO_3^- secretion into the intestinal lumen. Protons may exit the cell either apically or basolaterally via H^+-ATPase. In the lumen, CA IV (and/or other membrane-bound isoforms) catalyzes the dehydration of secreted HCO_3^-, a process that helps to maintain the gradient for HCO_3^- secretion into the lumen. Modified from Grosell M, Genz J, Taylor JR, Perry SF, and Gilmour KM (2009) The involvement of H^+-ATPase and carbonic anhydrase in intestinal HCO_3^- secretion in seawater-acclimated rainbow trout. *Journal of Experimental Biology* 212: 1940–1948.

In the lumen of the intestine, at least some HCO_3^- ions are dehydrated to CO_2 in a reaction catalyzed by CA IV and possibly other membrane-associated CA isoforms. The inhibition of either extracellular CA (using F3500) or both isoforms (using permeant sulfonamide inhibitors) reduces intestinal base excretion, attesting to the importance of CA in this process (**see also Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation).

Summary and Conclusions

Fish express a diversity of CA isoforms that contribute to gas exchange, acid–base balance, and ion transport, as well as many other physiological processes. Our knowledge of the diversity, distribution, function, and regulation of these CA isoforms is increasing and will continue to improve as better tools, including selective CA inhibitors and fish species- and isoform-specific CA antibodies, become available.

Glossary

Arterial Pertaining to blood that has been oxygenated.

Band-III protein anion exchanger The major membrane protein of most erythrocytes. With its help, the half-time of chloride equilibration between erythrocytes and plasma is decreased from a couple of hours to seconds in fish.

Bohr effect Effect of the proton concentration (pH) on the oxygen affinity of hemoglobin.

Carbamino compounds These are formed when carbon dioxide reacts with $-NH_2$ groups on proteins – particularly hemoglobin – to form carbamino compounds ($-NHCOO^-$).

Carbonic anhydrase A zinc metalloenzyme that reversibly catalyzes the reaction between CO_2 and H_2O to form H^+ and HCO_3^-.

Chloride shift The exchange of HCO_3^- and Cl^- ions across the red-blood-cell (RBC) membrane to maintain charge balance within the cell.

Equilibrium Pertaining to the situation when all forces acting are balanced by others, resulting in a stable unchanging system.

4-Acetamido-4′-isothiocyano-2,2′-disulfonic stilbene (SITS) A disulfonic stilbene derivative that inhibits most RBC band III proteins.

Haldane effect Proton binding to hemoglobin (as a function of oxygenation).

Jacob–Stewart cycle The cycling of CO_2 and bicarbonate across the RBC system, resulting in the transfer of acid between the plasma and the cell interior.

Na^+/H^+exchanger The protein involved in the transfer of sodium in exchange for a proton across a cell membrane.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

RBC sodium/proton exchanger An ion-transport pathway unique for teleost erythrocytes that plays a role in the control of red cell pH.

Rete mirabile (or simply *rete*, plural *retia mirabilia*) – Structure consisting of blood vessels arranged to facilitate the exchange of heat or oxygen.

Root effect Property of hemoglobins in some fishes such that, in the presence of acid, it is impossible for hemoglobin molecules to be completely saturated with oxygen, even at extremely high oxygen partial pressures.

Swimbladder A gas-filled bladder found in most but not all teleost fish.

Venous Pertaining to blood that has passed through tissues having had some oxygen removed for metabolism in fish.

Introduction

Fish take up oxygen and metabolize substrates, producing carbon dioxide, ammonia, and water. Carbon dioxide and especially ammonia are toxic and cannot be allowed to accumulate in the body, and any excess must be excreted. An increase in CO_2 acidifies body fluids. Elevated CO_2 levels inhibit growth and high levels cause narcosis, probably because of disturbances to the acid–base balance. Carbon dioxide reacts with water to form carbonic acid (H_2CO_3), a weak acid that dissociates into bicarbonate (HCO_3^-) and carbonate ions (CO_3^{2-}). Carbon dioxide also reacts directly with hydroxyl ions (OH^-) to form bicarbonate. The proportion of CO_2, H_2CO_3, HCO_3^-, and CO_3^{2-} in solution depends on the pH, temperature, and the ionic strength of the solution. In fish blood at normal pH the ratio of CO_2 to carbonic acid is approximately 1000:1, and the ratio of CO_2 to bicarbonate ions is about 1:20. Bicarbonate is, therefore, the predominant form of CO_2 in fish blood. The carbonate content may approach 5% of the total CO_2 content of the blood, especially at low temperatures. As partial pressure of carbon dioxide (PCO_2) or pH increases, the major change is an increase in the bicarbonate content of the blood. The pH of red blood cells (RBCs) is less than that of plasma, but because PCO_2 is in equilibrium across the cell membrane, bicarbonate levels are lower in erythrocytes than in plasma. In addition, plasma volume is usually greater than erythrocyte volume; thus, it follows that most of the bicarbonate in the blood is in plasma.

In addition to forming bicarbonate ions, carbon dioxide also reacts with $-NH_2$ groups on proteins – particularly hemoglobin – to form carbamino compounds ($-NHCOO^-$). Carbamino groups are more likely to form when hemoglobin is oxygenated. The extent of carbamino formation increases with the concentration of CO_2 and the number of terminal $-NH_2$ groups available. The terminal $-NH_2$ group of the α-chain of teleost fish hemoglobins, however, is acetylated, blocking the formation of carbamino groups. In addition, organophosphates bind at the same terminal $-NH_2$ group of the β-chain that forms carbamino groups, so organophosphate binding reduces carbamino formation. High pH reduces organophosphate binding and so augments carbamino formation by making more $-NH_2$ groups available. Because fish erythrocytes often have high organophosphate levels as well as acetylated α-chains, teleost fish rely less on carbamino formation for CO_2 transport than mammals. The hemoglobin α-chains of elasmobranchs are not acetylated, and therefore they have more carbamino CO_2 compared with teleosts.

The sum of all forms of CO_2 in the blood – that is, molecular CO_2, H_2CO_3, HCO_3^-, CO_3^{2-} and carbamino compounds – is referred to as the total CO_2 content of the blood. The total CO_2 content varies with PCO_2 and the relationship can be described graphically in the form of a CO_2 dissociation curve.

Most cell membranes are permeable to CO_2 and NH_3 but relatively impermeable to HCO_3^- and NH_4^+ ions. Blood pH in fish and other vertebrates is midway between the negative logarithm of the dissociation constants (pK's) of the carbon dioxide–bicarbonate and ammonia–ammonium reactions. A body pH that is midway between these pK's ensures adequate rates of excretion by diffusion of both CO_2 and NH_3. Because these pK's vary with temperature, so does the normal pH of blood. Plasma pH falls from about 7.9 to 7.6 as temperature increases from 5 to 30 °C, ensuring adequate rates of excretion of both CO_2 and NH_3 over a range of temperatures.

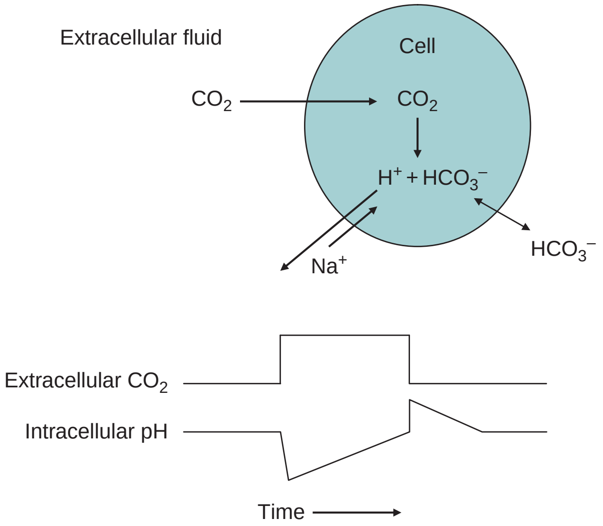

Figure 1 Following an increase, extracellular CO_2 will diffuse into and rapidly acidify cells. A reduction in extracellular CO_2 will have the opposite effect. Proton and bicarbonate excretion will gradually return the cellular pH to normal.

Transfer of Gases to and from the Blood

Carbon dioxide diffuses from the tissues into the blood, is transported in the blood, and diffuses across the gill surface into the environment. In most cases, membranes are much more permeable to CO_2 than to HCO_3^- and to CO_3^{2-}; thus, most of the transfer is as dissolved, gaseous CO_2. The movement of CO_2 will acidify the compartment into which it moves and alkalinize the compartment it leaves (**Figure 1**). In the tissues, CO_2 enters the blood and either is hydrated to form HCO_3^- or reacts with $-NH_2$ groups of hemoglobin and other proteins to form carbamino compounds. The reverse process occurs when CO_2 is unloaded from the blood at the respiratory surface. The greatest change is in the HCO_3^- concentration; changes in the levels of CO_2 and carbamino compounds usually represent less than 20% of total carbon dioxide excretion.

The uncatalyzed CO_2/HCO_3^- hydration/dehydration reactions are slow, requiring several seconds or even minutes at low temperatures. Such reaction rates are relatively slow compared with the time that blood within capillaries spends in contact with the tissue. However, in the presence of the enzyme carbonic anhydrase (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbonic Anhydrase in Gas Transport and Exchange), this reaction approaches equilibrium in much less than a second. Carbonic anhydrase also facilitates carbon dioxide transfer, referred to as facilitated diffusion of CO_2 which results from the simultaneous diffusion through the epithelium of bicarbonate and protons, the latter also augmented by release from buffers. Because carbonic anhydrase is present in RBCs of teleost fish but not in the plasma, most CO_2 hydration/dehydration occurs in the erythrocytes. In addition, the oxygenation of hemoglobin releases H^+'s, further increasing CO_2 production from bicarbonate in the RBC; conversely, deoxygenation results in the binding of H^+'s to hemoglobin, increasing bicarbonate levels, reducing the change in PCO_2 and pH as CO_2 enters the blood; this phenomenon is termed the Haldane effect (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect and Red Blood Cell

Function). Many fish hemoglobins show a large Haldane effect.

On entering the blood from the tissues, CO_2 diffuses into RBCs (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function), where HCO_3^- is formed rapidly in the presence of carbonic anhydrase (**Figure 2**). As the HCO_3^- levels within erythrocytes rise, HCO_3^- ions move into the plasma across the RBC membrane. Charge balance within the cell is maintained by anion exchange; as HCO_3^- ions leave the RBCs, there is a net influx of Cl^- ions from the plasma into the cells, a process called the 'chloride shift'. Teleost and elasmobranch RBCs, unlike many other cells, are very permeable to both Cl^- and HCO_3^- because their membranes have a high concentration of an anion carrier, band-III protein, which binds Cl^- and HCO_3^- and transfers them in opposite directions across the membrane. This anion exchange is passive and depends on concentration gradients to drive the process, which can occur in either direction, so bicarbonate can flow out of the erythrocyte in the tissues and into the erythrocyte at the respiratory surface. The fish RBC anion exchangers have a similar molecular size and drug sensitivity similar to that described for mammals; however, they operate at higher rates and are less temperature sensitive than human band III, as would be expected for fish living in changing temperatures where operating temperatures are usually much colder than that of mammalian RBCs. Band-III anion exchanger in carp (*Cyprinus carpio*) RBCs, however, appears to be insensitive to disulfonic stilbene derivatives such as 4-acetamido-4′-isothiocyano-2,2-disulfonic stilbene (SITS), whereas all other teleost band-III proteins investigated are inhibited by SITS. The band-III proteins also vary between fish showing differences in rates of anion exchange. Operation of the anion exchange may be pH and hemoglobin-oxygenation sensitive, but this is not certain.

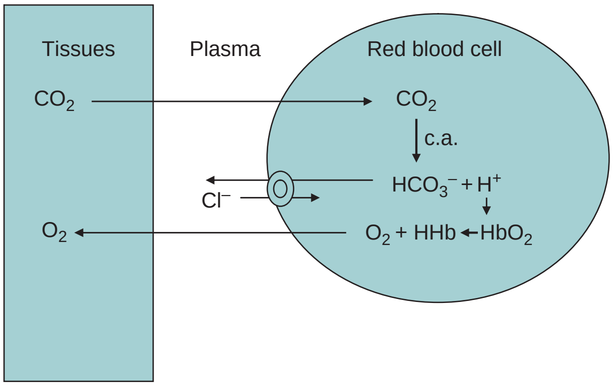

Figure 2 CO_2 diffuses into the red blood cell (RBC) and, in the presence of carbonic anhydrase (c.a.), rapidly acidifies the RBC. Bicarbonate is exchanged for chloride via band-III protein in the RBC membrane. Protons bind to hemoglobin and enhance the release of oxygen.

Excretion of CO_2 in teleost fish is limited by the rate of bicarbonate–chloride exchange across the erythrocyte membrane. The surface-to-volume ratio of erythrocytes, as well as their capacity for bicarbonate–chloride exchange mediated by band-III protein, will be important in determining the rates of carbon dioxide excretion. RBCs from rainbow trout (*Oncorhynchus mykiss*) are larger than RBCs from humans and have a much higher concentration of band-III protein in their membranes, which presumably compensates for the increased cellular volume and offsets, at least to some degree, the effects of a lower body temperature on anion-exchange rates. Even so, anion exchange is slower across trout RBCs at 15 °C than across human RBCs at 38 °C. However, transit times for erythrocytes through the gills are longer than those in the lungs, allowing more time for anion exchange across the RBC. Anion exchange rates are faster in turbot (*Scophthalmus maximus*) and Atlantic cod (*Gadus morhua*) than in rainbow trout and in European eels (*Anguilla anguilla*), which have similar, slower rates of exchange. However, hematocrit and blood-transit time through the gills also vary. Because all these fish are extant, one can presume that these features are to some extent correlated; it is probable that the rapid rates of anion exchange across RBC membranes are coupled to fast gill-blood-flow transit times. Despite these considerations, it is still not clear why different species have evolved RBCs of such different sizes. Those animals with large RBCs also have large cells generally. Thus, cell size may have been selected for reasons other than for efficient gas transfer and may be unrelated to gas-transfer rates. For instance, triploid salmon (*Oncorhynchus tshawytscha*) have RBCs 1.5 times the size of those of their diploid cousins (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Physiology of Triploid Fish) but have the same hemoglobin concentration and swim just as fast, indicating that their efficiency of gas transfer is comparable even though RBC size is different. Large blood cells may not mean longer diffusion distances because the cells are flat and may present their flat surface to the gill endothelium.

Cyclostome erythrocytes lack band-III protein. In these animals, bicarbonate stays within the RBCs, and there is no anion transfer between the erythrocyte and the plasma with changes in $[CO_2]$. In lampreys, like teleosts, there is no carbonic anhydrase activity in the plasma or on the gill endothelium. Carbonic anhydrase is in the RBC, and bicarbonate dehydration in the RBC accounts for about 80% of CO_2 excretion. Lamprey blood has a large Haldane effect and the protons produced by hemoglobin oxygenation promote bicarbonate deydration. The RBCs have a Na^+/H^+ exchanger and proton excretion from the RBC may enhance bicarbonate formation in the tissues. The lamprey Na^+/H^+

exchanger, however, is catecholamine insensitive. Hagfishes also appear to lack physiological levels of band-III protein, but they have a smaller Haldane effect and no RBC Na^+/H^+ exchange. Thus, there is a smaller bicarbonate change in each hagfish RBC flowing through the gills compared with that of lampreys. Some hagfish species (e.g., *Eptatretus*) have a larger Haldane effect and so may have increased bicarbonate excretion from each RBC. It appears that the pattern of CO_2 excretion is similar in lampreys and hagfish, but much less is known about the situation in hagfish. For example, it is not known if there is carbonic anhydrase activity available to plasma on the gill endothelium.

In teleost fishes, such as the trout, the plasma perfusing the gills is not exposed to carbonic anhydrase. In these animals, almost all excretion of CO_2 occurs through the RBCs and is tightly coupled to O_2 uptake through proton production by oxygenation of hemoglobin (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange). Interestingly, many teleost hemoglobins have a relatively low buffering capacity because of a reduced number of the histidine side chains that normally are involved in buffering (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect). This means that protons released during oxygenation are available for bicarbonate dehydration, facilitating the tight coupling of oxygen and carbon dioxide transfer within the RBCs. This tight coupling also ameliorates the oscillations in blood pH during CO_2 transfer. The proton pump in the apical membrane of the gills of freshwater fishes excretes acid and develops an electrochemical gradient that brings sodium into the gill epithelium. The activity of the proton pump is pH dependent, and oscillations in blood pH could have a marked effect on the pump if they were rapidly transferred into the gill epithelium. Thus, the structure of the hemoglobin molecule is finely tuned not only to the animal's requirements for oxygen and carbon dioxide transfer, but also for ion transfer across the respiratory epithelium and pH regulation. On the other hand, elasmobranchs, such as dogfish (*Squalus acanthias*), have lower levels of erythrocytic carbonic anhydrase than do trout and have only a loose coupling between oxygen and carbon dioxide flux in the RBCs. These fishes have significant levels of carbonic-anhydrase activity in the blood plasma as well as a broad distribution in the gill epithelium, facilitating carbon dioxide excretion from plasma directly across the gill epithelium.

Regulation of RBC pH

In most vertebrate RBCs, unlike most other cells, hydrogen ions are passively distributed across the membrane, and the membrane potential maintains a lower pH inside the RBC than in the blood plasma (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function). A sudden addition of acid to the plasma (e.g., following anaerobic production of H^+'s) results in a fall in erythrocyte pH. The acid is transferred from the plasma to the interior of the erythrocyte not by diffusion of H^+, but by bicarbonate–chloride exchange. The addition of H^+'s to the plasma causes the PCO_2 to increase as HCO_3^- is converted to CO_2, which then diffuses into the RBC and is converted to HCO_3^-, thereby reducing intracellular pH. Bicarbonate then diffuses out of the cell via the chloride–bicarbonate exchange mechanism. Thus, in erythrocytes, the CO_2/bicarbonate system operates to transfer acid from the plasma to the cell interior, sometimes referred to as the Jacob–Stewart cycle.

Cells become acidotic during hypoxia and following burst-swimming activity. This proton production causes a drop in plasma pH, which can be very large in fish because nearly two-thirds of their bodies are made up of white muscle fibers all of which can be activated during burst swimming. If this pH drop was transferred to the RBC, oxygen and CO_2 transfer would be seriously impaired in teleost fish, especially those with a large Root-shift hemoglobin (where a reduction in blood pH reduces blood-oxygen-carrying capacity; **see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems). Many teleosts, however, have a Na^+/H^+ exchange mechanism in the RBC membrane to regulate RBC pH, preventing a Root-off shift and maintaining hemoglobin oxygenation in the face of a plasma acidosis (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function). Proton excretion is coupled to sodium uptake and is stimulated in oxygenated blood and by increased circulating catecholamine levels. Thus, teleost RBC Na^+/H^+ exchange is augmented during hypoxia, violent activity, and stress by an increase in blood catecholamine levels. The subsequent increase in RBC pH results in an increase in RBC bicarbonate, which moves out into the plasma in exchange for chloride. Thus, the net effect of Na^+/H^+ activation is an increase in RBC pH and NaCl content, the latter causing water to enter and the cell to swell (**Figure 3**).

Bicarbonate levels are high in plasma leaving the gills because RBC-anion exchange is the rate-limiting process in CO_2 excretion. Plasma-bicarbonate dehydration in the gills and in arteries is uncatalyzed in teleost fish. Slow uncatalyzed plasma-bicarbonate dehydration continues to form CO_2 as the blood flows away from the gills, resulting in a gradual rise in plasma pH. The formation of CO_2 in plasma and its subsequent entry into the RBC cause a fall in red cell pH. This in turn causes a rise in partial pressure of oxygen (PO_2) via the Root-off shift as blood flows from

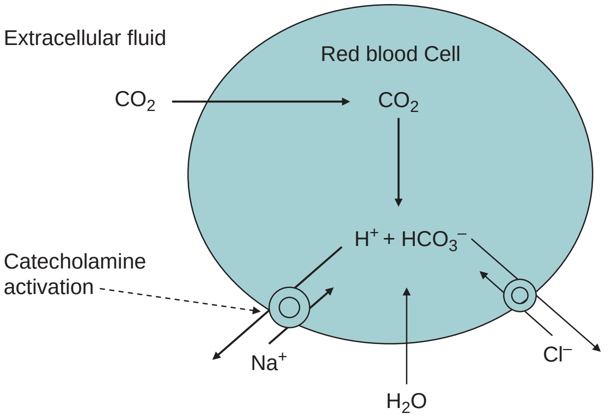

Figure 3 Catecholamines activate proton excretion coupled to sodium uptake in many teleost red blood cells. The increase in pH causes an increase in bicarbonate and the stimulation of chloride–bicarbonate exchange. The result is an uptake of NaCl and water, causing the RBC to swell.

the gills to the tissues. The transit time for blood flow to the tissues must be of the order of a few seconds, sufficient for the CO_2/bicarbonate system to approach equilibrium. Such an increase in PO_2 would augment oxygen delivery to the tissues. Activation of RBC Na^+/H^+ exchange reduces plasma pH which further enhances the magnitude of the disequilibrium in the bicarbonate dehydration reaction in plasma flowing away from the gills (**Figure 4**). Arterial blood flowing to a region where there is carbonic anhydrase imbedded in the capillary endothelium would immediately catalyze plasma bicarbonate dehydration and cause a rapid rise in CO_2. CO_2 will diffuse into the RBC and lower pH, generating a Root-off shift which will further enhance tissue oxygenation (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange).

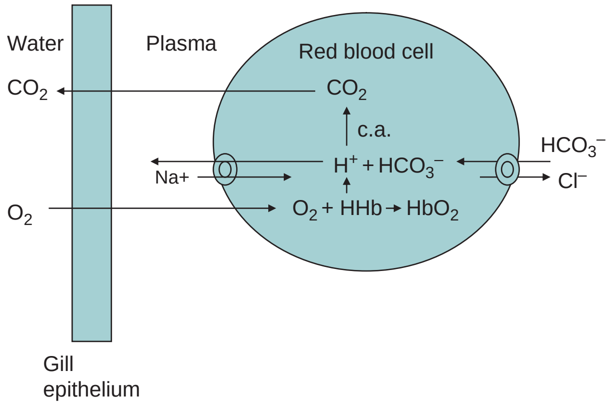

Figure 4 CO_2 diffuses into the water and bicarbonate is removed from the RBC more rapidly than it can enter. Na^+/H^+ exchange removes protons produced by hemoglobin oxygenation, creating a large plasma bicarbonate dehydration disequilibrium in the absence of carbonic anhydrase (c.a.) in the plasma. As blood flows away from the gills, plasma CO_2 increases raising RBC pH and blood PO_2 via the Root-off shift.

Patterns of Carbon Dioxide Excretion

The pattern of CO_2 excretion is different between elasmobranchs and teleosts. Movements of oxygen and carbon dioxide are closely linked in teleost fish, the coupling occurring in the RBC due to the presence of carbonic anhydrase in the erythrocyte and not in the plasma. Teleosts' hemoglobin has reduced buffering but large Bohr and Root shifts to further enhance this coupling. Elasmobranchs have carbonic anhydrase in both plasma and RBC and, consequently, the coupling of CO_2 and oxygen is much less pronounced, the Root shift is absent, and there is no Na^+/H^+ exchange across the RBC membrane. Hemoglobin buffering is much larger in elasmobranch hemoglobin than that in teleosts. As discussed earlier, lamprey have Na^+/H^+ but no anion exchange in the RBC membrane; hagfish lack both Na^+/H^+ and anion exchange in the RBC membrane. Clearly, the pattern of CO_2 excretion in teleosts varies from that observed in terrestrial vertebrates with the pattern in elasmobranchs being most similar to that of terrestrial vertebrates. The teleost pattern is one in which CO_2 and O_2 transfer are highly coupled and may result in augmented transfer of oxygen into the tissues. This has been clearly shown in the swimbladder and eye of teleosts and may be the case in many other tissues (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange).

Carbon dioxide is involved in gas secretion into the swimbladder (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). The swimbladder is filled with gas in most fish and has several functions including buoyancy (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). If a fish swims deeper, the water pressure increases and the bladder is compressed. The fish must add gas at pressure to maintain buoyancy. Some teleost fish have a bladder without a duct to the gut connecting it to the environment. The only way gas can get into this bladder in these fish is from the blood. The bladder is filled with oxygen at pressures that increase by 1 atm with every 10-m increase in depth; that is, the bladder can be filled with oxygen at many atmospheres pressure, and the oxygen has diffused across the gills into the blood at no more than 0.2 atm and from the blood into the bladder. There are gas glands situated in the bladder wall with a very extensive blood supply from which oxygen can diffuse into the bladder. The arterial blood supply to the gas gland forms a countercurrent exchange with venous blood leaving the gas gland, the arterial and venous vessels consisting of a large number of capillaries forming a so-called rete mirabile (marvelous network). A gas gland produces acid which drives oxygen from the hemoglobin raising PO_2 levels in the gas gland and oxygen diffuses into the bladder. Oxygen can also diffuse from venous blood leaving the gas gland across the rete mirabile into the arterial capillaries. This serves to retain oxygen in the bladder and allows the buildup of very high oxygen levels. Acid produced in the gas gland is transferred into the RBC by CO_2 which is also recycled through the rete. A similar mechanism occurs in the teleost eye, which also has very high oxygen levels in the ocular fluid. It is clear that CO_2 is very much involved in the transfer of oxygen at high pressure into the bladder and the eye of teleost fish (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). It is possible that CO_2 plays a similar role in the delivery of oxygen to many other tissues in teleost fish, for example, muscle, but there is little evidence for or against this mechanism (see above).

There is some bicarbonate excretion across the apical membranes of the gill but this constitutes only a small portion of CO_2 excretion. In addition, not all CO_2 is excreted across the gills. Marine teleosts are more dilute than the surrounding seawater and continually lose water across their body surfaces. They drink seawater to compensate for the water loss but must excrete the ionic load contained in the seawater. Marine fish excrete calcium and magnesium as calcite (calcium carbonate), producing chalk-like white feces. Thus, a component of CO_2 excretion occurs as carbonate across the gut of marine teleosts. The proportion excreted via the gut is probably around 1–5% of total CO_2 excretion by the fish. The associated protons are presumably excreted across the gills. The white fecal pellets sink to depths of the ocean and eventually dissolve at high pressure. Thus, fish acidify the surface layers of the ocean and contribute to carbonates taken to depth. Fish may contribute somewhere between 3% and 15% of marine carbonate production.

The Effect of Temperature and Variations in Environmental CO_2 Levels

In an aquatic fish, body PCO_2 levels are only a few torr (i.e., mmHg) above ambient. This is because of the countercurrent nature of the flows of blood and water at the gills and the absence of any large diffusion distances. Water flow to supply the oxygen requirements of the fish is more than sufficient to keep CO_2 levels in the blood around 2 or 3 torr and excretion is limited by the rate of Cl^-/HCO_3^- exchange across the red-cell membrane. Although increases in CO_2 cause increases in gill ventilation, fish cannot regulate blood CO_2 levels, and therefore blood pH, via changes in ventilation in a manner similar to that in terrestrial vertebrates. Oscillations in water CO_2 are transferred into the fish and pH compensation occurs via changes in bicarbonate, resulting from changes in proton and/or bicarbonate excretion across the gills and/or the kidney; that is, pH regulation in fish is not mediated by changing CO_2 levels via ventilation (**see also Control of Respiration**: The Ventilatory Response to CO_2/H^+) but rather by the excretion of acid or base into the environment.

The aquatic environment is often hypoxic and many fish supplement their oxygen supply by breathing air. Air breathing in fish involves an air-breathing organ (ABO) that is not usually the gills (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction). Gills collapse when air exposed and become nonfunctional, except in a few fish such as *Amia* and mudskippers with more rigid gills. The ABO can be a modified buccal cavity, swimbladder, gut, or skin. Fish predation occurs when they rise to the surface to breathe air, especially by birds. Thus, fish tend to take large infrequent air breaths resulting in large oscillations in blood-oxygen levels. The circulation of the ABO is in series with the gills such that venous blood is pumped first through the gills and then to the ABO. Much of the CO_2 is removed from the blood during passage through the gills, and then oxygen is added from air in the ABO; that is, many air-breathing fish excrete CO_2 into the water via the gills and take up oxygen from the air via an ABO. Many of these fish live in hypoxic waters, and so there are selective pressures to reduce the size of the gills to prevent oxygen loss from the blood as it passes through the gills. A consequence of smaller gills is greater CO_2 retention by the fish, but nevertheless the larger CO_2 gradient across the gills maintains an adequate CO_2 excretion rate. Consequently, air-breathing fish often have higher blood CO_2 levels than completely aquatic fish. Although CO_2 levels can oscillate within a fish and vary among fish, pH is adjusted to a similar value in all fish by adjustment of bicarbonate.

Temperature can have a marked effect on body pH despite blood pH regulation at a given temperature. Fish increase plasma pH with a decrease in temperature (e.g., at 5 °C they have a plasma pH of 7.9–8.0). Adequate excretion rates of both CO_2 and NH_3 can be maintained when blood pH is regulated. Tissues are generally less alkaline than plasma. For example, the intracellular pH of erythrocytes is about 0.5 pH units less than the pH of plasma, and the intracellular pH of muscle cells is about 7.0, but all tissues increase pH with decreasing temperature. Temperature has a marked effect on the p*K* values of plasma proteins and the CO_2/HCO_3^- system, with the p*K* values increasing as temperature decreases. The temperature-induced changes in plasma pH offset the temperature-dependent changes in the p*K* of plasma proteins so that the extent to which the plasma proteins dissociate remains unchanged. The important point is that if body pH changes with temperature in the same way as the p*K* of proteins, then the charge on proteins should remain unchanged. If there is little or no change in the net charge on proteins, their function will be retained over a wide range of temperatures. The apparent p*K* (pK_{app}) of the CO_2 hydration–dehydration reaction changes less with temperature than does blood pH; the ratio of CO_2 to HCO_3^- in the blood must be changed to regulate pH if the charge on proteins is to remain constant. Fish are unable to modulate CO_2 levels, but bicarbonate levels increase as temperature decreases to regulate pH.

Glossary

Arterial Adjective pertaining to blood that has been oxygenated.

Bohr effect Effect of the proton concentration (pH) on the oxygen affinity of hemoglobin.

Carbonic anhydrase A zinc metalloenzyme that reversibly catalyzes the reaction between CO_2 and H_2O to form H^+ and HCO_3^-.

Equilibrium Pertaining to the situation when all forces acting are balanced by others resulting in a stable unchanging system.

Haldane effect Proton binding to hemoglobin (as a function of oxygenation).

Hypercarbia High levels of carbon dioxide in water or air.

P_{50} The oxygen partial pressure at half-maximal oxygen saturation of blood or hemoglobin.

Partial pressure The pressure that one gas would have if it alone occupied the same volume at the same temperature as the mixture.

Root effect Property of hemoglobins in some fishes such that, in the presence of acid, it is impossible for hemoglobin molecules to be completely saturated with oxygen, even at extremely high oxygen partial pressures.

Venous Adjective pertaining to blood that has passed through tissues having had some oxygen removed for metabolism.

Introduction

All animals produce about the same amount of CO_2 as O_2 consumed through the process of metabolism. O_2 is taken up from the environment and delivered to the tissues by the blood, and CO_2 is released by the tissues and transported by the blood for release to the environment. Hemoglobin (Hb), encapsulated within the red blood cell (RBC), plays a vital role in both O_2 and CO_2 transport in the blood of all vertebrates (with the exception of icefish, the only vertebrate lacking Hb). This article focuses on the nature of the interaction between O_2 and CO_2 at the level of Hb, a topic that has been well studied since the dual role of Hb was discovered in the early 1900s.

Oxygen uptake at the gas-exchange organ (referred to as the gills from this point forward, although the skin and various air-breathing organs can contribute to gas exchange in some fishes) facilitates CO_2 removal through the Haldane effect, where Hb-oxygenation releases H^+'s that combine with HCO_3^- to form CO_2, which diffuses into the environment (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion, Carbonic Anhydrase in Gas Transport and Exchange, and Red Blood Cell Function). CO_2 removal at the gills and the associated increase in blood pH results in an increase in Hb-O_2 affinity, which increases the driving force for O_2 diffusion across the gills, ultimately facilitating O_2 uptake via the Bohr effect (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect). At the tissues, the reverse occurs. CO_2 diffusion into the blood creates an acidosis that facilitates O_2 delivery to the actively metabolizing tissues via the Bohr effect. Oxygen delivery facilitates CO_2 uptake by Hb, and thus CO_2 removal from the tissues via the Haldane effect. Thus, there is an intimate interaction between O_2 and CO_2 transport at both the gills and the tissues at the level of Hb within the RBC, which is determined in part by the magnitude of the Bohr and Haldane effects.

Tremendous diversity in Hb characteristics exists within the fishes, making this group of animals particularly interesting for investigating the interaction between O_2 and CO_2 exchange. Some fish possess very small, even nonexistent Bohr and Haldane effects with relatively high Hb-buffer values, substantially limiting the interaction between O_2 and CO_2 exchange. However, the majority of fishes (teleosts) possess large Bohr and Haldane effects (as well as a Root effect, where oxygen-carrying capacity of the blood is reduced at low pH) and low Hb-buffer values, collectively resulting in tightly coupled O_2 and CO_2 exchange. Furthermore, many teleost fishes exhibit a nonlinear Bohr and Haldane effect over the region of the oxygen-equilibrium curve (OEC), which has further implications for the nature of the interaction between O_2 and CO_2 exchange.

Basis for the Interaction between O_2 and CO_2: Bohr–Haldane Effect

The interaction between O_2 and CO_2 exchange is largely determined by the Bohr and Haldane effects as discussed above; however, their respective magnitudes are important in determining the nature of the interaction. The Bohr effect describes how the affinity of Hb for O_2 is affected for a given change in the H^+ concentration (pH) of the blood. It is calculated as follows:

$$\text{Bohr coefficient } = -\Delta \log P_{50}/\Delta p\text{H} \qquad [1]$$

where P_{50} refers to the partial pressure of O_2 (P_{O_2}) at which 50% of the Hb molecules are oxygenated.

The Haldane effect describes how the affinity of Hb for H^+'s and CO_2 is affected by changes in Hb-O_2 saturation. It is calculated as follows:

$$\text{Haldane coefficient} = \Delta\text{H}^+ \qquad [2]$$

where ΔH^+ refers to the moles of H^+'s released per mole of O_2 bound to Hb.

Although the Bohr and Haldane effects are often discussed in terms of their respective roles relative to O_2 and CO_2 dynamics at the level of the Hb, they are actually mirror images of the same phenomenon. While the Bohr effect describes changes in Hb-O_2 affinity that arise from a change in H^+ concentration, the Haldane effect describes the changes in Hb–H^+ affinity that arise from a change in P_{O_2}, and therefore Hb-O_2 saturation. Thus, the Bohr and Haldane effects are linked functions, as has been recognized by the classic Wyman linkage equation:

$$(\log P_{O_2}/\text{pH})\,Y = (\text{H}^+/Y)\text{pH} \qquad [3]$$

where Y refers to Hb-O_2 saturation and H^+ refers to the number of protons bound per heme molecule. Assuming that the shape of the OEC is symmetrical and H^+ release is linear with Hb-binding O_2, which is often the case in vertebrates (but not always, as described below in section Nonlinear Bohr–Haldane Effect), the linkage equation is often reduced to the following:

$$-\Delta\log P_{50}/\Delta\text{pH} = \Delta\text{H}^+ \qquad [4]$$

The point is that the Bohr and Haldane coefficients are numerically equivalent, and will be referred to as the Bohr–Haldane coefficient, and reported as a positive value from this point forward. Further, this relationship has been experimentally validated. Air-breathing animals typically have moderate Bohr–Haldane coefficients (i.e., 0.35), while most teleosts have relatively large Bohr–Haldane coefficients (0.5 to >1.0). The numeric value has large implications for the nature of the interaction between O_2 and CO_2 exchange *in vivo*, as described in the following section.

Theoretical Bohr–Haldane Coefficient Optimal for Oxygen Delivery

The potential benefit to tissue-O_2 delivery associated with the Bohr effect is quantified as the product of the pH change associated with metabolic CO_2 production during blood transit through a tissue (arterial–venous pH change (pH_{a-v})) and the magnitude of the Bohr–Haldane coefficient. A large Bohr effect is often assumed to convey a greater benefit to tissue O_2 delivery, but this will only be true if the pH change described above is sufficient. Associated with a large Bohr effect is a large Haldane effect; therefore, upon deoxygenation, Hb will bind H^+'s, thereby reducing the magnitude of the pH_{a-v} and consequently the expression of the Bohr effect at the tissues. In 1983, Lapennas conducted an analysis to determine the optimal Bohr coefficient for O_2 delivery under steady-state conditions. Assuming that the pH_{a-v} arises from tissue CO_2 production (and associated conversion to HCO_3^- and H^+) and that most animals have a tissue respiratory quotient (RQ) between 0.7 and 1.0 (moles of CO_2 produced per mole of O_2 consumed; **see also Tissue Respiration**: Cellular Respiration), a Bohr–Haldane coefficient of 0 will result in the largest pH change within the tissues. This would be due to the absent Haldane effect and associated H^+ binding upon deoxygenation, but would have no effect on O_2 delivery due to the lack of pH sensitivity of the Hb (i.e., no Bohr effect). Conversely, a Bohr–Haldane coefficient equivalent to the RQ (e.g., 1.0) will result in no pH change due to the increased H^+ binding associated with the large Haldane effect. That is, all protons produced by CO_2 production at the tissues will be bound by Hb as O_2 is released to the tissues, and, despite the presence of a pH-sensitive Hb with a large Bohr effect, there may be no benefit to O_2 delivery due to the lack of pH_{a-v}. Furthermore, a Bohr–Haldane coefficient greater than RQ may result in a reverse pH_{a-v}, during blood transit, which actually could impair tissue-O_2 delivery.

Lapennas determined that the optimal Bohr coefficient for O_2 delivery under steady-state conditions (and with many assumptions) is 0.5 × RQ. This represents a compromise between pH sensitivity of the Hb and the resulting pH change that occurs during capillary blood transit. Because many air-breathing vertebrates have Bohr–Haldane coefficients of 0.35 (which is very close to optimal if RQ is assumed to be 0.7), he concluded that their Hbs have been optimized for O_2 delivery (**Figure 1**). Given that most teleost fish possess Bohr–Haldane coefficients much greater than 0.5 × RQ (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect), it has been assumed that, under steady-state conditions in most tissues, fish Hbs may be optimized for CO_2 transport and acid–base homeostasis rather than tissue-O_2 delivery. This clearly does not apply to the unique structures within the swimbladder and eye, where there exists a tremendous potential for generating and localizing an acidosis, which in conjunction with the Root effect and associated large Bohr–Haldane coefficients generates incredibly high O_2 tensions (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems and Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). However, in other tissues, given Lapennas' assumptions, a very large Bohr–Haldane coefficient would not benefit tissue-oxygen delivery. Despite Lapennas' many assumptions, his analyses serve as an interesting framework for hypothesizing how different Bohr–Haldane coefficients within and between species may influence the interaction between O_2 and CO_2 exchange *in vivo*.

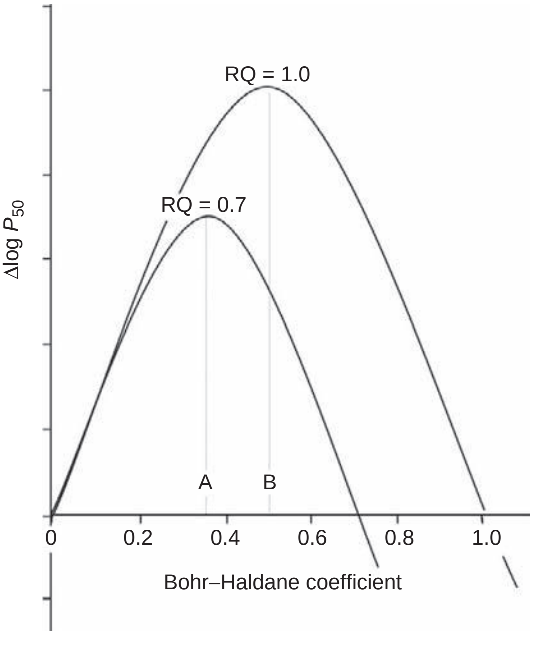

Figure 1 The optimal Bohr–Haldane coefficient: theoretical Bohr shifts, as described by a change in P_{50} (Δlog P_{50}) during blood capillary transit using two respiratory quotients (RQs). Units have been omitted intentionally from the *y*-axis, because the magnitude of this response will vary by species, depending on Hb buffer values. A and B indicate Bohr–Haldane coefficients optimal for O_2 delivery for RQ values of 0.7 and 1.0, respectively. Each curve crosses the *x*-axis at both zero and the RQ, two points at which Lapennas suggests there will be no benefit to O_2 delivery associated with the Bohr–Haldane effect. Modified from Lapennas GN (1983) The magnitude of the Bohr coefficient: Optimal for oxygen delivery. *Respiration Physiology* 54(2): 161–172.

Nonlinear Bohr–Haldane Effect within the OEC

The assumption for many models depicting vertebrate Hb function is that the magnitude of the Bohr–Haldane coefficient is relatively constant across the entire OEC. Although this may be true for most air-breathing vertebrates, it is not the case in several fish species, where most of the Bohr–Haldane effect occurs in the upper reaches of the OEC (between 50% and 100% Hb-O_2 saturation) with very little expression below 50% Hb-O_2 saturation. The nonlinear Bohr–Haldane effect is typically associated with species that possess Root-effect Hbs, perhaps suggesting that nonlinearity is common among teleosts. When fish use different regions of the OEC for gas exchange *in vivo*, implications for a nonlinear Bohr–Haldane effect influencing the interaction between O_2 and CO_2 exchange become interesting.

The entire Bohr–Haldane effect may be exploited in resting fish, where venous Hb–O_2 saturation levels rarely fall below 50%. In resting rainbow trout *Oncorhynchus mykiss*, the Bohr–Haldane coefficient calculated over the region of the OEC used *in vivo* is approximately 1.0, a value close to RQ. Therefore, CO_2 excretion at the gills and CO_2 and acid–base transport at the tissues will be maintained because Hb will bind all H^+'s released from the tissues during O_2 delivery. However, when fish are forced to swim, the arterial–venous O_2 difference increases, requiring a greater region of the OEC to be used for gas exchange. The magnitude of the Bohr–Haldane coefficient calculated over the region of the OEC used for gas exchange during exercise is reduced to a value of 0.4–0.5, remarkably close to the value deemed optimal for O_2 delivery by Lapennas. Accordingly, during periods of increased activity and therefore muscle-O_2 demand, the nonlinear Bohr–Haldane effect may be important for optimizing O_2 delivery. Thus, the nature of the interaction between O_2 and CO_2 exchange, if a nonlinear Bohr–Haldane effect is present, changes with exercise intensity and the region of the OEC exploited for gas exchange.

Implications of Non-Steady-State Conditions for the Interaction between O_2 and CO_2 Exchange

Most of the discussion to this point has assumed steady-state, equilibrium conditions; however, it is unlikely that such conditions exist *in vivo,* because gas exchange consists of a complex combination of blood flow, boundary layers, chemical reactions, and diffusion. For example, if CO_2 from the tissues diffuses into the blood faster than O_2 diffuses to the tissues, a large Bohr–Haldane coefficient could facilitate O_2 delivery during blood capillary transit. The only way to determine whether this occurs *in vivo* is by direct measurement, which is very difficult. In the only published study to date where this has been conducted in fish, P_{O_2} was measured in real time via an optode implanted in the red muscle of resting rainbow trout. Results indicate a much higher tissue P_{O_2} than in mammals. Despite an *in vivo* Bohr–Haldane coefficient of 1.0 under resting conditions (far greater than the optimal value determined as described above), it could be that general O_2 delivery is enhanced in rainbow trout, and perhaps other fish species. Clearly, additional studies of this nature are required to investigate this further.

In fish, the greatest disequilibrium state at the level of the RBC is likely associated with catecholamine-stimulated Na^+/H^+ exchange. During stress, or when Hb-O_2 saturation falls below 50%, metabolic CO_2 and H^+ production may be elevated. Catecholamines such as adrenaline and noradrenaline are released into the circulation and bind to β-adrenergic receptors on the RBC membrane. Through adenylate cyclase, which activates 3′,5′-cyclic monophosphate (cAMP), the β-adrenergic Na^+/H^+ exchange (βNHE) on the RBC membrane is activated. The carbonic anhydrase (CA)-catalyzed hydration of CO_2 inside the RBC produces H^+ and HCO_3^-; the former are removed in exchange for Na^+ via the βNHE to restore pH_i and therefore Hb-O_2 affinity, but at the cost of decreasing plasma pH. The HCO_3^- is removed via anion exchange for Cl^-. The resulting osmotic gradient activates the Na^+, K^+ pump, and osmotically obliged water enters the RBC, causing the cell to swell (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion and Red Blood Cell Function). This process is thought to have evolved to protect O_2 uptake at the respiratory surface during a general acidosis in species possessing Root-effect Hbs, where an acidosis drastically decreases not only Hb's affinity but also carrying capacity for O_2. However, this is also an example of a disequlibrium state where O_2 and CO_2 transport dynamics do not follow steady-state models.

The adrenergically activated βNHE elevates pH_i but only in the absence of plasma-accessible CA. If CA were accessible to the plasma, this would short-circuit the RBC βNHE, because H^+'s would combine with HCO_3^- to form CO_2 and back-diffuse into the RBC, decreasing pH_i (**Figure 2**). Fish lack plasma-accessible CA at the gills and thus adrenergically activated βNHE protects O_2 uptake at the respiratory surface; however, CA may be plasma accessible in some tissues, where the CA IV isoform (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbonic Anhydrase in Gas Transport and Exchange) is bound to endothelial cells and plasma oriented. When the βNHE is activated during stress, and blood passes through capillaries possessing CA, the RBC βNHE is short-circuited, resulting in a much larger pH_{a-v} than which would otherwise occur, greatly facilitating O_2 delivery to the tissues.

Short-circuiting of RBC βNHE has been validated *in vitro.* When CA is added to adrenergically stimulated, mildly acidified RBCs in a closed system, it results in a rapid acidification of RBC pH_i and a dramatic increase in P_{O_2}. Accordingly, short-circuiting of RBC βNHE *in vivo* could potentially have large effects. In rainbow trout implanted with an O_2 optode in red muscle, which allows real-time tissue P_{O_2} monitoring, inducing a mild acid–base disturbance by exposing fish to elevated environmental CO_2 levels (hypercarbia) results in a significant increase in tissue P_{O_2}. However, when plasma-accessible CA is subsequently inhibited following the addition of a non-membrane-permeable CA inhibitor to the blood, the hypercarbia-induced increase in tissue P_{O_2} is abolished, indicating that short-circuiting of RBC βNHE may be operational *in vivo* and may greatly facilitate O_2 delivery. Therefore, although rainbow trout have a large Bohr–Haldane effect, a large pH_{a-v} in the RBC may occur via exploiting disequilibrium states *in vivo.* Furthermore, this system would operate with every pass through the tissues, effectively harnessing the general acidosis to create a RBC pH_{a-v}, which will be localized to tissues that possess plasma-accessible CA.

Concluding Remarks

The intricate relationship between O_2 and CO_2 exchange has been described in past models that assume equilibrium conditions, which link the Bohr–Haldane relationship to the RQ in order to make predictions as to optimal O_2 delivery or CO_2 transport and acid–base homeostasis. However, equilibrium conditions probably never occur *in vivo.* In addition, teleosts possess a large Bohr–Haldane coefficient, which according to Lapennas' theory may be detrimental to tissue O_2 delivery. Yet, real-time measurements confirm elevated muscle P_{O_2} in rainbow trout, suggesting that a mechanism is in place to enhance O_2 delivery in fish. Teleosts' unique Root-effect Hbs convey a great potential for O_2 delivery, and possessing a nonlinear Bohr–Haldane effect allows different parts of the OEC to

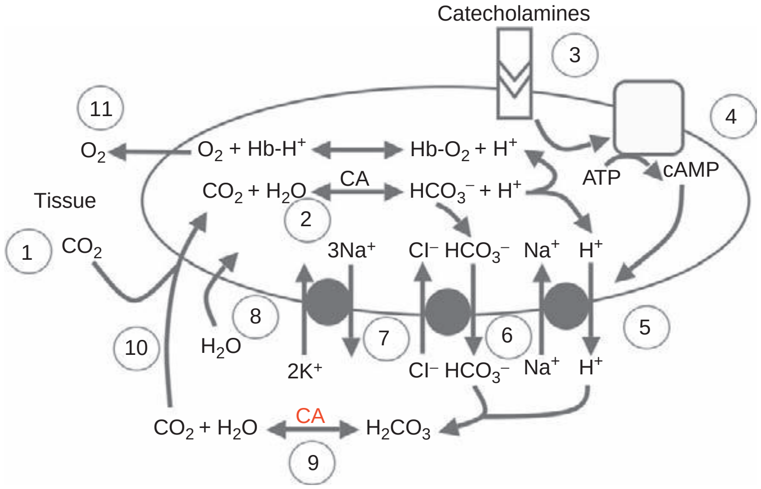

Figure 2 Short-circuiting the β-adrenergic response at the red blood cell: With the advent of an acidosis or when metabolic CO_2 production is high, the red blood cell (RBC) intracellular pH (pH_i) can decrease substantially. Metabolic CO_2 enters the RBC (1) and is catalyzed by carbonic anhydrase (CA) to form HCO_3^- and H^+ (2), the latter of which will bind hemoglobin (Hb), thus releasing O_2. Catecholamines such as adrenaline and noradrenaline are released into the circulation to bind to receptors on the RBC membrane (3), activating adenlylate cyclase and 3′,5′-cyclic monophosphate (cAMP) (4), which activates the Na^+, H^+ exchanger (βNHE) (5). As protons (H^+) are removed from the RBC in exchange for Na^+, pH_i increases and Hb–O_2 affinity is restored. Bicarbonate (HCO_3^-) is removed from the RBC in exchange for Cl^- via the anion exchanger (6), resulting in an osmotic gradient that activates the Na^+, K^+ pump (7). Osmotically obliged water enters the cell (8) resulting in RBC swelling. As long as βNHE rates are high and CA is not accessible to the plasma, this results in an increase in RBC pHi. However if CA is plasma accessible (9), which may occur in the tissues, H^+ and HCO_3^- removed from the RBC would be catalyzed to form CO_2 that would back-diffuse into the RBC (10). This would short-circuit the original protective function of the βNHE mechanism and favor O_2 unloading from the Hb (11), which in the case of Root-effect Hbs would be substantial, creating enhanced O_2 delivery localized to tissues possessing plasma-accessible CA.

be utilized under different conditions. Indeed, the potential exists, and during non-steady-state conditions such as intense exercise or hypoxia exposure, adrenergic stimulation of the RBC βNHE creates the acid–base disequilibrium needed to maximize this potential. Plasma-accessible CA in select locations within metabolizing tissue may be localizing the acidosis by short-circuiting the βNHE, therefore facilitating O_2 delivery to tissues to a much greater degree than that in air-breathing vertebrates. Root-effect Hbs evolved long before the eye and swimbladder retia, structures typically associated with the unique pH-sensitive Hb, suggesting a general use for such great O_2 delivery potential (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems). Along with the increase in and nonlinearity of the Bohr–Haldane effect, teleosts appear to greatly facilitate O_2 transport with only moderate whole-blood pH changes.

Glossary

Allosteric binding Binding of an effector molecule to a protein site that is different from the active site.

Bohr effect The property of vertebrate hemoglobins whereby changes in pH affect the hemoglobin-oxygen affinity, supporting loading (in the lungs/gills) and unloading (in the tissues) of oxygen from hemoglobin.

Equilibrium Pertaining to the situation when all forces acting are balanced by others, resulting in a stable unchanging system.

P_{50} The oxygen partial pressure at half-maximal oxygen saturation of blood or hemoglobin.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

Root effect The property of hemoglobins of some fishes such that in the presence of acid, it is impossible for the hemoglobin molecule to be completely saturated with oxygen, even at extremely high oxygen partial pressures.

Discovery and Definition of the Bohr Effect

The Bohr effect generally describes the effect of pH on the blood-O_2-binding affinity. It is named after the eminent Danish respiratory physiologist Christian Bohr, who in 1904 together with his pupils, Karl Hasselbalch and the later Nobel prize winner August Krogh, published their observations on the effect of the CO_2 tension (i.e., partial pressure) on the binding of O_2 by dog blood. They showed that an increase in carbon dioxide partial pressure (P_{CO_2}) decreased the affinity of the blood for O_2 and realized immediately the physiological importance of this effect. They predicted that what became to be known as the Bohr effect would enhance O_2 delivery to the tissues, where CO_2 was released into the blood, and facilitate O_2 uptake in the lungs, where CO_2 was discharged from the blood. They also observed that the effect of CO_2 on blood-O_2 binding decreased at oxygen partial pressure (P_{O_2}) values approaching those of air, where the blood approached complete O_2 saturation and the effect of P_{CO_2} became negligible. The Bohr effect occurs in the blood of many vertebrates and, in **Figure 1**, the original data of Bohr and colleagues are replotted in the form of a series of blood-O_2 binding curves with increasing P_{CO_2} and compared with data on carp (*Cyprinus carpio*) blood.

The effect of CO_2 on blood-O_2 binding can be mimicked by lactic acid and it is now known that the Bohr effect is mainly due to the hydrogen ions that are generated in the hydration of CO_2 and subsequent dissociation into bicarbonate and protons:

$$CO_2 + H_2O \leftrightarrow HCO_3^- + H^+ \qquad (1)$$

Although the concept of pH was only introduced after its original discovery, the Bohr effect is now generally assessed by determining the pH-dependence of the blood-O_2 affinity. When pH is decreased within the physiological pH range, blood exhibiting a Bohr effect requires a higher P_{O_2} for half-maximal O_2 saturation (the P_{50}).

Distinction between a Bohr Effect and a Root Effect

In many fishes, CO_2 or low pH exert an additional effect on blood-O_2 binding. In 1931, Root discovered that the effect of CO_2 on blood-O_2 binding persists in some marine fishes at high P_{O_2} values, such that blood cannot be fully saturated with O_2 even at atmospheric P_{O_2} values. This latter feature is widespread among ray-finned fishes, including teleosts, and is known as the Root effect. The

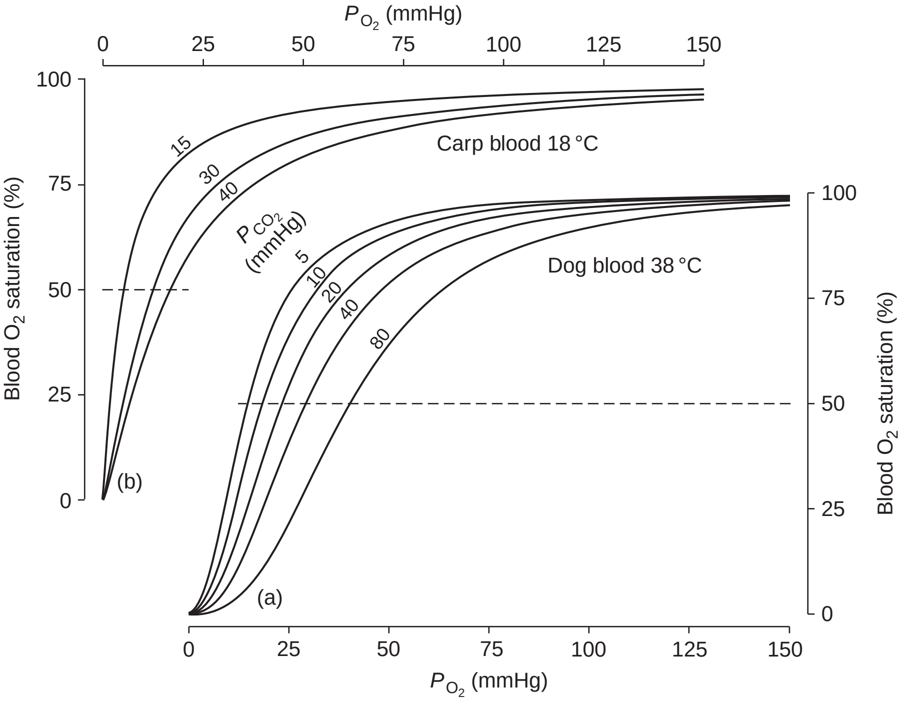

Figure 1 Effect of carbon dioxide partial pressure (P_{CO_2}) on blood-oxygen binding in dog (a) and carp (b) blood. In both cases, increasing P_{CO_2} increases the oxygen partial pressure (P_{O_2}) at half-maximal saturation (dashed lines). Curves are fits to the original data reported (a) by Bohr C, Hasselbalch K, and Krogh A (1904) *Skandinavisches Archiv für Physiologie* 16: 402–412 and (b) by Wastl H (1928) *Biochemische Zeitschrift* 197, 363–380.

Root effect is an important component of the mechanism for O_2 secretion in the swimbladder and eye of many fishes (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder).

Figure 2 shows a series of blood-O_2 binding curves of the marine goosefish *Lophius americanus* at different pH values to illustrate the difference between the Bohr effect and the Root effect. Between pH 8 and 7, a decrease in blood pH shifts the O_2-binding curve toward the right so that higher P_{O_2} values are needed for half-maximal O_2 saturation. Extension of the measurement range for P_{O_2} up to 750 mmHg (close to 1 atmosphere of O_2) shows that pH in this range does not affect the maximal O_2-binding capacity, because the blood can be still 100% saturated at high P_{O_2}. This indicates a Bohr effect. After further acidification below pH 7, high P_{O_2} values fail to fully saturate the blood as indicated by the asymptotic maximum of the curves falling below 100%. This is typical of the Root effect. A more detailed analysis of the curves shows that below pH 7 the curves are no longer S-shaped and approach the shape of a rectangular hyperbola. This loss of cooperative O_2 binding is not seen in Bohr-effect hemoglobins (Hbs) and is another distinguishing characteristic of the Root effect.

Factors Modulating the Magnitude of the Bohr Effect in Vertebrates

The magnitude of the Bohr effect can vary within a species, depending on the type of Hbs and their microenvironment inside the red blood cell. It is most often quantified by the change in the logarithm of P_{50} per change in pH ($\Delta\log P_{50}/\Delta$pH). Usually the Bohr effect shows a maximum within the physiological pH range inside red blood cells and declines at higher and lower pH values. At very low pH values, the Bohr effect can be reversed, meaning that a decrease in pH actually increases Hb-O_2 affinity. This is called a negative or acid Bohr effect as compared to the normal or alkaline Bohr effect.

The Bohr effect is generally reduced by low organic-phosphate concentrations and in many species also by low chloride concentrations and/or elevated P_{CO_2}. The blood of many fish species contains more than one Hb type and these can differ in their functional properties. Thus, the blood of salmonids, such as rainbow trout *Oncorhynchus mykiss*, and of eels, such as the European eel *Anguilla anguilla*, contains Hb components that can constitute about 20–40% of the total Hb and that lack, or even show a reverse Bohr effect, thereby reducing the Bohr effect of the composite Hb system.

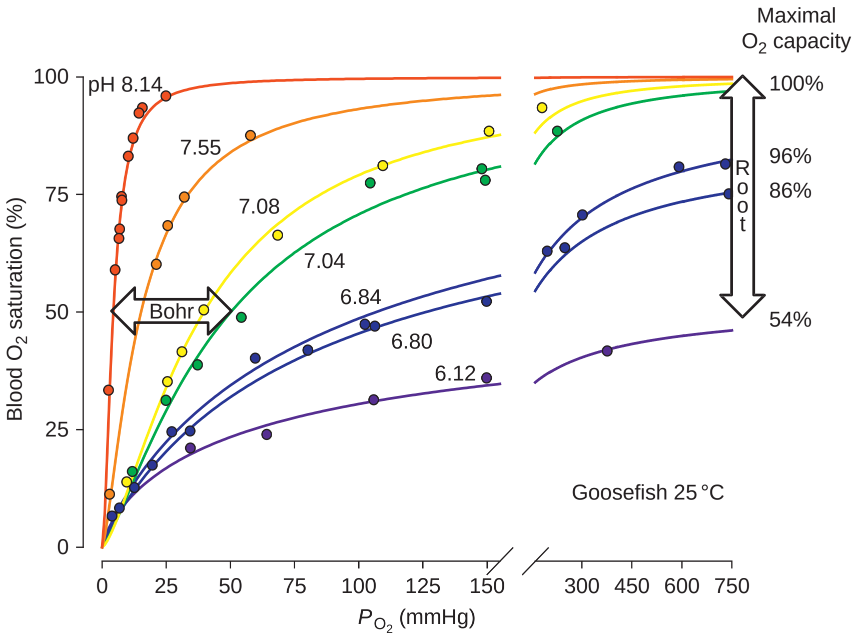

Figure 2 Effect of pH on whole-blood-oxygen binding in a teleost, the goose fish. Above pH 7, the blood displays a classical Bohr effect, namely a decrease in pH increases the oxygen partial pressure (P_{O_2}) required for half-maximal oxygen (O_2) saturation but 100% blood O_2 saturation is still achieved at high P_{O_2}. Below pH 7, a Root effect is displayed: a decrease in pH increases the P_{O_2} at half-maximal saturation and decreases the apparent maximal O_2 capacity. Modified from Green AA and Root RW (1933) *Biological Bulletin* 64: 383–403.

Another source for (apparent) variability lies in the reference pH that is used for Bohr-effect assessments. Blood pH measurements essentially assess the pH of the plasma. The intracellular pH of red blood cells in the vicinity of Hb is usually lower than that of the plasma and any change in plasma pH is not completely transferred to intracellular pH, particularly when red cell pH is regulated by the activation of ion regulatory pathways (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function). Therefore, even when other factors, such as P_{CO_2} and the concentrations of chloride, Hb, and organic phosphate are kept the same, the whole-blood Bohr effect underestimates the true effect of pH on Hb-O_2 affinity, which is obtained by relating it to intracellular pH or the buffer pH of Hb solutions.

Occurrence of the Bohr Effect in Animals

A Bohr effect of similar magnitude to that originally found in dog blood by Bohr and colleagues is also found in blood of humans, other mammals, and most tetrapods (exceptions include tadpoles and a caecilian). The effect is of approximately similar size in lungfishes, e.g., *Lepidosiren paradoxa*, the coelacanth *Latimeria chalumnae*, and basal members of the ray-finned fishes such as bichir, sturgeon, and gar (*Polypterus senegalus, Acipenser ruthenus*, and *Lepisosteus platyrhincus*, respectively).

Most teleost fishes have a particularly strong Bohr effect. However, in elasmobranchs and hagfishes, elevated P_{CO_2} or a pH decrease has only a small effect on blood-O_2 affinity. In lampreys, the Bohr effect is as pronounced as in teleosts. The Bohr effect is not only found in bloods containing intracellular Hb but also found in the giant extracellular Hbs of annelid worms, hemocyanins of cephalopods and crustaceans, and in the hemerythrins of brachiopods. The latter two groups of respiratory pigments have quite different protein structures compared to globins and the O_2-binding sites consist of Cu atoms and non-heme-bound Fe, respectively. The fundamental differences in the nature of the O_2-binding site and/or in the protein structure of the diverse invertebrate respiratory pigments and vertebrate Hbs already indicate that the Bohr effect in animal bloods evolved several times and by quite different molecular mechanisms.

Molecular Mechanism(s) of the Bohr Effect in Vertebrate Hbs

The pH-induced change in O_2 affinity involves allosteric binding of protons to Hb at specific sites, which then decrease the O_2 affinity of the O_2-binding sites. The molecular mechanism of the Bohr effect has been most extensively studied on human Hb. According to the two-state allosteric model, tetrameric Hb of jawed vertebrates exists in equilibrium between two different

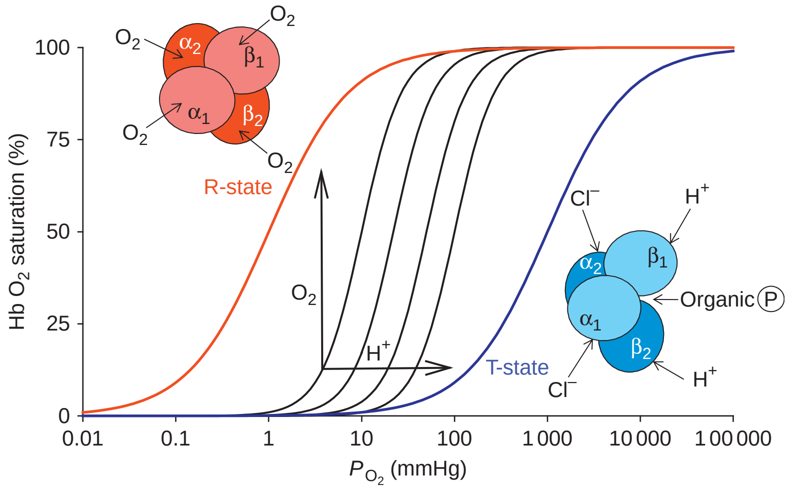

Figure 3 Schematic explanation of the Bohr effect according to the two-state allosteric model. Hb tetramers exist in equilibrium between the R-state and T-state conformations, which have inverse affinities for O_2 and H^+ (indicated by arrows). High P_{O_2} promotes the transition (black lines) from the low-O_2-affinity T-state to the high-O_2-affinity R-state (red line), which is the basis for cooperative O_2 binding (increased steepness of black curves at intermediate O_2 saturations). Protons stabilize the low-O_2-affinity T-state (blue line). This increases P_{50} by delaying the T- to R-state transition. Chloride and organic phosphates enhance the effect of protons by additional stabilization of the T-state. Note that the R-state and T-state O_2-binding curves are really rectangular hyperbolas when depicted on a nonlogarithmic *x*-axis scale.

conformations that differ in their intrinsic O_2 affinity: a tense (T-state) conformation with low O_2 affinity and a relaxed (R-state) conformation with a high O_2 affinity (**Figure 3**). The T-state prevails at low P_{O_2} values and has a relative high affinity for protons, organic phosphates, and chloride, while the R-state is favored at high P_{O_2} and has a lower affinity for protons, organic phosphates, and chloride.

The two-state allosteric model is an oversimplification, because there is increasing evidence that the O_2 affinity in the R-state and T-state itself can also vary with pH. However, the model is useful in explaining the cooperative nature of Hb-O_2 binding by the shift from a low-O_2-affinity T-state at low P_{O_2} to a high-affinity R-state at higher P_{O_2} values. It accounts for the Bohr effect by simply assuming that an increase in the proton concentration shifts the equilibrium between the two Hb conformations toward the low-O_2-affinity T-state, thereby lowering the overall O_2 affinity of the system. Using the two-state allosteric model, it is easy to see how elevated chloride or organic phosphate concentrations could enhance the Bohr effect by additionally stabilizing the T-state conformation.

The magnitude of the Bohr effect can also be expressed in terms of the number of protons that can be additionally bound by, and thereby stabilize, the low-O_2-affinity T-state conformation compared to the high-O_2-affinity R-state conformation. Under standardized conditions of temperature, pH, chloride, CO_2, and organic phosphate concentrations, the number of these so-called Bohr protons can be used to compare the magnitude of the Bohr effect between different species. The molecular sites on Hb where these Bohr protons bind, and thereby the molecular mechanism of the Bohr effect, have been intensively studied. Recently, it has become clear that even within vertebrates no single mechanism can account for the Bohr effect observed in mammals, teleost fishes, and lampreys.

Mammals

In mammals, in general, about two Bohr protons per Hb tetramer are additionally bound by the low-O_2-affinity T-state, compared to the R-state Hb. In humans, the terminal histidine amino acid residue in position 146 of the beta chain of the Hb tetramer is the major site for the binding of Bohr protons, accounting for 63% of the Bohr effect under standard conditions (**Figure 4(a)**). Another 22% of the Bohr effect is contributed by proton binding to other histidine residues at different positions, with three histidine residues in the alpha chain and two in the beta chains having a moderate positive effect and two other beta-chain histidine residues having a moderate negative contribution to the Bohr effect. The remaining 14% of the total Bohr effect can be explained by non-histidine Bohr-proton-binding sites. Thus, in the T-state, chloride binding to the amino group of the N-terminal amino acid in the alpha chains allows additional binding of Bohr protons.

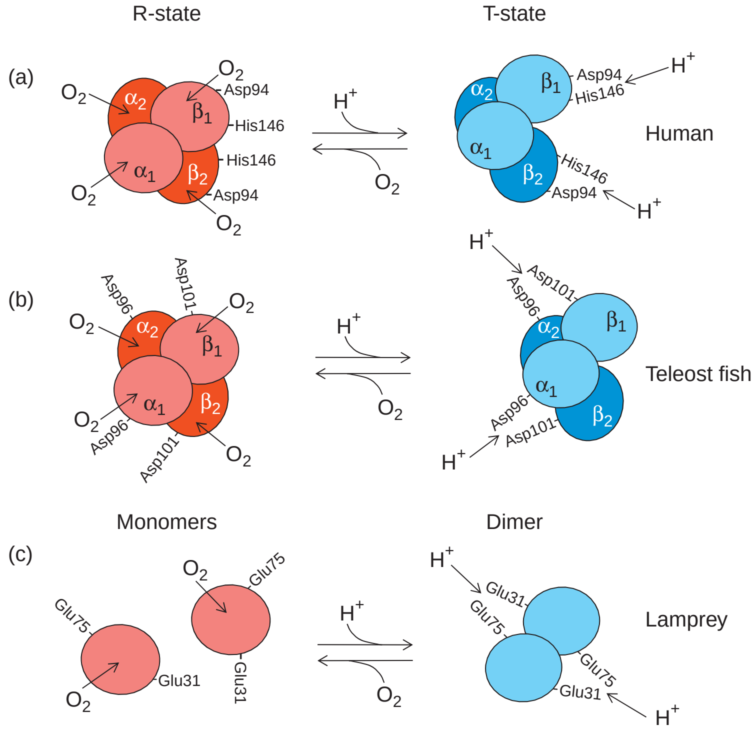

Figure 4 Molecular mechanisms of the Bohr effect in vertebrate Hbs, schematically indicating major proton-binding sites that stabilize low-O_2-affinity conformations over high-O_2-affinity conformations. (a) In human Hb, the Bohr effect is largely caused by proton binding to the imidazole side chain of the terminal histidines (His) in the two beta chains. This allows formation of a salt bridge with an aspartic-acid (Asp) residue in the same chain, which stabilizes the low-O_2-affinity T-state (blue). This interaction is not possible in the high-O_2-affinity R-state (red). (b) In teleost fishes, the pH sensitivity of Hb-O_2 binding is largely caused by stabilization of the T-state through proton binding at a different site. Two Asp residues at the alpha–beta interface between the two dimers (shaded light and dark) that make up the Hb tetramer form a negative cluster in the T-state conformation that allows proton binding. (c) In lamprey Hb, the low-O_2-affinity dimer is stabilized over the high-O_2-affinity monomers by proton binding at two clusters of glutamic acid (Glu) residues at the dimer interface. Amino acids are numbered according to their position in the 2 alpha- and 2 beta-globin chains (α_1, α_2 and β_1, β_2).

Teleost Fishes

In most teleost fish Hbs, the Bohr effect is twice as strong as in mammals because up to four additional protons are bound, thereby stabilizing the low-O_2-affinity T-state. However, the overall Bohr effect in the blood of some teleost species is not higher than in mammals due to the presence of additional Hb components with no, or even a reverse, Bohr effect, as in eels and trout (see above). Like in mammals, and indeed tetrapods, fish Hbs with a Bohr effect generally possess a histidine at position 146 in their beta chains. Studies on carp Hb, in which this histidine was chemically removed, suggest that this treatment may reduce the Bohr effect by 50%. However, structural studies on several other fish Hbs suggest that histidine beta 146 is not involved in the Bohr effect in these species. Teleost fishes further have a much-reduced histidine content in their alpha- and beta-globin chains, so that most of the other histidines implicated in the Bohr effect in human Hb are missing. In addition, the terminal amino group of the alpha chain is chemically blocked, so that the chloride-dependent binding of Bohr protons at this site that occurs in human Hb is also impaired. Thus, the majority of the Bohr protons in teleosts must bind at other sites than in human Hb.

Indeed, in Hb of tuna (*Thunnus thynnus*), carp, Antarctic emerald rockcod (*Trematomus bernacchii*), and in Hb IV of trout, about half of the Bohr protons may bind to two clusters of aspartic-acid residues that are formed in the T-state conformation at the interface between the two alpha–beta dimers in the tetramer (**Figure 4**(**b**)). The other half of the Bohr-proton-binding sites are still debated and may vary among the Hbs of different teleost species. In addition, the presence of the two aspartic-acid residues at the dimer interfaces appears a necessary, but not sufficient, condition for contributing to a Bohr effect because these residues are also present in Hbs that show no Bohr effect as well as in human Hb, where their local protein environment prevents the formation of a cluster and thus proton binding at this site. It is also unclear which of the different Bohr-proton-binding sites discussed above are merely contributing to the pH-induced shift in Hb-O_2 affinity and which are also involved in the reduction of the maximal O_2-binding capacity and the loss of cooperativity that characterize the Root effect (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems). Thus, the molecular mechanism of the large Bohr effect in teleosts remains incompletely explained, although it is clearly different from the mechanism in both humans and lampreys, as discussed subsequently.

Lampreys

Lamprey Hbs have a large Bohr effect that approaches the size of the effect in some teleosts. Yet, their Hbs have none of the amino acid residues that are involved in the Bohr effect in human Hb. Lamprey Hbs further differ from all other higher vertebrates by comprising a type of globin chain that exists in a monomer–dimer equilibrium (**Figure 4(c)**). The monomer has a higher O_2 affinity than the dimer. Similar to the two conformational states of tetrameric Hb discussed above, proton binding to the dimer stabilizes the low-O_2-affinity form. Structural and mutational studies have shown that about 50% of the large Bohr effect in lamprey Hb can be accounted for by proton binding to two clusters of glutamic-acid residues that are formed during dimer formation at the interface between the two monomers.

These case studies show that the Bohr effect in mammals, teleosts, and lampreys is achieved by three entirely different mechanisms and, therefore, the Bohr effect likely evolved independently at least 3 times. Specific differences in the influence of chloride, organic phosphates, and CO_2 on the Bohr effect in bird Hbs relative to mammalian Hbs may suggest even a fourth case of independent Bohr-effect evolution in vertebrates.

Benefits and Evolution of the Bohr Effect

The presence of a Bohr effect allows more-efficient blood-O_2 transport because under the acidic conditions in the tissue capillaries, where CO_2 or lactic acid are released into the blood, the Hb-O_2 affinity is decreased. The right-shift of the O_2-binding curves allows increased offloading of O_2 without compromising venous P_{O_2}. Thereby the O_2-diffusion gradient from the blood to the tissues can be maintained. In the absence of a Bohr effect,

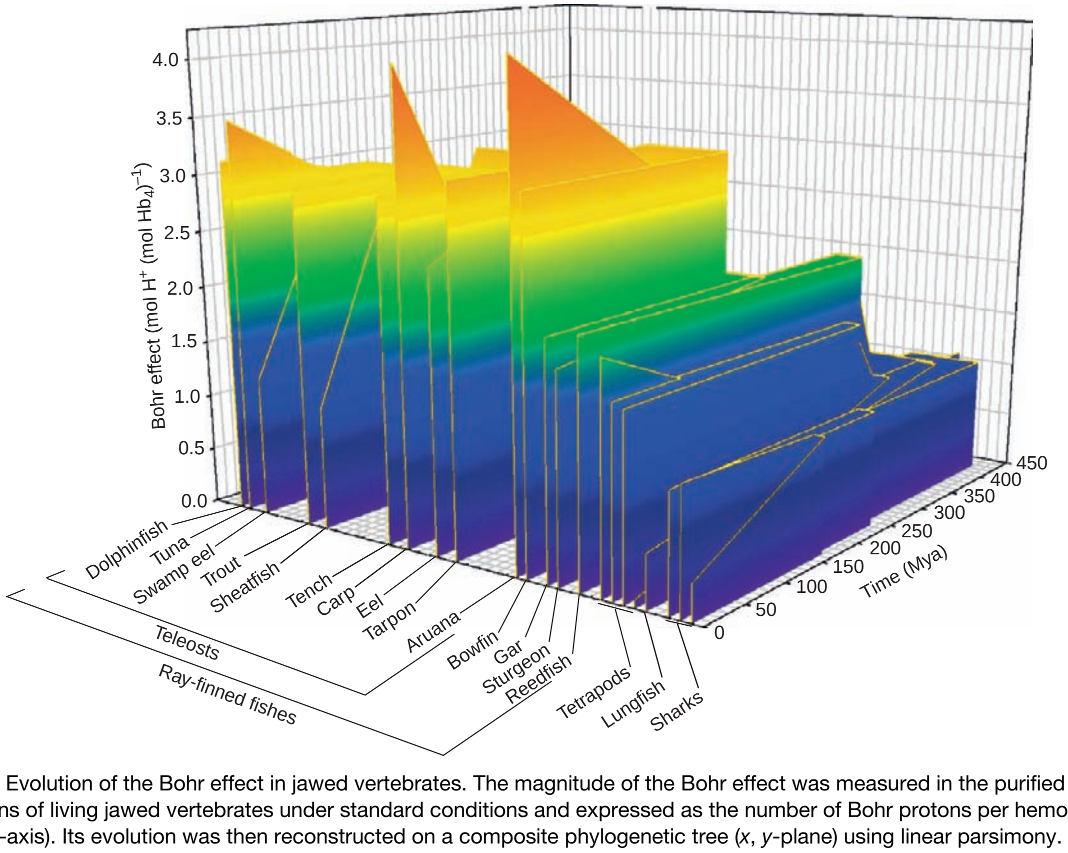

Figure 5 Evolution of the Bohr effect in jawed vertebrates. The magnitude of the Bohr effect was measured in the purified hemoglobins of living jawed vertebrates under standard conditions and expressed as the number of Bohr protons per hemoglobin tetramer (*z*-axis). Its evolution was then reconstructed on a composite phylogenetic tree (*x*, *y*-plane) using linear parsimony. The reconstruction shows an increase in the Bohr effect in tetrapods and early ray-finned fishes about 350 million years ago (Mya). A second increase occurred 250 Mya in the ancestor of bowfin and teleosts. Dolphinfish *Coryphaena hippurus*, swamp *eel Monopterus albus*, sheatfish *Silurus glanis*, tench *Tinca tinca*, tarpon *Megalops cyprinoides*, aruana *Scleropages jardinii*, bowfin *Amia calva,* reedfish *Erpetoichthys calabaricus*. Modified from Berenbrink M, Koldkjær P, Kepp O, and Cossins A (2005) Evolution of O_2 secretion in fishes and the emergence of a complex physiological system. *Science* 307: 1752–1757.

increased O_2 offloading in the tissue capillaries requires a decrease in venous P_{O_2}, which decreases the driving force for O_2 diffusion into the tissues. As noted by Bohr and colleagues in 1904, the effects of CO_2 on O_2 binding at the elevated P_{O_2} values in lung blood are minimal, ensuring that O_2 loading is not impaired by, for example, elevated environmental CO_2 levels.

The Bohr effect also aids in blood-CO_2 transport, as the uptake of Bohr protons by Hb in tissue capillaries shifts the equilibrium between CO_2 and bicarbonate (see eqn (1)) in such a way that deoxygenated blood carries more bicarbonate than oxygenated blood at constant P_{CO_2} (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion and Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange).

These two well-known benefits for blood O_2 and CO_2 transport may have selected for the multiple evolution of a Bohr effect in the respiratory pigments of the otherwise so-very-different cephalopods, crustaceans, annelid worms, brachiopods, and vertebrates. However, the Bohr effect evolved more than once even in vertebrates. Increasing evidence suggests that the Hb monomers of lampreys do not resemble the ancestral globin of higher vertebrates before the latter became duplicated and evolved into alpha and beta globins. Thus, the very different Bohr-effect mechanism in lampreys and the tetrameric Hb of higher vertebrates may not be unexpected.

Surprisingly, as detailed above, the molecular mechanism of the Bohr effect in mammals and teleost fishes now suggests that the Bohr effect evolved independently in these two groups as well. This is independently supported by a reconstruction of the evolution of the Bohr-effect magnitude on a phylogenetic tree of jawed vertebrates. As explained above, the magnitude of the Bohr effect is quite variable even within a species. Therefore, such comparisons need to be made under carefully standardized conditions, to exclude as much as possible nonheritable variation in the data. When this is done, it is seen that the magnitude of the Bohr effect has dynamically changed during the 450-million-year history of jawed vertebrates (**Figure 5**).

The analysis suggests that the last common ancestor of jawed vertebrates, some 450 Mya, had a low Bohr effect similar to the values still seen today in living sharks and lungfish. Around 300 Mya, a Bohr effect with a magnitude of around two Bohr protons per tetramer had evolved in tetrapods and in the last common ancestor of ray-finned fishes. This can still be seen in today's mammals and in the

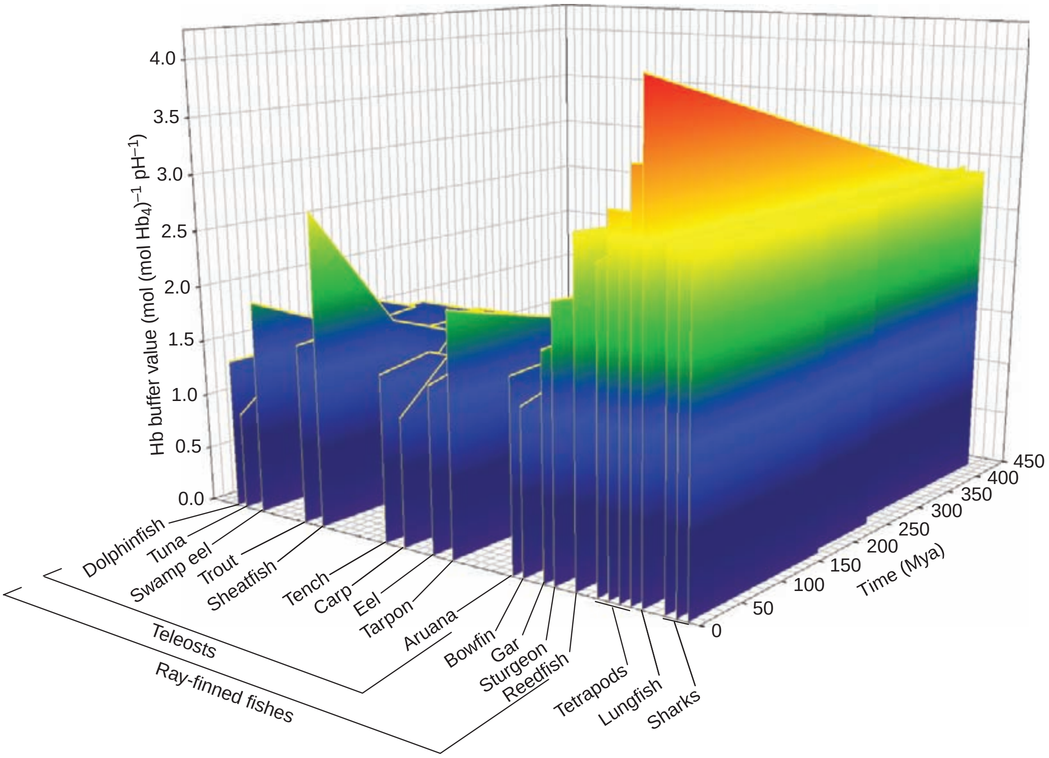

Figure 6 Evolution of hemoglobin (Hb) buffer properties in jawed vertebrates. The Hb buffer value (moles of protons needed to decrease the pH of a 1 molar solution of tetrameric Hb by 1 pH unit, *z*-axis) was measured in living species and its evolution reconstructed on a phylogenetic tree (*x*, *y*-plane) by linear parsimony. Hb buffer value was high in the last common ancestor of jawed vertebrates 450 million years ago (Mya) and substantially decreased during the evolution of modern ray-finned fishes. Reconstructed using data from Berenbrink M, Koldkjær P, Kepp O, and Cossins A (2005) Evolution of O_2 secretion in fishes and the emergence of a complex physiological system. *Science* 307: 1752–1757.

surviving members of basal ray-finned fish lineages, such as reedfish (*Erpetoichthys calabaricus*), sturgeon, and gar. At 250 Mya, a second increase of the Bohr effect occurred in ray-finned fishes, namely in the last common ancestor of the bowfin (*Amia calva*) and teleost fishes. Most teleost fishes have retained this large Bohr effect of around four Bohr protons per Hb tetramer until today.

It has been mentioned earlier that teleost Hbs contain fewer histidine amino acids in their alpha and beta globin chains relative to other jawed vertebrates. The imidazole side group of histidine is the most important proton buffer group in proteins. Interestingly, the evolutionary increase of the Bohr effect in teleosts is closely paralleled by a decrease in the proton buffer value of their Hbs (**Figure 6**). This means that during the evolution of ray-finned fishes, blood pH may have become more prone to change for a given acid-loading event at the same time as the pH sensitivity of Hb-O_2 affinity increased via the Bohr effect. Thus, a given lactic-acid load or increase in P_{CO_2} in blood passing tissue capillaries has a much greater effect on Hb-O_2 affinity in teleost fishes compared to, for example, mammals for two reasons. First, because the Bohr effect is about twice as high in teleosts, and, second, because blood pH is much more weakly buffered in teleost fishes compared to mammals.

Water-breathing fishes have much lower blood P_{CO_2} levels than air breathers (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes). Based on the heightened CO_2 sensitivity of teleost fish blood, it was once suggested that the early vertebrates emerging onto dry land in the Devonian first had to evolve stronger blood acid–base buffering and Hb with a reduced CO_2 sensitivity. However, the evolutionary reconstruction of the Bohr effect and Hb-buffer values now suggest that the fish ancestors of the first tetrapods emerging onto land never had low Hb-buffer values nor a Bohr effect as large as today's teleost fishes.

Glossary

Arterial Pertaining to blood that has been oxygenated.

Avascular Pertaining to the lack of blood vessels or capillaries.

Bohr effect The property of vertebrate hemoglobins, whereas changes in pH affect the hemoglobin-oxygen affinity, supporting loading (in the lungs/gills) and unloading (in the tissues) of oxygen from hemoglobin.

Choroid Pertaining to a vascular structure behind the retina; so-called because it resembles the chorion, the membranous structure that surrounds an embryonic mammal and contributes to the development of the placenta.

Hemibranch A half branch (gill arch) with only one row of filaments.

Operculum/opercular The bony gill cover of teleost fish/pertaining to gill cover.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

Pseudobranch A reduced mandibular gill arch, in elasmobranchs the spiracular gill, in teleosts located on the inside of the operculum. In teleosts with ocular oxygen secretion, blood is supplied to the eye only via the pseudobranch.

Rete A Structure consisting of densely packed blood vessels, mostly with a countercurrent blood flow scheme, arranged to facilitate the exchange of, for example, heat or oxygen.

Root effect The property of hemoglobins of some fishes such that in presence of acid it is impossible for the hemoglobin molecule to be completely saturated with oxygen, even at extremely high oxygen partial pressures.

Venous Pertaining to blood that has passed through tissues and has had some of its oxygen removed for metabolism.

Definition of the Root Effect

The Root effect is predominantly defined as the reduced oxygen (O_2) carrying capacity of hemoglobin at low pH values, even at atmospheric O_2 partial pressures (P_{O_2}). This is in contrast to the Bohr effect, which is defined as the reduction in hemoglobin-O_2 affinity caused by a reduced pH (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect). In general, vertebrate hemoglobin is fully saturated with O_2 at atmospheric P_{O_2}. Due to cooperativity between its four subunits, tetrameric hemoglobin (Hb_4) exhibits a sigmoidal O_2-binding curve (saturation plotted against P_{O_2}, **Figure 1**), with the P_{50} depicting the P_{O_2} of half saturation. The pH effect, termed Bohr effect, affects O_2 affinity, shifting the O_2-binding curve, that is, the P_{50}, horizontally to the left (increased pH), or to the right (reduced pH). Since the horizontal shift of the O_2-binding curve occurs around the P_{50} and therefore only at a fraction of the atmospheric P_{O_2}, the saturation levels at this high P_{O_2} are not affected. The Root effect, however, describes the pH-dependent vertical shift of the O_2-binding curve (**Figure 1**). It not only decreases saturation up to atmospheric O_2 levels, but also continues to be effective even at extremely high P_{O_2} of several hundred atmospheres, severely limiting the O_2-carrying capacity of the blood.

The Root effect is almost exclusively found in teleost fish. Different from humans, who have only one type of hemoglobin, rainbow trout (*Oncorhynchus mykiss*), for example, has four types of hemoglobin, which are readily distinguishable by gel electrophoresis. Only hemoglobin type IV, the electrophoretically anodic type, shows the distinct reduction in O_2-carrying capacity at low pH, while the more cathodic hemoglobins, types I–III, do not exhibit this effect. Depending on the relative content

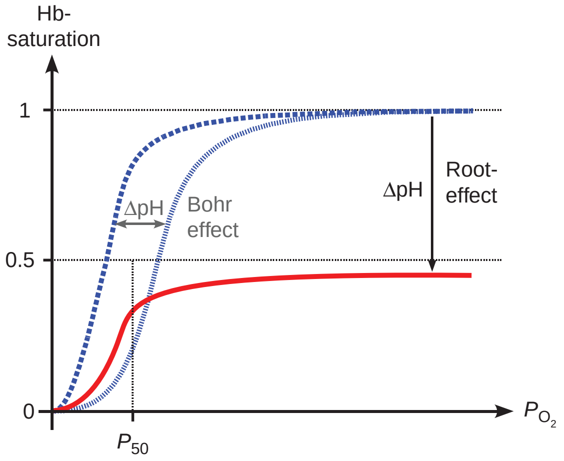

Figure 1 O_2-binding curves showing the Bohr effect and Root effect. The Bohr effect describes pH-mediated changes in the O_2 affinity of hemoglobin, delineated by a horizontal shift of the binding curve around the P_{50} (blue lines). The Root effect describes a reduction in O_2-carrying capacity of the hemoglobin at low pH (red line), prohibiting complete saturation of hemoglobin with O_2 even at high P_{O_2}.

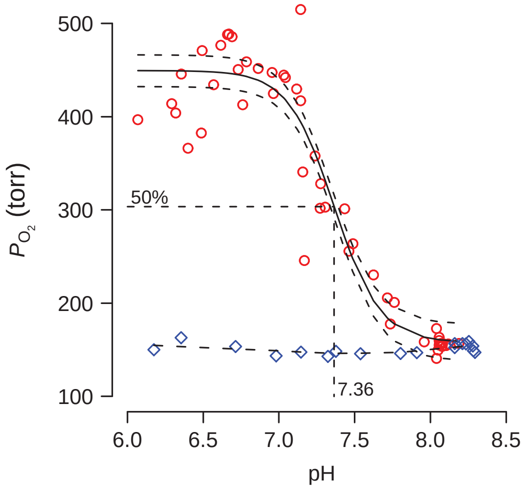

Figure 2 Root effect expressed as an increase in P_{O_2} following acidification of sealed blood samples. Red symbols: trout blood, blue symbols: human blood. Adapted from Waser W and Heisler N (2005) Oxygen delivery to the fish eye: Root effect as a crucial factor for elevated retinal P_{O_2}. *Journal of Experimental Biology* 208:4035–4047.

of the Root-effect-sensitive hemoglobin, at a low pH, a significant, and in some species the larger, proportion of the hemoglobin therefore is unavailable for O_2 binding and hence O_2 transport. The actual magnitude of the Root effect is species specific and can produce up to an 80% reduction of hemoglobin saturation. Apart from teleosts, the Root effect has also been demonstrated in several nonteleost species, some sharks, *Xenopus laevis* (African clawed frog) and some cephalopod hemocyanins. In teleosts, the Root effect has a clear physiological (see next section) and evolutionary explanation (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems), but in other animals its function is unclear.

Functional Role of the Root Effect

Despite its universal definition in textbooks and review articles as the reduced O_2-carrying capacity of hemoglobin, this is a confusing term for the actual functional role of the Root effect. Teleosts do not control the total amount of O_2 transported in the blood via the adjustment of pH, as might be surmised from its definition. Arterial blood is instead typically fully saturated with O_2 and the crucial aspect of the Root effect concerns the fate of O_2 when this fully saturated blood is acidified within a closed system, that is, it is the effect of unloading hemoglobin-bound O_2 on arterial P_{O_2} (**Figure 2**). The concomitant reduction of hemoglobin-saturation levels via acidification is only secondary.

Gases in Solution

According to Henry's gas law

$$C_{O_2} = \alpha_{O_2} P_{O_2} \tag{1}$$

the concentration of physically dissolved O_2 depends on the solubility coefficient α and the P_{O_2}. O_2 that is chemically bound to hemoglobin does not affect this equation. Therefore, at an atmospheric P_{O_2} of 20.9 kPa (156.6 mmHg) and with a solubility coefficient α of about 13 $\mu mol\, l^{-1}\, kPa^{-1}$ (1.7441 $\mu mol\, l^{-1}\, mmHg^{-1}$ for blood plasma at 15 °C), a total of 272 $\mu mol\, l^{-1}$ of O_2 will be physically dissolved in blood plasma. However, blood can hold >20 times more O_2 per unit volume because it contains hemoglobin. O_2 concentration of fully saturated blood would be 6.272 $mmol\, l^{-1}$ in a rainbow trout with an Hb_4 concentration of about 1.5 $mmol\, l^{-1}$.

The activation of the Root effect via acidification causes the release of some of the O_2 chemically bound to hemoglobin, which in a closed system increases the amount of physically dissolved O_2 in the plasma. This additional physically dissolved O_2 now significantly affects Henry's equilibrium

$$P_{O_2} = \frac{C^{Pl}_{O_2} + C^{Hb}_{O_2}}{\alpha_{O_2}} \tag{2}$$

between concentration, solubility, and P_{O_2}. Accordingly (eqn (2)), it causes a rise in P_{O_2} (**Figure 2**).

The Root effect is therefore more correctly described as the increase in P_{O_2} following acid-mediated desaturation of oxy-hemoglobin.

Single-Pass Root Effect

The amount of O_2 released following the activation of the Root effect depends on the proportion of Root-effect-sensitive hemoglobin, which is species specific. In rainbow trout, for example, Hb_4 IV, the Root-effect-sensitive hemoglobin comprises about 60% of the total hemoglobin concentration of 1.5 mmol l^{-1}. With the Root effect fully activated, 3.6 mmol l^{-1} of the 6 mmol l^{-1} of the O_2 bound to hemoglobin will be released. This then raises the concentration of physically dissolved O_2 over 10-fold from 272 μmol l^{-1} to 3.872 mmol l^{-1}. This, in turn, increases P_{O_2} from the atmospheric value of 20.9 to 298 kPa, or 2.94 atm.

Of course, the circulation is not a closed system and O_2 is free to diffusion down its partial pressure gradient. As a result of the Root effect, there is a 10-fold increase in this gradient in the above example, which allows more O_2 to diffuse than would otherwise be possible. In addition, the tissues are also exposed to higher P_{O_2} values.

The final delivery of O_2 to cells and mitochondria is realized via diffusion according to Fick's law:

$$\dot{M}_{O_2} = K_{O_2}\,\Delta P_{O_2}\,\frac{A}{L} \qquad (3)$$

The amount of O_2 delivered per unit time depends primarily on the P_{O_2} gradient ΔP_{O_2} and the diffusion distance L, because the diffusion coefficient K and exchange area A are fixed by tissue composition and geometry restraints. Therefore, increasing P_{O_2} via the Root effect allows for O_2 delivery over far greater distances than would be possible with normal P_{O_2}, allowing an increase in size. In addition, capillary density can be reduced, with the blood vessels taking up less space in a tissue. Conversely, a high P_{O_2} is detrimental due to O_2 toxicity. In humans, O_2 becomes toxic at partial pressures above 1.8 atm, and teleosts have been shown to die of O_2 toxicity at about 2 atm of O_2. Curiously, this occurs at less than the maximal P_{O_2} attainable by full Root-effect activation in rainbow trout.

Physiological Significance – Eye and Swimbladder

Providing a mechanism to increase blood and hence tissue P_{O_2} far above atmospheric values via acidification of O_2-saturated blood, the Root effect has great functional and physiological significance for two organs in teleosts, the retina in the eye and the swimbladder.

Retina

As a neuronal tissue, the retina has one of the highest metabolic rates of all tissues and depends on a high and constant supply of O_2. It is rather surprising, therefore, that the ancestral mode of nourishing the retina in vertebrates, as seen in fish, does not include an intraretinal blood supply, that is, vascularization of the retinal layers. This avascular state of the retina exists in many teleosts, with the blood supply being limited to the choriocapillaries outside of the pigment epithelium. Furthermore, an extra challenge concerning O_2 supply exists in many teleosts because their retina is significantly thicker than those of other vertebrates. Diffusion distances can be up to 6 times larger than the ~140 μm observed in the vascularized retina of mammals. Hence, to maintain O_2 supply over this greater diffusion distance, the P_{O_2} gradient needs to be increased.

Modeling of O_2 diffusion into actively O_2-consuming tissues shows that the required ΔP_{O_2} is proportional to the square of the diffusion distance. Doubling diffusion distance requires a fourfold increase in P_{O_2}. Therefore, a sixfold increase in diffusion distance, as observed in some teleosts' retinas, requires a 36-fold increase in P_{O_2}. Starting from arterial P_{O_2} of about 13.3 kPa (100 mmHg), an elevated partial pressure of 480 kPa (3600 mmHg, 4.73 atm) would be needed to maintain O_2 delivery. This huge gradient is almost achieved by the Root effect, but is still 60% higher than the maximally attainable P_{O_2} in rainbow trout blood by complete activation of the Root effect, indicating that other processes are necessary to further increase the blood P_{O_2} to properly supply the eye.

Countercurrent Multiplication

The process and structure boosting the Root effect to achieve P_{O_2} levels sufficiently high for retinal oxygenation and swimbladder filling is a countercurrent multiplication in special vascular structures, the choroid rete mirabile (for the eye) and the (swimbladder) rete mirabile. **Design and Physiology of Arteries and Veins**: The Retia. Briefly, the blood vessels supplying the O_2-secreting tissues are arranged in a closed-loop, countercurrent vascular arrangement, with the inflowing and outflowing blood coming into very close, large-surface, contact within the rete mirabile (**Figure 3**, crm), an arrangement of a huge number of densely packed arterial (inflow) and venous (outflow) capillaries. In the eye, this choroid rete mirabile lies within the eyecup between retina and sclera, encircling the optic nerve. After passage through the arterial capillaries of the choroid rete mirabile, the blood flows through the choriocapillaries (**Figure 3**, chc) underlying the retina. Since most of the blood from the

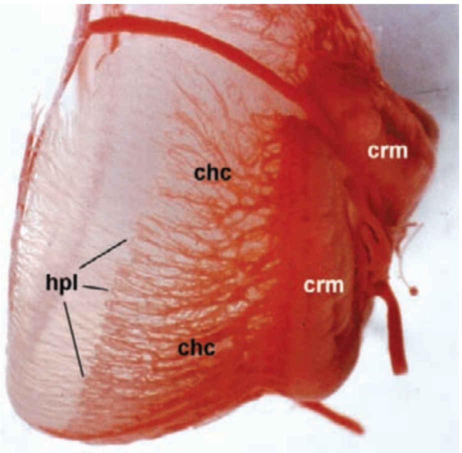

Figure 3 Lateral view of a corrosion cast of the ocular vascular system of an Atlantic cod eye. crm, choroid rete mirabile; chc, choriocapillaries; hpl, hairpin loops of choriocapillaries.

choriocapillaries returns via the venous capillaries of the choroid rete mirabile, the choriocapillaries constitute the apex of the vascular closed-loop system (**Figure** 3, hpl), where the Root effect is activated by acidification of the blood causing a rise in P_{O_2} directly adjacent to the retina. Elevated P_{O_2} in the venous blood returning through the choroid rete mirabile is then transferred to the inflowing arterial blood, preloading the blood with physically dissolved O_2. Within the choriocapillaries, the Root effect is then again activated, now in the preloaded blood, elevating P_{O_2} in excess of the already-raised P_{O_2}. The combination of the closed-loop countercurrent exchange system with an active concentration step at the loop's apex effectively multiplies the single-pass Root effect and generates very high P_{O_2} **see Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes for further details. This multiplication effect easily provides the 60% increase in P_{O_2} needed beyond that of the Root effect alone.

Swimbladder

The second organ in teleost fish where an elevated P_{O_2} is needed is the swimbladder. For a detailed treatment of the topic, **see Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes. In contrast to the eye, where O_2 remains physically dissolved, rendering the gas-secretion process independent of hydrostatic pressure, the swimbladder is filled with gas, mainly O_2. P_{O_2}, therefore, equals the surrounding hydrostatic pressure, which changes by about 1 atm per 10-m depth change and reaches several hundreds of atmospheres at several kilometers of depth. Gas pressure in the swimbladder is therefore much higher and much more variable than in the eye, posing far more demanding requirements on the gas-secretion processes.

Ocular Blood Supply and Pseudobranch

Vascular Supply to the Eye

The ocular rete mirabile is supplied with arterial blood only indirectly, via a special organ, the pseudobranch (see below). In rainbow trout (and Atlantic cod, *Gadus morhua*, **Figure 4**), the ventral efferent artery of the first gill arch (**Figure 4**, b), carrying freshly oxygenated blood, constitutes the afferent pseudobranch artery, providing this organ with O_2-saturated blood. After passage through the pseudobranch's vascular structures, the efferent pseudobranch artery (**Figure 4**, e), connected to its contralateral counterpart by a small commissura (**Figure 4**, f), becomes the ophthalmic artery (**Figure 4**, g), supplying the ocular rete mirabile with blood. In other species, the arterial blood supply of the pseudobranch can also, or alternatively, originate at the cephalic circle. In contrast, the swimbladder receives arterial blood via the dorsal aorta and celiac artery.

The Pseudobranch

The teleost pseudobranch is a reduced mandibular gill arch, located on the inside of the operculum (**Figure 5(a)**), and homologous to the spiracular hemibranch of elasmobranchs. Among teleosts, pseudobranch structure ranges from free, gill-like structures fully exposed to the water (e.g., flounder, *Platichthys flesus*,

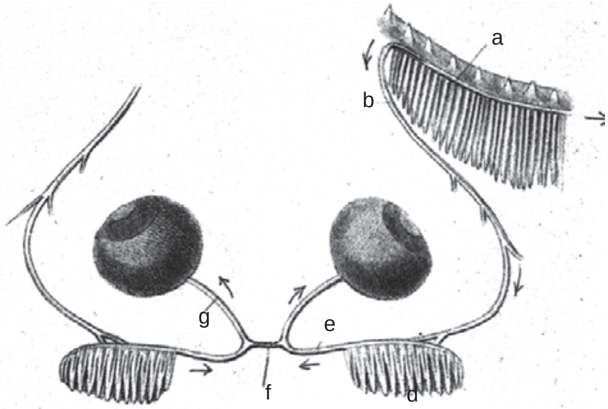

Figure 4 Drawing of Müller,1839, of the vascular connections from the gill, via the pseudobranch, to the eye of Atlantic cod. (a) first gill arch, (b) efferent ventral gill artery carrying oxygenated blood, (d) pseudobranch, (e) efferent pseudobranch artery, (f) commissura between left and right efferent pseudobranch artery, and (g) ophthalmic artery.

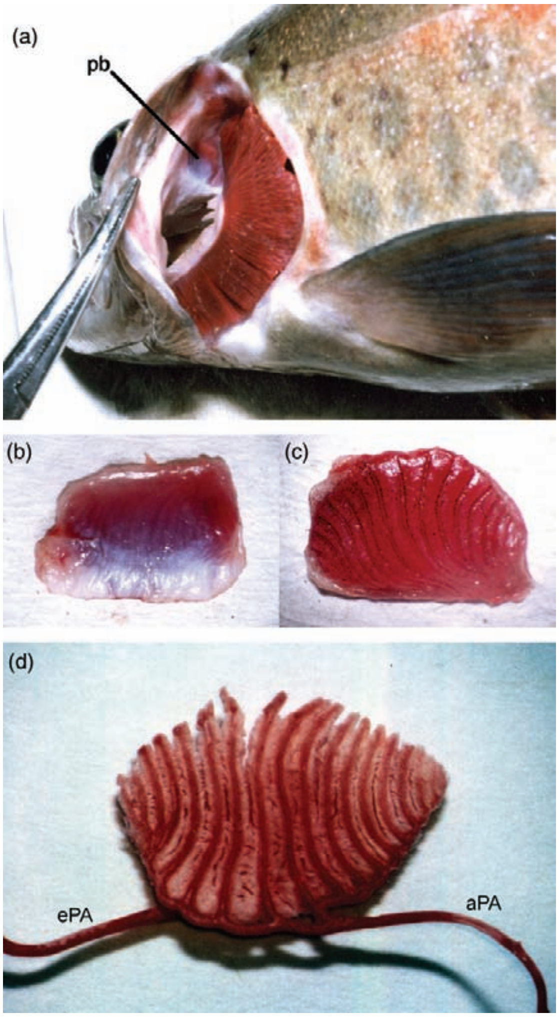

Figure 5 Rainbow trout pseudobranch. (a) Location at the dorsal articulation of the operculum. pb, pseudobranch. (b) Outer and (c) inner surface of freshly excised pseudobranch. In Rainbow trout, the pseudobranch is covered by epithelium that leaves only the very tips of the filaments exposed. The inner surface is only loosely attached to the underlying muscle and provides a better view of the filaments. (d) Corrosion casts of pseudobranch vasculature (left pseudobranch, inner surface). aPA, afferent pseudobranch artery (= efferent ventral gill artery); ePA, efferent pseudobranch artery (= ophthalmic artery). Filamental arteries (dark red) and lamellae (light red, in between filamental arteries) are clearly visible.

black goby, *Gobius niger*), to glandular pseudobranchs, with fused lamellae, deeply buried in the opercular tissue, and without any contact to the external medium (e.g., Cyprinidae, Atlantic cod, and killifish, including *Fundulus*).

Being derived from a former gill arch, the internal morphology of the pseudobranch still closely resembles that of a hemibranch (**Figures 5(b)**–**5(d)**), even in the more glandular types. The pseudobranch exhibits one row of filaments, each bearing numerous secondary lamellae (**Figure 5(d)**). Filaments contain the filamental cartilage, filamental artery and vein, and a venous sinus.

Pseudobranch lamellae also resemble gill lamellae, with the internal blood space held open by pillar cells. Lamellae in free pseudobranchs are spaced so that water flow between the lamellae is possible. In the more glandular-type pseudobranchs, which are mostly completely covered by opercular epithelium, the lamellae are fused, obliterating the interlamellar space and rendering diffusional exchange between water and blood all but impossible. In contrast to gills, pseudobranchs contain a unique cell type, termed 'pseudobranchial cells'. These cells are characterized by many tubular invaginations of their basal membranes associated with numerous mitochondria, pointing to a large capacity for active transmembrane transport processes.

Pseudobranch Function

Based on neurophysiological experiments, a number of different sensory functions (e.g., baro-, osmo-, iono-, and O_2-receptor) have been proposed for the pseudobranch. Denervation or ablation of the pseudobranch, however, did not impair circulatory, respiratory, or osmoregulatory parameters. Endocrine and glandular functions have also been attributed to the pseudobranch, but could not be corroborated in investigations. The most notable features of the pseudobranch are its gill-like lamellae and its peculiar position within the blood supply pathway to the choroid rete mirabile. These observations not only have led early (**Figure 4**) to suggestions that the pseudobranch plays a role for vision but also have stimulated recent research into the possible role of the pseudobranch for ocular O_2 secretion.

The conserved, gill-like anatomical layout of the pseudobranch provides a large-surface-contact area between blood and tissue. In combination with the special mitochondria-rich pseudobranchial cells, this would suggest a high capacity for active membrane transport processes. These transport processes could potentially regulate some aspects of blood chemistry en route to the retina. Since the neural tissue of the retina could be damaged by locally low pH values that are necessary for the Root effect, a hypothesis that has been advanced is that the pseudobranch might preadjust blood pH in the blood flowing to the eye. This would lower blood pH toward a Root-effect threshold value and would enable O_2 secretion in the choriocapillaries with only a minimum local acidification, thereby avoiding damage of the retina due to high rates of acid production.

Key enzyme activity patterns, lactate production rates, and respiratory quotient values support this hypothesis, as do high concentrations of vacuolar H^+-ATPase in pseudobranchial cells. In fact, acid secretion by isolated pseudobranchial cells *in vitro* has been demonstrated. However, experiments undertaken to directly measure an acidification effect of the pseudobranch on the passing blood provided ambiguous results. When the pseudobranch was perfused *in situ*, with pH values of the perfusate varying over a large range, above and below the threshold value for the Root effect, no adjustment of perfusate pH by the pseudobranch could be demonstrated. The physiological function of the pseudobranch, having been studied only in a few teleost species, therefore remains an unsolved mystery.

Glossary

Allosteric binding Binding of an effector molecule to a protein site that is different from the active site.

Bohr effect The property of vertebrate hemoglobins whereby changes in pH affect the hemoglobin-oxygen affinity, supporting loading (in the lungs/gills) and unloading (in the tissues) of oxygen from hemoglobin.

Choroid Pertaining to a vascular structure behind the retina, so-called because it resembles the chorion, the membranous structure that surrounds an embryonic mammal and contributes to the development of the placenta.

Countercurrent Flowing in opposite directions.

Equilibrium Pertaining to the situation when all forces acting are balanced by others resulting in a stable unchanging system.

P_{50} The oxygen partial pressure at half-maximal oxygen saturation of blood or hemoglobin.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

Rete mirabile (or simply rete, plural retia mirabilia) Structure consisting of blood vessels arranged to facilitate the exchange of heat or oxygen.

Root effect The property of hemoglobins of some fishes such that in the presence of acid, it is impossible for the hemoglobin molecule to be completely saturated with oxygen, even at extremely high oxygen partial pressures.

Vascular Pertaining to blood vessels.

Vascularized Supplied by blood vessels.

Discovery of the Root Effect

The Root effect is named after Raymond W. Root, who in 1931 described a peculiar characteristic of the blood-oxygen (O_2)-binding curve in marine fishes. He observed that elevated carbon dioxide (CO_2) partial pressures (Pco_2's) prevented the blood of the sea robin *Prionotus carolinus*, toadfish *Opsanus tau*, and mackerel *Scomber scombrus* from becoming fully saturated with O_2 at the O_2 partial pressure (P_{O_2}) of air. Previous work by Christian Bohr and colleagues on mammalian blood had shown that upon elevating CO_2, increasingly higher P_{O_2} values were required for 50% O_2 saturation of the blood (P_{50} values). In contrast to marine fishes, however, close to 100% blood O_2 saturation could still be obtained in mammals when the P_{O_2} was elevated to the level of air (150–160 mmHg) (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect. Root observed that in his fishes the O_2-binding curve at high P_{CO_2} appeared to approach an upper asymptotic maximum that was distinctly lower than 100%. This was later confirmed in experiments where the P_{O_2} was elevated to as high as 140 atm of pure O_2 and still 100% oxygen saturation could not be reached in some (but not all) of the investigated fishes. Root also demonstrated that the effect of P_{CO_2} could be reproduced by addition of lactic acid and that low pH was the crucial parameter that produced the apparent loss of the maximal O_2 carrying capacity of fish blood. **Figure 1** illustrates the difference between the so-called Bohr and Root effect using the original data on goosefish *Lophius americanus* blood.

Careful analysis of the O_2-binding curves of fish blood at different pH reveals that not only the asymptotic maximum, but also the general shape of the curves changes with pH. Thus, in the example of the goosefish in **Figure 1**, two families of curves can be distinguished. Between pH 8 and 7 the curves are slightly S-shaped or sigmoid; below pH 7, they take the shape of a rectangular hyperbola. The S-shape is due to cooperative O_2 binding, meaning that binding of O_2 to the first of the four

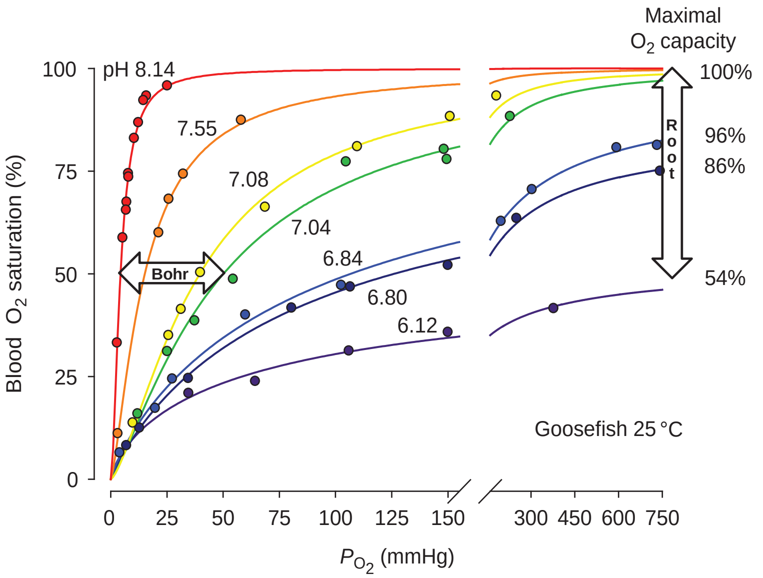

Figure 1 Effect of pH on blood O_2 binding in a marine teleost, the goosefish. Above pH 7, the blood displays a classical Bohr effect, namely a decrease in pH increases the P_{O_2} required for half maximal O_2 saturation (P_{50}) but close to 100% saturation is still achieved at high P_{O_2} (note different scale after axis break). Below pH 7, a Root effect is displayed: a decrease in pH increases the P_{50} and decreases the indicated apparent maximal O_2 capacity as well. Similarly colored lines and symbols refer to the same pH value, as indicated. Modified from Green AA and Root RW (1933) The equilibrium between hemoglobin and oxygen in the blood of certain fishes. *Biological Bulletin* 64: 383–403.

O_2-binding heme groups in the hemoglobin (Hb) tetramer induces structural changes in the globin subunits that increase the O_2 affinity of the other heme-binding sites. The loss of cooperativity of O_2 binding at low pH in the blood of many fishes is another characteristic of the Root effect that distinguishes it from the Bohr effect.

The Root Effect is Only Loosely Defined

There are no strictly defined and commonly accepted criteria for distinguishing whether blood of a given species has a large Bohr effect or rather a small Root effect. Theoretically, all blood or Hb O_2-binding curves only asymptotically approach, but never reach, 100% saturation, even in the case of a Bohr effect. Only few Hbs have been tested for pH-sensitive O_2 binding at P_{O_2} values higher than 1 atm of pure O_2, and it is difficult to predict whether close to 100% O_2 saturation will, or will not be reached at high-enough P_{O_2} values based on extrapolation of data obtained at low P_{O_2}.

The pH-induced decrease in the cooperativity of O_2 binding is of great general interest for understanding protein function, but this criterion for the Root effect is rarely used by whole organism biologists. For practical reasons, the presence of a Root effect is commonly accepted by respiratory physiologists and biochemists alike, when blood or Hb O_2 saturation under air-equilibration ($P_{O_2} \sim 150$ mmHg) and at high pH, which is often taken as the maximal O_2-binding capacity, is considerably reduced by low pH. 'Considerably' is again not defined, but in this context could mean more than in humans where low pH under these conditions causes a decrease in O_2 saturation to approximately 95%.

Variations in the Magnitude of the Root Effect

The extent by which acidification decreases the apparent maximal O_2-binding capacity varies with pH. In **Figure 2**, the O_2 saturation of goosefish blood at various P_{O_2} values from **Figure 1** is plotted as a function of pH. At the P_{O_2} of air (150 mmHg) and above pH 7.5, a decrease in pH has hardly any effect on maximal blood O_2 saturation. Between pH 7.5 and 6.5, blood O_2 saturation rapidly falls with acidification, and below pH 6.5 a lower plateau of blood O_2 saturation is reached. The shape and lower plateau of the curve relating pH and O_2 saturation clearly depend on the P_{O_2} used for comparison. At typical arterial P_{O_2} for many fishes of 80 mmHg, the level of the lower plateau is decreased and O_2 saturation begins to drop already at higher pH values. Conversely, under pure O_2 ($P_{O_2} \sim 750$ mmHg) the lower plateau of O_2 saturation is increased and lower pH values are needed to reach it.

The pH dependence of the Root effect also differs between species, even when compared at the same P_{O_2}. Thus, at atmospheric P_{O_2}, (1) the pH at which blood O_2 saturation falls most precipitously (midpoint pH), (2) the steepness of the curve at midpoint pH, and (3) the lower plateau of O_2 saturation, all differ between the bloods of

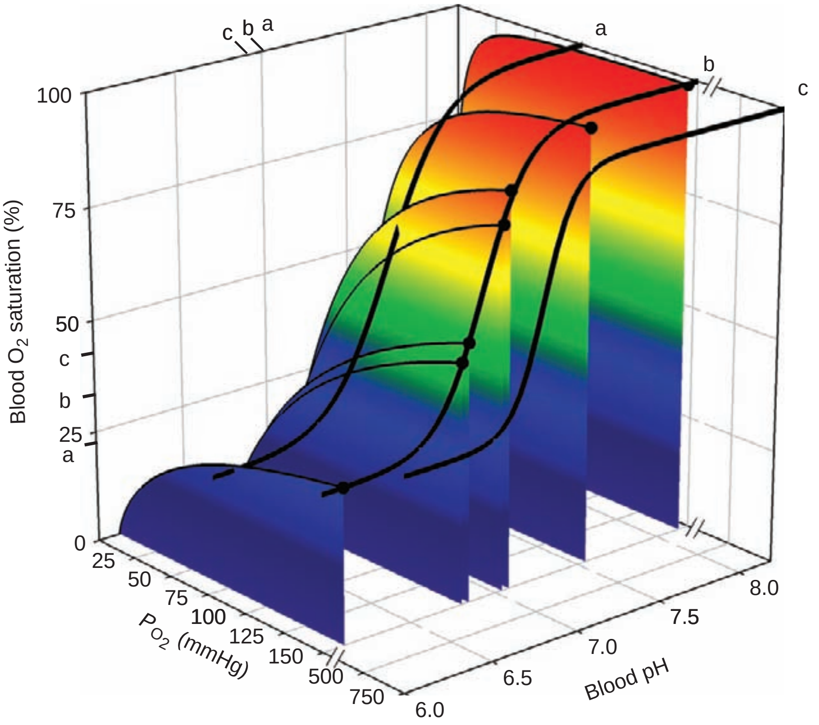

Figure 2 Low pH-induced decrease of Hb O_2 saturation as a function of P_{O_2}. In going from P_{O_2} 80 to 150 and 750 mmHg (black curves a–c), the lower plateau of blood O_2 saturation progressively increases and the pH required for half maximal effect more and more decreases, as indicated by the respective letters on the axes. O_2-binding curves are from Figure 1. Black curves are sigmoid fits of O_2 saturation as a function of pH at constant P_{O_2}. Note axis break and different scale after P_{O_2} 150 mmHg.

different species, such that no two species show the same curve. For example, at P_{O_2} 150 mmHg, blood O_2 saturation in the sea robin is half maximally reduced at pH 7.5, whereas goosefish blood needs to be acidified to pH 7.0 to show the same level of pH-induced deoxygenation (**Figure 3**). Similarly, the pH dependence of the Root effect

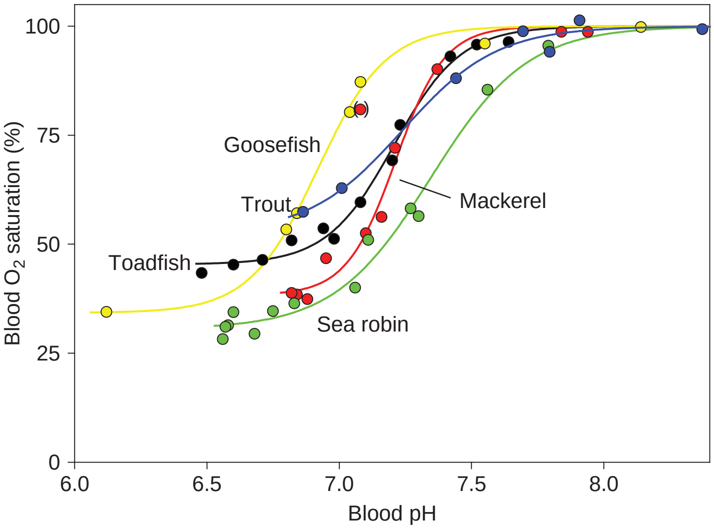

Figure 3 Species differences in the pH dependence of the Root effect, which is here taken as the acid-induced decrease in O_2 saturation of air-equilibrated blood or red blood cell suspensions. Species differ in the saturation plateau that is reached at low pH, the midpoint pH, and the maximal steepness of the curve relating O_2 saturation to pH. Similarly colored lines and symbols refer to the same species, as indicated. Goosefish data re-plotted from Figure 1, trout *Oncorhynchus mykiss* data from Berenbrink M, Völkel S, Heisler N, and Nikinmaa M (2000) O_2-dependent K^+ fluxes in trout red blood cells: The nature of O_2 sensing revealed by the O_2 affinity, cooperativity and pH dependence of transport. *Journal of Physiology* 526: 69–80. All other data from Root RW (1931) The respiratory function of the blood of marine fishes. *Biological Bulletin* 61: 427–455.

in mackerel blood is much steeper than in sea robin, although the two species show about the same magnitude of the Root effect, that is, acidification leads to the same lower plateau of blood O_2 saturation. Finally, the magnitude of the Root effect is distinctly lower in the toadfish than in the sea robin (*c.* 55% vs. 70% maximal acid-induced deoxygenation, respectively) What is the basis for these differences?

The Root effect is a property of Hb inside the red blood cells (RBCs) and depends on the intracellular pH of these cells. Therefore, pH regulatory mechanisms that prevent a plasma acidosis to be transferred to the intracellular pH of RBCs may weaken or even mask the presence of a Root-effect Hb in some fishes. Thus, the β-adrenergically activated sodium, hydrogen exchanger in the RBC membrane of many teleost fish species maintains intracellular pH under exercise-induced acidosis (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function and Hemoglobin).

Many fish species express functionally different Hb isoforms in their RBCs, some of which show the Root effect, whereas others are non-Root-effect Hbs. Thus, the anodic (at high pH negatively charged) Hbs of salmonid fishes and eels, which make up about 60% of the total Hb, show a Root effect, while the cathodic (positively charged) Hbs do not. Differences in the relative proportion of these Hbs between species will change the maximal extent of the overall Root effect in these bloods. The pH at which the lower O_2 saturation plateau is reached is increased by elevated concentrations of small intracellular effector molecules like chloride and the organic phosphates adenosine triphosphate and guanosine triphosphate. The extent to which protons can decrease Hb O_2 saturation finally depends on the general O_2 affinity of the O_2-binding sites of Hb, the H^+ affinity of the H^+-binding sites, and the molecular mechanism of Hb that links the two together and causes H^+ binding to release O_2. This is encoded in the molecular structure of the protein and thereby an inherited property that depends on the genetic makeup of each species.

Mechanism of the Root Effect

Hb is arguably one of the most-studied proteins and elucidating how its structural features on the molecular level allow its functional diversity across vertebrates is of great value in understanding protein function in general. However, the molecular mechanism by which the affinity and cooperativity of O_2 binding of many fish Hbs are so drastically reduced at low pH has remained an enigma, despite more than two decades of research. Only recently significant progress in elucidating the molecular mechanism of the Root effect has been obtained.

The Two-State Allosteric Model of Hb and the Root Effect

Initially, the Root effect was interpreted in the framework of the two-state allosteric model of Hb. This was based on the structural observations of Nobel laureate Max Perutz and his colleagues, who found that the structure of oxy Hb and deoxy Hb differed in important aspects. Hbs of jawed vertebrates generally exist as tetramers. These are formed by two dimers which are each formed by the aggregation of one α and one β globin chain. Contact sites within these dimers are denoted $\alpha1$–$\beta1$ (or $\alpha2$–$\beta2$) contacts. Contact sites between the two dimers in the Hb tetramer are denoted $\alpha1$–$\beta2$, $\alpha1$–$\alpha2$, or $\beta1$–$\beta2$ contacts (**Figure 4(a)** and **4(b)**). Each globin subunit carries a heme group with a Fe^{2+} center that is the binding site for O_2. Structural changes in the globin chains can alter the heme environment and thereby the affinity of the O_2-binding sites. Perutz and colleagues observed that the conformation of the Hb tetramer changes upon releasing O_2. The two α–β dimers rotate relative to each other and move slightly away from each other, opening a central cavity between the $\beta1$ and $\beta2$ subunits. This deoxy conformation is assumed to have a fixed, low O_2 affinity, is stabilized by internal salt bridges, and is called the tense, T-state conformation. Conversely, the oxy conformation is assumed to have a fixed high O_2 affinity, has fewer internal salt bridges, and is called the relaxed, R-state conformation. In the two-state allosteric model, the binding of the first O_2 molecules to the low O_2-affinity T-state conformation is assumed to promote the allosteric shift toward the high O_2-affinity R-state conformation. This T-state to R -state transition gives rise to cooperative O_2 binding. Several other allosteric effector molecules, such as chloride, protons, and organic phosphates, have a higher affinity to the T-state conformation, and binding of these effectors to the T-state impedes the transition from the T-state to the R-state conformation. This results in higher P_{50} values and shifts the overall O_2-binding curve toward the right. According to the two-state allosteric model, the Root effect results from an over-stabilization of the T-state conformation by proton binding at low pH. Thereby the transition to the R-state is blocked and Hb becomes fixed in the low O_2-affinity T-state. This would explain incomplete Hb O_2 saturation under air or even pure O_2 and also account for the loss of cooperative O_2 binding at low pH, which are both observed in Root-effect Hbs. The model also explains the observation that in the presence of chloride and organic phosphates, protons exert a stronger effect on Hb O_2 saturation, as all these allosteric effectors work together in stabilizing the T-state and impeding the transition to the R-state.

On the molecular level, the principal proton-binding site that stabilizes the T-state was thought to be the same

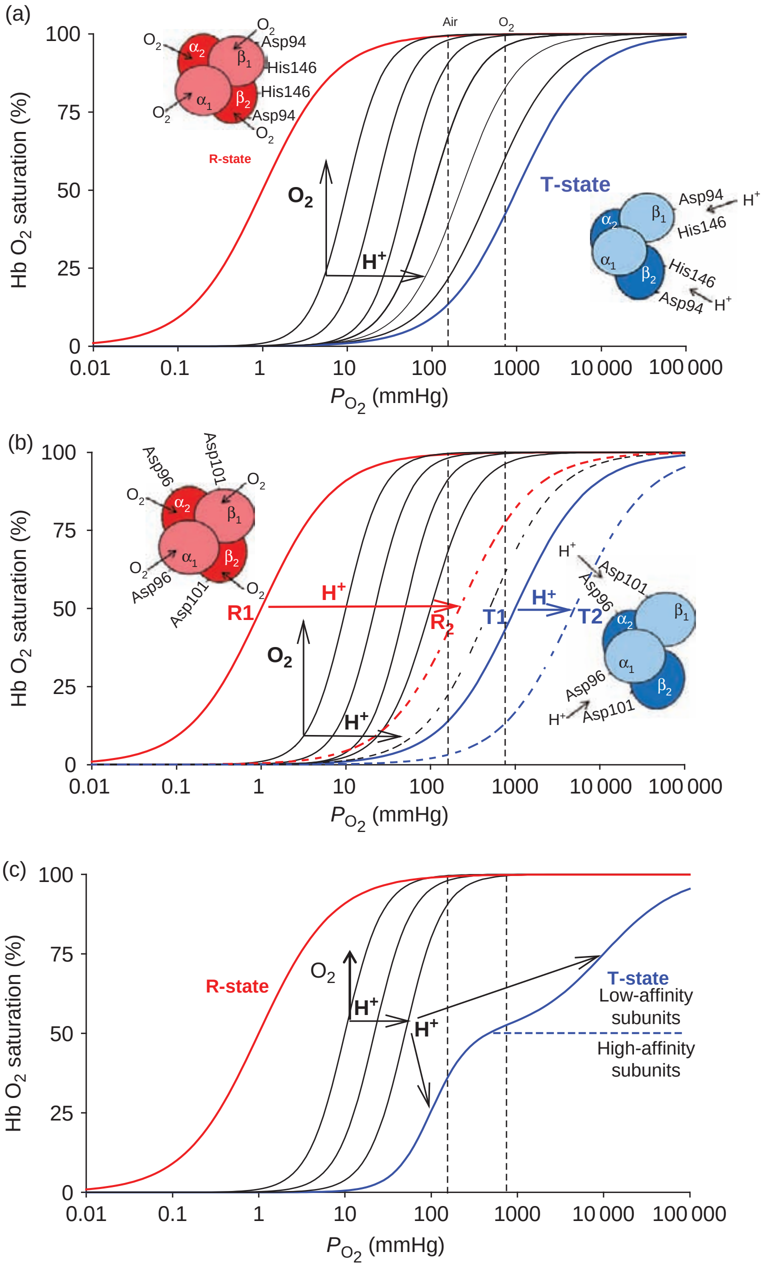

Figure 4 Different perspectives on the molecular mechanism of the Root effect, explaining the loss of cooperative O_2 binding and incomplete Hb O_2 saturation at low pH, even under air or pure oxygen (dotted vertical lines). (a) According to the two-state allosteric model, Hb tetramers exist in equilibrium between the R-state and T-state conformations, which have inverse affinities for O_2 and H^+ (indicated by arrows). High P_{O_2} promotes the transition (black lines) to the high O_2-affinity R-state (red line) and causes cooperative O_2 binding (increased steepness of curves at intermediate O_2 saturations). Protons stabilize the low O_2-affinity T-state (blue line) by binding to residues in the β-chains similar to those principally responsible for the Bohr effect in human Hb. This increases P_{50} by delaying the T–R transition. Strong stabilization of the T-state at very low pH abolishes cooperative O_2 binding. (b) The multistate model expands the two-state allosteric model by allowing pH-induced changes in O_2 affinity within the R- and T-states (substates R1, R2 and T1, T2). Low pH stabilizes the low O_2-affinity R and T substates, decreasing P_{50} and cooperativity. T-states are stabilized by proton binding to sites at the $\alpha1$–$\beta2$ interface, which differ from the sites causing the Bohr effect in human Hb. (c) In some species at low pH, α- and β-subunits in the T-state have widely different O_2 affinities, causing apparent anti-cooperative O_2 binding (flattening of the curve at intermediate O_2 saturations). Note logarithmic x-axis scales which cause sigmoid appearance also of the rectangular hyperbolas characterizing the R- and T-state O_2-binding curves.

as the site responsible for the major part of the Bohr effect in human Hb, namely the terminal histidine residue of the β chain (**Figure 4**(a); **see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect). This histidine side chain, when protonated, forms a strong salt bridge with an aspartate residue of the same chain in the T-state, but not R-state, which influences the heme environment and causes a reduced O_2 affinity. Certain amino acid substitutions in Root effect Hbs that were found in the vicinity of the β terminal histidines were thought to cause much stronger proton binding and salt-bridge formation in the T-state of Root-effect Hbs than in human Hb and to thereby cause the Root effect. Thus, the Root effect was merely considered an enhanced or exaggerated Bohr effect of human Hb.

This elegantly simple explanation of the Root effect is, however, challenged by several sets of observations. First, analysis of precise O_2-binding curves at different pH and very high and very low O_2 saturation, which allows determination of the O_2-binding affinity of the first and the fourth O_2 and thereby of the T- and R-state, revealed different O_2-binding affinities within the T-state conformations, that is, the O_2-affinity of the T-state is not fixed and is affected by proton binding within this conformational state. Second, structural analyses revealed that the salt bridge of the β-terminal histidine, which is crucial for the Bohr effect in human Hb, is not formed in several fish Hbs that nevertheless display a strong Root effect. Third, the Root effect has been observed in Hb with arginine as the β-terminal amino acid residue, although the side chain of arginine is unable to bind protons at low pH. Finally, mutations in human Hb, which were designed to produce the Root effect according to the above mechanism, failed to do so and in fact increased Hb O_2 affinity, rather than reducing it. Thus, the two-state allosteric model of the Root effect needed to be expanded and the search for the structural explanation of the Root effect continued.

Multistate Model of the Root Effect

Later structural studies on Root-effect Hbs in the R-state (oxy) conformation and the T-state (deoxy) conformation have revealed a new proton-binding site that is only formed in the T-state conformation between two aspartate amino acid residues at the $\alpha1$–$\beta2$ interface **Figure 4**(**b**). Binding of a shared proton at this site is assumed to stabilize the T-state, impede the shift to the R-state, and to be responsible for 50% of the Root-effect magnitude. Further structural studies on Northern bluefin tuna *Thunnus thynnus* Hb at low and high pH indicate additional modulation of O_2 affinity by proton binding within the T-state. Thus, a specific histidine residue of the β-chain picks up a proton at low pH and forms a salt bridge with a neighboring aspartate of the same chain. This causes structural changes in the vicinity of the heme group of that β-subunit that are predicted to change its O_2 affinity without altering the overall conformational state of the tetramer.

Earlier structural studies on Hb of the teleost spot (*Leiostomus xanthurus*) have been taken to suggest proton binding at low pH also to the R-state conformation that may cause its destabilization and transition to the low O_2-affinity T-state. (**Figure 4**(**b**)) However, it is not clear whether proton binding in this case is also associated with O_2 affinity changes within the R-state. This is certainly a possibility based on recent experiments on human Hb.

Subunit Differences in Oxygen Binding at Low pH

The reduction of cooperative (sigmoidal) O_2 binding that is seen in Root-effect Hbs at low pH has been ascribed to Hb being locked under this condition in a T-state conformation, in which the O_2 affinity is assumed to be fixed and similar in all four binding sites. In some Root-effect Hbs, binding of O_2 to the first half of heme groups seems to impede further O_2 binding to the other half at low pH, indicating apparently anti-cooperative O_2 binding. This may, however, be due to distinctly different O_2-binding affinities between the α- and β-subunits of the tetramer at low pH (**Figure 4**(**c**)). This is supported by structural data on T-state Hbs at high and low pH, which indicate two different proton-binding sites in the α- and β-chains, that alter the heme environment, and presumably O_2 affinity, differently in the T-state α- and β-chains.

Taken together, all these structural and functional studies suggest that the strong effect of protons on the Hb O_2 affinity in Root-effect Hbs is due to a complex mechanism involving pH-induced changes within and between conformational stages that are related to proton-binding sites that are quite different from those involved in the Bohr effect of human Hb.

Physiological Roles of the Root Effect

The Root effect allows an acid-triggered O_2 release from the Hb inside red blood cells even at super-atmospheric P_{O_2} values, where Hb of other vertebrates remains fully O_2 saturated. This property forms the basis for O_2 secretion into the fish swimbladder for buoyancy regulation and for generating elevated P_{O_2} values for enhanced O_2 diffusion from the capillary system underlying the retina into the poorly vascularized fish retina itself (**see also Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes). However, some teleost fishes, such as herring *Clupea harengus* and trout *Oncorhynchus mykiss*, are unable to secrete O_2 into their swimbladders, while others, such as the eel *Anguilla rostrata*, are unable to generate high P_{O_2} values at their retinas. Clear evidence for such ability is the presence in the swimbladder or at the retina of P_{O_2} values above those of air. Thus, determining whether or not acidification of air-equilibrated blood or Hb of a given fish species decreases O_2 saturation is a good indicator of whether a species may be able to secrete O_2, regardless of whether this is by a strong Bohr effect or a Root effect.

Furthermore, greatly elevated blood P_{O_2} values are generally associated with a vascular counter-current exchange system known as the rete mirabile (Latin: wonderful network, plural: retia mirabilia; (**see also Design and Physiology of Arteries and Veins**: The Retia). Upon local blood acidification in the choroid capillaries behind the retina or in the swimbladder capillaries, the Root effect allows release of Hb-bound O_2 even at already elevated P_{O_2} (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). The rete mirabile increases the efficiency of this process in two ways. First, it prevents washout of the released O_2 by allowing back-diffusion of O_2 from the venous capillaries into the arterial capillaries of the rete mirabile. This serves to augment the initial P_{O_2} increase elicited by acidification and the Root effect. Second, the rete mirabile keeps the blood acidification localized by allowing CO_2 back-diffusion from the venous site to the arterial site of the rete mirabile. This is important because in the case of a general blood acidosis, blood O_2 loading in the fish gills may be impaired in the presence of a Root effect. However, a rete mirabile in the absence of a Root effect may be disadvantageous, because venous blood with low P_{O_2} leaving a tissue may cause a diffusive shunt of O_2 from arterial to venous capillaries in the rete mirabile, thereby compromising tissue O_2 supply. Perhaps for this reason heat-exchanging retia mirabilia are usually comprised of large-diameter capillaries, which allow sufficient heat transfer but are less efficient in gas exchange compared to retia mirabilia comprised of low capillary diameter.

Evolution of the Root Effect and Rete Systems

Evidently, efficient O_2 secretion requires a Root effect and a rete mirabile. However, the two components appear disadvantageous on their own. As their simultaneous evolution seems unlikely, the question arises, which of the two components came first and how its negative aspects were avoided during the evolution of O_2 secretion? Once O_2 secretion had evolved in one organ, it may have facilitated its evolution also at the other organ. Thus, finding out whether O_2 secretion first evolved in the eye or in the swimbladder may allow identifying the initial selection pressures that led to its existence.

Reconstructions of the evolution of the ocular (choroid) rete mirabile and the swimbladder rete mirabile suggest that the choroid rete evolved first and just once about 250 million years ago in the ray-finned fishes, more precisely in the last common ancestor of the bowfin *Amia calva* and teleosts (**Figure 5**). Most living teleosts thus possess a choroid rete mirabile, although it has been secondarily lost in members of several different groups of fishes, such as in the elephantfishes *Campylomormyrus numenis* and *Gnathonemus petersii*, the European eel *Anguilla anguilla*, some loaches and catfishes, and the swamp eel *Monopterus albus*. In addition to these species, the choroid rete mirabile has also been lost in four lineages of Antarctic fishes of the suborder Notothenioidei. **Figure 5** also indicates the magnitude of the Root effect in each species by giving the maximum acid-induced decrease in the percentage O_2 saturation of air-equilibrated hemolysates at physiological temperature. It is seen that most living teleosts have Root-effect magnitudes of 40% desaturation or more.

The Root effect is only ever reduced below that level in species that have lost the choroid rete mirabile and thereby also lost the ability for elevating retinal P_{O_2} above air. In some species without a choroid rete, such as elephantfishes, the European eel, and some loaches, the Root effect is only slightly reduced. Separate evolutionary reconstructions have revealed that these groups have all independently evolved a swimbladder rete mirabile. The persistence of a reduced Root effect in these three separate groups strongly suggests that the Root effect is used to secrete O_2 into their swimbladders. The almost total loss of the Root effect in catfishes and the swamp eel, which do not possess choroid or swimbladder retia mirabilia, supports this conclusion (**Figure 5**).

Some basal ray-finned fish lineages that never evolved a choroid or swimbladder rete mirabile nevertheless have Root effects as high as 25–40% (sturgeon *Acipenser baeri* and gar *Lepisosteus platyrhincus*, respectively).

Indeed, the evolutionary reconstruction of Root-effect magnitude suggests that the Root effect of early ray-finned fishes gradually increased in the lineage leading to teleosts, attaining values of up to 40% already before the first occurrence of a choroid rete mirabile.

What may then have been the driving force behind the evolution of the Root effect? It very likely was not the generation of super-atmospheric P_{O_2} values, as these usually require that the washout of O_2 released from Hb is minimized by back-diffusion from venous to arterial capillaries in a rete mirabile. In the absence of a rete mirabile, acid-induced O_2 secretion via the Root effect is also difficult because CO_2 generated during blood acidification cannot be recycled via the rete mirabile. This would then entail large amounts of acid entering the general circulation, potentially impeding sufficient O_2 loading in the gills because the Root effect could prevent full Hb saturation even in fully air-equilibrated water.

However, studies on the Hb buffer values of teleosts and basal ray-finned fishes have shown that species such as reedfish *Erpetoichthys calabaricus*, sturgeon, and gar have

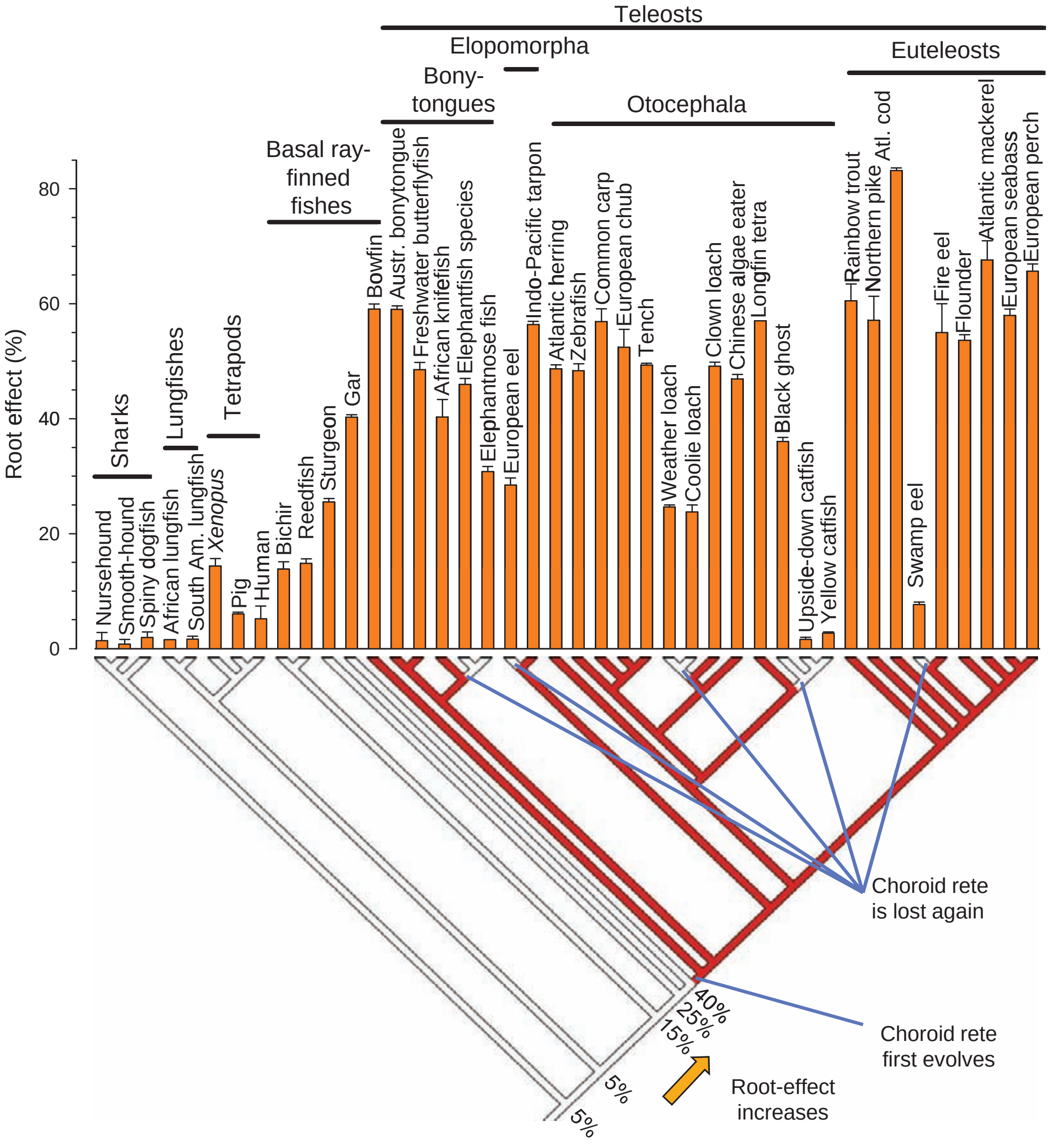

Figure 5 Evolution of the choroid rete mirabile and the magnitude of the Root effect. The presence (red branches) and absence (white branches) of the choroid rete mirabile have been mapped onto a phylogenetic tree of selected jawed vertebrates. The magnitude of the Root effect (mean values and SEM) has been estimated as maximum acid-induced deoxygenation of air-equilibrated hemolysates at physiological body temperatures. Evolutionary reconstruction of these data indicates that the Root effect increased before the evolution of a choroid (or swimbladder) rete mirabile (arrow). However, in living teleosts, the Root effect only ever decreases below 40% in species that have lost the choroid rete mirabile, indicating a functional link. Major taxonomic groups are labeled with bars. Scientific species names from left to right are: Sharks-*Scyliorhinus stellaris, Mustelus asterias, Squalus acanthias*; lungfishes -*Protopterus* sp., *Lepidosiren paradoxa*; tetrapods - *Xenopus laevis, Sus scrofa, Homo sapiens*; basal ray-finned fishes - *Polyterus ornatipinnis, Erpetoichthys calabaricus, Acipenser baeri, Lepisosteus platyrhincus, Amia calva*; bony tongues - *Scleropages jardinii, Pantodon buchholzi, Xenomystus nigri, Campylomormyrus numenius, Gnathonemus petersil*; Elopomorpha - *Anguilla anguilla, Megalops cyprinoides*; Otocephala - *Clupea harengus, Danio rerio, Cyprinus carpio, Leuciscus cephalus, Tinca tinca, Misgurnus anguillicaudatus, Pangio kuhlii, Botia macracanthus. Gyrinocheilus aymonieri, Brycinus longipinnis, Apteronotus albifrons, Synodontis greshoffi, Pelteobagrus fulvidraco*; euteleosts - *Oncorhynchus mykiss, Esox lucius, Gadus morhua, Monopterus albus, Mastacembelus erythrotaenia, Platichthys flesus, Scomber scombrus, Dicentrarchus labrax, Perca fluviatilis*. about twice as high Hb buffer values than typical teleosts. Similarly high Hb buffer values in the South American lungfish *Lepidosiren paradoxa*, and sharks indicate that this may have been the ancestral state of ray-finned fishes and jawed vertebrates in general (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect). This means that blood pH was comparatively well buffered when the Root effect first evolved and that a general acidosis was less likely to impair full Hb oxygenation in the gills.

Why did the Root effect evolve then? To answer the question, it is important to remember that the lack of achieving full O_2 saturation in Root-effect Hbs even at the P_{O_2} of air or higher is only seen at low pH values and that these may be rarely achieved in well-buffered blood and without an acid-conserving rete mirabile. At the pH values normally occurring in the general circulation of fishes, Root-effect Hbs behave similar to the Bohr-effect Hbs of mammals (**Figure 1**), even if the Hb-O_2-binding affinity usually shifts twice as much upon a given change in pH in Root-effect Hbs. Thus, although the molecular mechanism for the pH-induced shift in Hb O_2 affinity is quite different in Bohr- and Root-effect Hbs, they may have evolved in the mammal and ray-finned fish lineages for the same purpose, namely improved efficiency of general gas transport by increased O_2 unloading in metabolic active, acid-producing tissues and increased O_2 loading in relatively CO_2 poor gill blood. This idea is consistent with the multiple evolution of a Bohr effect in other animal groups with entirely different respiratory pigments, such as in lampreys, cephalopods, and crustaceans (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect).

The later evolution of retia mirabilia, first behind the retina and later several times independently at the swimbladder, then allowed evolution of O_2 secretion, by enabling the localized generation of low blood pH, and thereby the exploitation of the special characteristics of Root-effect Hbs.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Orthologous genes Genes in different species that are similar to each other because they originated from a common ancestor.

Root effect The complete loss of cooperativity (indicated by a Hill coefficient equal to 1), and thereby the inability to saturate the ligand sites at low pH even at high O_2 pressure in the hemoglobin molecule, is a distinctive property with respect to the Bohr effect, and is referred to as the Root effect.

Introduction

Few proteins have been studied as widely as hemoglobin, and recent discoveries on its structure–function relationship keep stimulating interest. Hemoglobins are found in bacteria, protists, fungi, plants, and animals. The different and widespread hemoglobins appear to be encoded by orthologous genes, thereby implying that they are descended from an ancient, common ancestral gene.

Genome sequencing suggests that the evolutionary tree of the family of globin proteins extends back 1800 million of years, a time when the O_2 began to accumulate in the atmosphere. The atmospheric O_2 content reached its present levels only about 540 million years ago. At that time, a hemoglobin-like ancestor was likely adapted for scavenging excessive O_2 concentration and/or in detoxification of O_2.

Hemoglobins are also ancient proteins that probably evolved from enzymes used to protect tissues against toxic O_2 levels. Fish hemoglobin, which is a tetramer of two identical α and β globin chains, is a relatively recent adaptation of the hemoglobin molecule to widely different environmental conditions. The evolution of a simple O_2-binding globin protein into multi-unit hemoglobin protein and then its combination with the development of the circulatory system greatly enhanced the ability of blood to transport O_2 to metabolizing cells.

The expression of α and β chains and their post-translational assembly into $\alpha_2\beta_2$ tetramers is fundamental to the function of most vertebrate hemoglobins. In all vertebrates, there is a strong evolutionary pressure favoring the expression of equal amounts of the two types of chains, because all the functional properties displayed by hemoglobin, for example, cooperativity, pH sensitivity, and anionic regulation, occur only in the $\alpha_2\beta_2$ tetramers. In fish, the expression of multiple α and β chains is the basis for functional adaptations because the single chains by themselves do not show the sophisticated allosteric properties of the assembled tetramer.

Fish hemoglobins have, for many years, attracted the attention of biochemists and physiologists for the huge spectrum of functional properties they display. Adaptive hemoglobin structural and functional variations are necessary because fish are influenced to a great extent by their environments. Fish hemoglobins function at the interface between organism and environment; consequently, this molecule can identify key links between molecular and ecophysiological adaptations. Fish experience temporal and spatial variations in O_2 availability, salinity, ionic composition, pH, and temperature. Fish hemoglobins are especially interesting because the gills are in contact with a medium endowed with higher O_2 and lower carbon dioxide tensions when compared to the situation in the alveoli of mammalian lungs. In fish, as well as in most vertebrates, cellular processes rely on rapid responses to external stimuli. The basic molecular events associated with these processes are the protein structural conformational transitions involved. Therefore, fish hemoglobins deserve special attention to elucidate these processes at the atomic and molecular level.

The Basic Structure of Fish Hemoglobins

While fish hemoglobins have evolved structural and functional diversity to adapt to very diverse environments, a large number of amino-acid residues are well conserved in the predominantly helical structure. Since all animal hemoglobins share the same heme group differences in their properties, including O_2 affinity, electrophoretic mobility, and pH sensitivity, must ultimately reside in the differences among a few specific amino-acid residues of the primary structure.

The three-dimensional structure of vertebrate hemoglobin was determined half a century ago. The resolved structure revealed basic principles of protein architecture, with the ≈150-residue globin chain wrapped around the single heme to form the hydrophobic pocket site. In a typical fish hemoglobin, as well as in most vertebrates, iron performs its function in the ferrous state. It is well known that modern vertebrate globins have evolved to control multiple properties simultaneously, including affinity for the heme group, iron-redox potential, dependence of O_2 affinity on pH, temperature, and effector concentration. Heme is chemically highly active and has ancient roots. To remain soluble, heme needs to be surrounded by a hydrophobic environment that is possible with a few structural protein arrangements, the most common being the globin fold. Vertebrate evolution has conserved distinctive globin folds (the so-called 3-on-3 α-helical sandwich) characteristic of myoglobin, despite a rather large sequence divergence and particularly if one considers the other two vertebrate lineages comprising neuroglobins and cytoglobins, recently discovered, which occur widely in vertebrates including fishes (**Figure 1**).

Fish hemoglobin is a hetero-tetramer (**Figure 2**). In all vertebrates, the primary structures of α and β globins are approximately 50% identical, suggesting a common precursor in ancestral vertebrates. Globins are paired in two dimers, $\alpha_1\beta_1$ and $\alpha_2\beta_2$. In fish hemoglobins, the α and β chains have 142 and 147 residues. Humans have one residue less in each of the chains, 141 and 146, respectively. The basic unit is the globin polypeptide chain, associated with a planar complex of ferrous iron and protoporphyrin IX (heme). The globin chain contains seven or eight α-helical segments, named from A to H starting from the N terminus. The nonhelical segments between helices are named AB, BC, CD, etc. The only residues common to all globins are proximal histidyl F8 and phenylalanyl CD1. On the distal ligand site of the heme, distal His E7 and Val E11 are normally present.

Affinity and Cooperativity in Fish Hemoglobins

Hemoglobins are endowed with specific ligand-binding affinity and generally exhibit ligand-binding cooperativity. The reversible reaction of O_2 binding to the four subunits of hemoglobin is nonlinear and does not correspond to a simple equilibrium. The curve

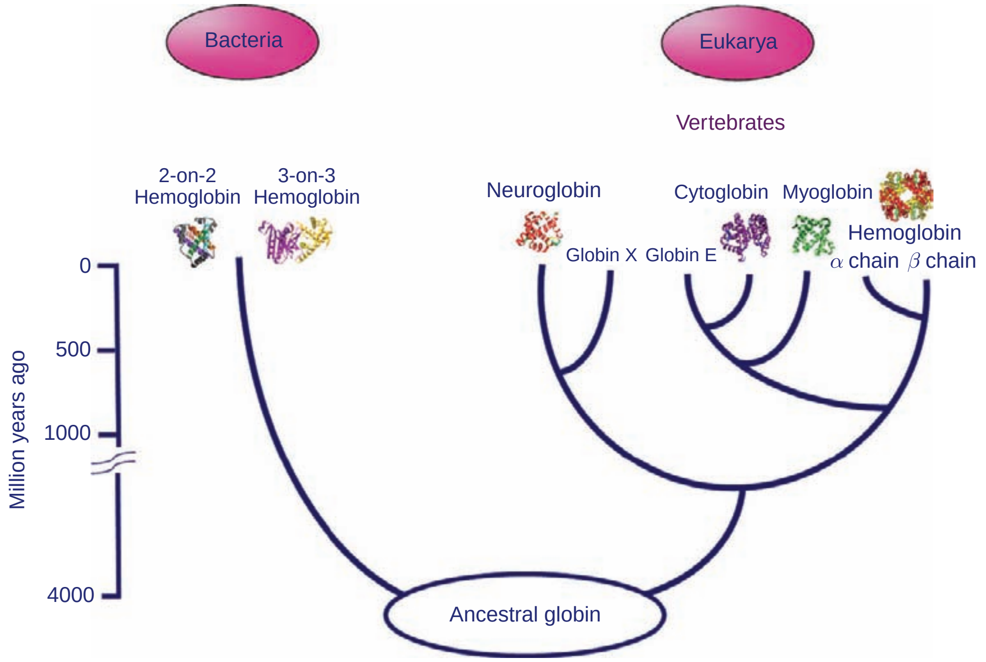

Figure 1 A simplified phylogenetic tree of vertebrate globins. From Vinogradov S, Hoogewijs D, Bailly X, *et al*. (2005) Three globin lineages belonging to two structural classes in genomes from the three kingdoms of life. *Proceedings of the National Academy of Sciences of the United States of America* 102: 11385–11389.

describing O_2 binding in blood as a function of its partial pressure is sigmoidal (**Figure 3**), indicating a cooperativity between the subunits (homotropic interactions, see below). The binding of the first O_2 molecule increases the affinity for the second molecule, and so forth. The specific mechanisms whereby inter-subunit interactions lead to a sigmoidal O_2-binding curve have long been the subject of scientific debate. All models presented to date are based on the interplay of tertiary structural changes induced by O_2 binding within a subunit. The overall affinity of hemoglobin for O_2 is expressed as the gas partial pressure required to achieve half-saturation (P_{50}). In a noncooperative system (e.g., myoglobin), where the O_2-binding curve as a function of the gas partial pressure is hyperbolic, this value corresponds to the equilibrium constant for the dissociation reaction.

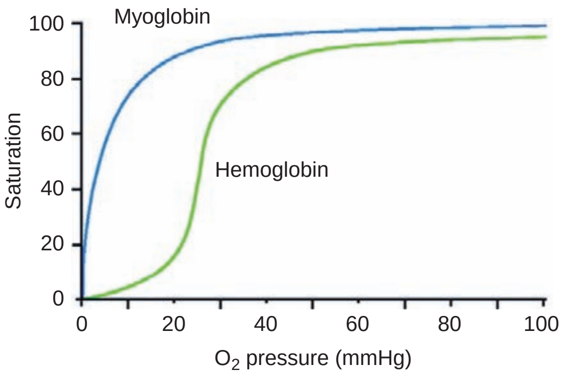

Figure 3 Fractional saturation of myoglobin and hemoglobin. The hyperbolic curve of myoglobin binding is typical for a noncooperative process; the sigmoidal curve of hemoglobin binding is typical for cooperativity.

Affinity and cooperativity may be adaptively modified in different hemoglobins to provide adequate O_2 supply under a wide variety of environmental and physiological conditions. Many of the functional differences observed in fish hemoglobins may be interpreted in terms of substitutions of amino-acid residues, although others are due to changes in the composition of the medium in which the protein works. Changes in levels of physiological effectors also affect binding properties and modify the affinity. Fishes display great ability to control the modulator concentrations.

Changes in the concentration of hemoglobin within a red blood cell (RBC) is another strategy for environment adaptation. Thus, fish may vary the synthesis of hemoglobins and, selectively, the expression of some but not all hemoglobin genes; for further discussion, the reader is referred to the section entitled ‘Fish hemoglobin functional differentiation’.

Allostery and the Monod, Wyman, and Changeux Model

After more than a century of experimental, theoretical, and computational studies, there is no general agreement on the mechanisms underlying the fine regulation of hemoglobin in fish. The crystal structures of myoglobin and hemoglobin provided the first basis to understand the relationship between protein structure and function. The four-subunit quaternary structure also prompted the classic theories and structural studies of allosteric conformational change. The main concept of the two-state allosteric model of Monod, Wyman, and Changeux (MWC) is that the molecule can only exist in two quaternary states, corresponding to a low-affinity structure (T, tense) and a high-affinity structure (R, relaxed) (**Figure 4**). According to the MWC model, cooperative O_2 binding arises due to a shift from the T to the R structure as O_2 binding increases. The pioneering achievements of Perutz identified that distinct structural T and R states are associated with the deoxygenated and the oxygenated form of the protein, respectively. On this basis, a stereochemical model for the allosteric transition was proposed. Although Perutz’s overall view of allosteric transition is still valid, more recent crystallographic analyses have clearly shown that tetrameric hemoglobins possess a larger repertoire of structural states. However, despite the large amount of data accumulated on the endpoints of the transition, structural information on the intermediate forms of the process is still rather limited. Some interesting features of these states have recently been unveiled by a variety of techniques, but the three-dimensional models are unavailable as yet.

Complex and sophisticated molecular mechanisms have evolved to regulate fish O_2 transport in response to pH, carbon dioxide, organic phosphates, and temperature

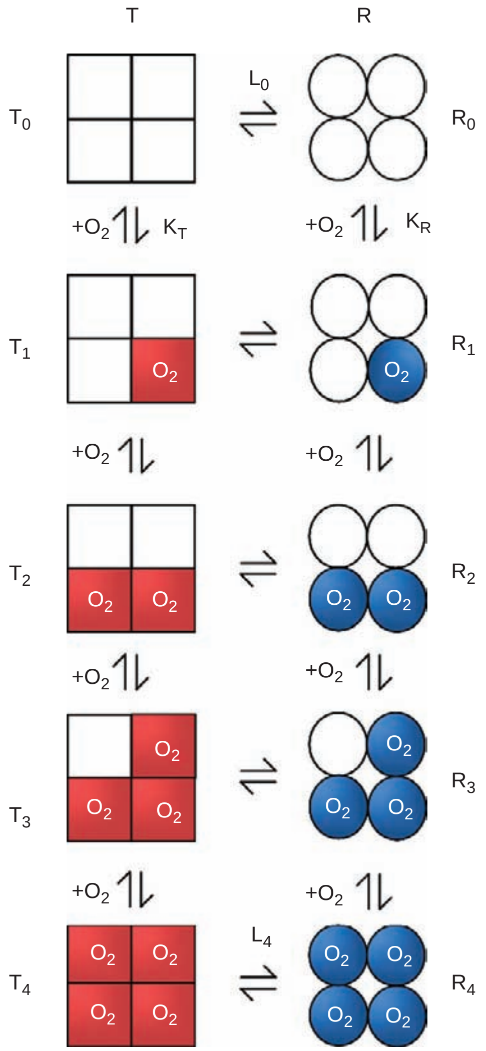

Figure 4 The hemoglobin tetramer is assumed to be in one of the two symmetric conformations: T state with low affinity (K_T) and R state with high affinity (K_R). In each conformation, there are five states subscripted by the number of O_2 bound. The equilibrium constant between the fully deoxygenated states is L_0 and between the fully oxygenated states is L_4.

effect. In allosteric molecules, the reactivity of the active site is modulated, through conformational equilibria, by binding of ligands to other sites of the same molecule. In vertebrates such as fish, the allosteric interactions may be either homotropic, if occurring among sites which bind the same ligand (i.e., O_2), or heterotropic, if the sites bind different ligands which affect O_2 affinity. The heterotropic effectors (phosphates and protons) regulate hemoglobin by modulating O_2 affinity, thus strengthening or weakening the T or R states.

The major effectors in fish are adenosine triphosphate (ATP) and protons. Organic phosphates preferentially bind to the T structure in the central cavity between the two β chains and decrease O_2 affinity.

The Bohr and the Root Effects

A decrease in O_2 affinity at lower physiological pH values is known as the alkaline Bohr effect. Decreasing the pH of blood therefore releases O_2 from hemoglobin. The acid Bohr effect, that is, an increase of O_2 affinity upon further pH decrease, may occur at pH lower than 6.0.

The physiological relevance of the Bohr effect is clear when one considers that highly active tissues release acidic metabolites (carbon dioxide and H^+). This release enhances O_2 unloading at tissues. Physiological concentrations of organic phosphates in RBCs increase the Bohr effect. The magnitude of the Bohr effect may vary among vertebrate classes. In fish, it is generally low in elasmobranchs and high in teleosts.

The Root effect corresponds to extreme pH sensitivity. In Root-effect hemoglobins, when the pH is lowered, the O_2 affinity decreases to such an extent that hemoglobins cannot be fully saturated even at very high O_2 pressure and the cooperativity is totally lost (**Figure 5**). The Root effect is almost exclusively present in teleosts.

The Root effect dictates to what extent the O_2 tension can be raised in an acid-producing tissue. Thus, its physiological role is to secrete O_2 against high gas pressures into the swimbladder, the poorly vascularized retina and possibly skeletal muscle as a result of local blood acidification. A countercurrent capillary system can amplify this effect in the swimbladder and eye. The swimbladder and the retina possess a specialized acid-producing tissue associated with the countercurrent capillary system, the *rete mirabile* (known as choroid *rete* in the eye). Among nonteleosts, the choroid *rete* is present only in *Amia* and evolved just once in fishes, in the clade comprising Amia and Teleostei. The choroid *rete* is well developed in the basal families of the dominant Antarctic perciform suborder Notothenioidei. In Antarctic fish families, many species have lost the *rete*, and the discovery of reduced and microscopic *retia* suggests that this loss may occur gradually. However, in notothenioids, the few species possessing hemoglobins without Root effect, as well as hemoglobin-less Channichthyidae, also lack the choroid *rete*.

The Structural Basis of the Root Effect

The ongoing debate on the structural interpretation of the Root effect envisages the possibility that in fish hemoglobins the classical MWC model is an oversimplified explanation of the pH modulation. C-terminal His in 146β appears to be involved in the Root effect in some hemoglobins but not in all. Moreover, a fundamental difference between Root-effect hemoglobins and hemoglobins with normal Bohr effect (and no Root effect) is that in the former hemoglobins, the $\alpha_1\beta_2$ interface remains stable in the T state upon oxygenation, whereas

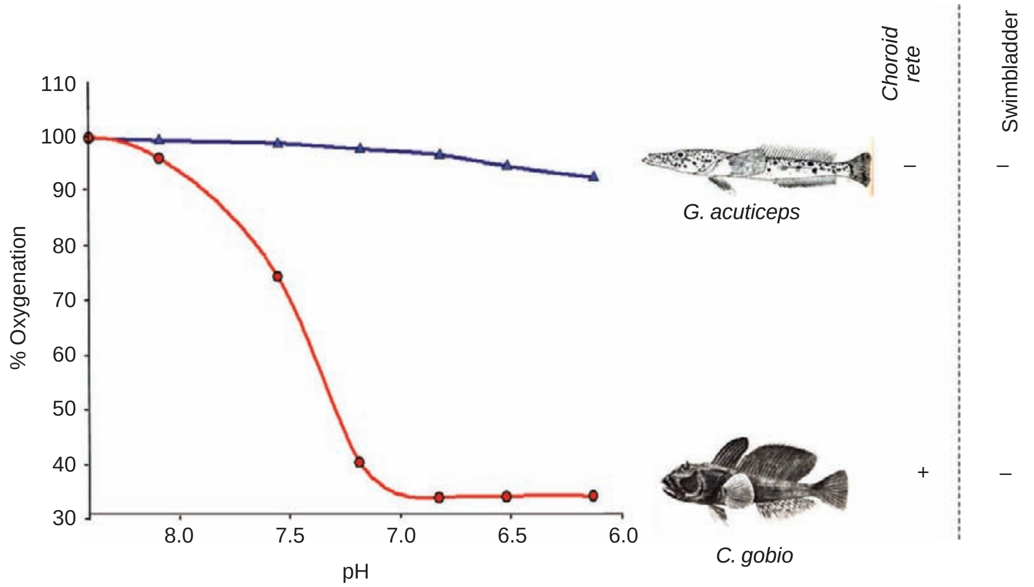

Figure 5 Presence and absence of the Root effect in hemoglobins of the Antarctic fish *Cottoperca gobio* and *Gymnodraco acuticeps*. Presence and absence of swimbladder and choroid *rete* are indicated. The O_2 saturation (expressed as percentage of oxygenation) is reported as a function of pH.

in the latter the switch to the R state occurs. Studies on the Root-effect hemoglobin of the spot, *Leiostomus xanthurus,* have suggested that destabilization of the R state (rather than stabilization of the T state) at low pH, inducing an R/T transition, may provide a molecular basis for the Root effect. Recently, O_2-binding experiments under a wide range of medium conditions have brought about a new model of allosteric regulation of hemoglobin, the global allostery model. This model highlights the role of heterotropic effectors in altering the tertiary structures of both T and R states and consequently in modulating the O_2 affinity and the Bohr/Root effect. Thus, it is feasible that the Root effect not only depends on the primary structure, but also on how and to what extent hemoglobin binds effectors in the T and R states. The pH modulation of Antarctic fish hemoglobins was attributed to changes in the tertiary structure within the T state, supporting the global allostery model. The crystal structure of the deoxygenated form of the cathodal hemoglobin from *Trematomus newnesi* (endowed with the Root effect) has been particularly illuminating to explain the proton heterotropic effect. The amino-acid sequence is characterized by extremely low histidyl content. The deoxygenated structure exhibits a hydrogen bond between Asp 95α and Asp 101β, stabilized by Asp 99β. Therefore, this structural motif *per se* is sufficient to generate the Root effect, and can be considered as the minimal structural requirement needed for designing Root-effect hemoglobins. The role played by the histidyl residues in modulating the strength of the Root effect has been highlighted by the crystal structures of tuna *(Thunnus thynnus)* and *Trematomus bernacchii* hemoglobins. Other authors, using a different approach and perspective, also highlight the role of histidyl residues in the molecular mechanisms of the Bohr and Root effects.

After more than three decades, it is virtually impossible as yet to ascribe the presence or absence of the Root effect to a single structural explanation. Indeed, the situation appears highly complex, and is probably linked to the combination and interplay of a number of factors in the architecture of the tetramer in a given species.

Fish Hemoglobin Functional Differentiation

Hypoxia

Fish live in environments that often show large variations in O_2 levels (the Southern Ocean is an exception). Hypoxia is common in aquatic habitats because O_2 dissolved in water (which can be in small amounts) is rapidly used up by aquatic organisms, and replacement requires either exchange at the interface with the atmosphere or photosynthesis.

Hypoxia tolerance is widely spread in the animal kingdom and probably arose independently at multiple times during evolution. Among the water-breathing teleosts, Cyprinidae are particularly hypoxia tolerant. These fish have evolved suitable adaptations in response to hypoxia, including hemoglobins with exceptionally high O_2 affinities, in contrast to those endowed with low affinity frequently observed in active fish living in well-aerated water. These examples highlight how the intrinsic properties of hemoglobins allow environmental and metabolic adaptations.

The first line of response to hypoxia is physiological, aimed at improving O_2 delivery through adjustments in capillarity, blood volume, or RBC mass. Complementary to the physiological adjustments are the biochemical adaptations in the molecule. Hemoglobin adaptations to hypoxia may include (1) increase in blood content, (2) changes in O_2 affinity, and (3) changes in regulation.

How and where hypoxia is sensed to allow response still remains a puzzle, since the response to environmental hypoxia is not the same as that to O_2 limitations due to swimming. For more than half a century, various, often conflicting hypotheses have considered the role of body size in hypoxia tolerance in fish. Recent evidence suggests that body size *per se* probably has little or no impact on O_2-uptake capacity during hypoxia; however, larger individuals have clear advantages over smaller ones, because the latter will much faster run out of glycogen or reach lethal levels of anaerobic end products. However, larger fish have a greater absolute O_2 demand.

Hemoglobin Multiplicity

Many fish express multiple hemoglobins with different O_2-binding properties, in order to meet O_2 demand under changing environmental conditions or metabolic challenges, rather than relying on a single respiratory protein. Multiplicity is also common in elasmobranchs. As suggested by some authors, multiple hemoglobins may protect against deleterious mutational changes in the globin genes and provide higher total hemoglobin concentration in the RBC (according to the phase rule, in a saturated solution, multiple proteins afford higher total concentration than a single protein).

Multiple hemoglobins may occur at different developmental stages; in genetically different strains of the same species, polymorphism of allo-hemoglobins also occurs, increasing the number of components. Most of these, however, cannot be properly characterized, due to either low levels of expression, or inadequacy of available purification techniques in the frequent cases of microheterogeneity.

Multiplicity is frequently found in fish that cope with highly variable conditions, whereas the presence of a single dominant hemoglobin is usually associated with stable conditions. For example, most Antarctic notothenioids are sluggish and have a single major hemoglobin, whereas temperate fish generally show high multiplicity. Multiple hemoglobins can finely tune O_2 delivery in response to environmental variability and/or variations in metabolic demands. The O_2-rich habitat of the Antarctic sea, in contrast, may have been permissive following the deletion of the globin genes in some Antarctic species such as icefish.

Unlike Antarctic notothenioids, many Arctic fish display multiplicity, usually interpreted as a sign of phylogenetic and molecular adaptation. For example, the spotted wolffish, *Anarhichas minor* (suborder Zoarcoidei), contains three functionally distinct major hemoglobins. High hemoglobin multiplicity, again with three major hemoglobins, is broadly found in the family Gadidae, in *Arctogadus glacialis* (Arctic cod), *Boreogadus saida* (polar cod), and *Gadus morhua* (Atlantic cod). For the Arctic ichthyofauna, it may be advantageous to maintain multiplicity, considering the need to adapt to a much more variable environment than the Antarctic one, where the Antarctic Polar Front maintains permanently stable conditions, including lower temperatures.

The well-documented adaptations in blood O_2-binding properties in response to environmental conditions comprise intraspecific adaptations (e.g., changes in organic phosphate concentrations in the RBC occurring in individuals) as well as interspecific adaptations (differences in hemoglobin structure and heterogeneity between species).

The functional differences in hemoglobins, due to gene duplications common in fish, are often minor and sometimes have not been shown to have adaptive physiological relevance. While cyprinids and cichlids (class I fish) possess only the electrophoretically anodal hemoglobin with relatively low O_2 affinity and marked Bohr and Root effects, the class II fish (comprising eels, salmonids, and some catfishes) additionally possess cathodal hemoglobins with high isoelectric points ($pI \geq 8.0$), high O_2 affinity, and low pH sensitivity (small Bohr effect).

The pH-insensitive hemoglobins generally carry a net charge different from that of Root-effect hemoglobins and migrate toward the cathode in electrophoresis experiments. They generally lack the histidyl residue at the *C* terminus of the β chain. Cathodal hemoglobins may function as O_2 carriers when the function of anodal components is impaired by acidification and hypoxia. During respiratory or metabolic acidosis, O_2 binding to anodal hemoglobins may be hampered by their strong Bohr and Root effect; however, O_2 transport may rely on pH-independent cathodal components often found in fishes with active lifestyle. The bluefish (*Pomatus saltatrix*), a highly active, globally distributed predator, contains highly pH-sensitive hemoglobins (Root-effect hemoglobins), while other hemoglobins show little or no pH dependence. The Root-effect hemoglobins are used for proton-driven O_2 unloading into the swimbladder to produce neutral buoyancy. However, the advantage in possessing pH-sensitive and -insensitive hemoglobins may vary in different fish.

The readers are cautioned that describing anodal hemoglobins as having marked Bohr and Root effect, and cathodal hemoglobins as having low pH sensitivity, is an oversimplification. In notothenioids, the situation is exactly reversed (**see** section 'The Structural Basis of the Root Effect').

Changes in globin gene expression during fish ontogeny have been described in many teleosts. In the rainbow trout, the embryonic and adult hemoglobins display different functional properties, with higher O_2 affinity and reduced Bohr effect in the former. Non-Bohr-effect hemoglobins may provide the embryo with enhanced O_2-carrying capacity over a wide pH range. In the rainbow trout, the change in hemoglobin composition was correlated with an apparent change in erythroid cell population. In general, the abundance of highly pH-sensitive anodal hemoglobins relative to pH-insensitive cathodal hemoglobins may vary in some fish with age and stress. The changes in hemoglobin composition may be very complex, as described in the Arctic charr, *Salvelinus alpinus*, with different numbers of components in embryos and in later stages. The exact functional meaning of these shifts, as well as the advantages in possessing a large number of globin genes in the early stages of development, remain poorly understood. Unfortunately, the biochemical characterization of embryonic fish hemoglobins is hampered by the small amount of protein. Hemoglobin switching was demonstrated for the globins of lampreys, suggesting that the switch mechanism was already present in the ancestral globin gene locus before the event of duplication generating the α- and β-globin loci.
